Abstract. Climate warming and the resulting acceleration of freshwater discharge from the Greenland Ice Sheet are impacting Arctic marine coastal ecosystems, with implications for their biological productivity. To accurately project the future of coastal ecosystems and place recent trends into perspective, palaeo-records are essential. Here, we show runoff estimates from the late 19th century to the present day for a large sub-Arctic fjord system (Nuup Kangerlua, southwest Greenland) influenced by both marine- and land-terminating glaciers. We followed a multiproxy approach to reconstruct spatial and temporal trends in primary production from four sediment core records, including diatom fluxes and assemblage composition changes and biogeochemical and sedimentological proxies (total organic carbon, nitrogen, C/N ratio, biogenic silica, $\delta^{13}\text{C}$, $\delta^{15}\text{N}$, and grain-size distribution). We show that an abrupt increase in freshwater runoff in the mid-1990s was reflected by a 3-fold increase in biogenic silica fluxes in the glacier-proximal area of the fjord. In addition to increased productivity, freshwater runoff modulates the diatom assemblages and drives the dynamics and magnitude of the diatom spring bloom. Our records indicate that marine productivity is higher today than it has been at any point since the late 19th century and suggest that increased mass loss of the Greenland Ice Sheet may continue pro-

moting high productivity levels at sites proximal to marine-terminating glaciers. We highlight the importance of palaeo-records in offering a unique temporal perspective on ice–ocean–ecosystem responses to climate forcing beyond existing remote sensing or monitoring time series.

1 Introduction

Arctic coastal ecosystems are experiencing profound and rapid changes that are predicted to intensify in the near future due to ongoing climate change (Lannuzel et al., 2020). Arctic ecosystems are impacted by sea-ice thinning and retreat (Arrigo and van Dijken, 2015; Stroeve and Notz, 2018) and by increasing freshwater discharge from melting glaciers and terrestrial runoff (Hopwood et al., 2020). During the last 2 decades, freshwater runoff from the Greenland Ice Sheet (GrIS) has rapidly increased and doubled in volume, amounting to ca. 1000 Gt yr^{−1} today (Bamber et al., 2018; Mankoff et al., 2020), and, under a warming climate, freshwater discharge is predicted to increase in the future (Fettweis et al., 2013). Glacial freshwater discharge changes the physical and chemical properties of the water column and nutrient (e.g. nitrate, phosphate, and silica) dynamics, which in turn impact

primary production, the process by which primary producers convert solar energy into organic compounds, the length of the productive season, species composition, and the distribution of biological communities (e.g. Hawkings et al., 2015; Hopwood et al., 2020). Recent studies have observed increased phytoplankton blooms and primary production rates as well as a more prolonged productive season in the high Arctic (Renaut et al., 2018; Lewis et al., 2020). However, these studies cover only the last few decades, whereas long-term records, providing the natural baseline for the recent changes, are scarce.

Greenland fjord ecosystems, at the interface between the ocean and the GrIS, maintain high biological productivity which is essential to sustain important socio-economic activities such as fisheries and harvesting of indigenous resources (mainly marine mammals). Higher-trophic-level organisms, such as mammals and birds, are typically not directly impacted by the freshwater increase, yet changes in their food sources have cascading effects with severe implications for these organisms (e.g. Berthelsen, 2014). Long-term records of primary production changes, as well as knowledge on its spatial variability, are needed to estimate the fate of these unique ecosystems under a changing climate. However, our current knowledge of freshwater impacts on marine productivity is largely based on modern observations (Meire et al., 2017; Hopwood et al., 2018, 2020) and on monitoring data spanning only a few decades (Greenland Ecosystem Monitoring programme; GEM). These studies have shown that the influence of glaciers on marine productivity depends on multiple factors such as glacier type (i.e. marine- vs. land-terminating), fjord geometry, and the resources (nutrients and light availability) that are limiting phytoplankton growth (Hopwood et al., 2020). In fjords with marine-terminating glaciers, subglacial discharge plays a key role in sustaining high productivity levels, as the upwelling meltwater plume brings crucial nutrients from the ambient deep water to the surface (Meire et al., 2017; Hopwood et al., 2018; Kanna et al., 2018). However, in the future, this nutrient source can shut down as marine-terminating glaciers retreat onto land or if glacier grounding-line depths change significantly.

The GrIS is presently losing mass (between tens of gigatons per year and $\sim 500 \text{ Gt yr}^{-1}$) with a long-term trend of increasing mass loss; most pronounced on the western side of the ice sheet (Mankoff et al., 2021). Nuup Kangerlua (Godthåbsfjord), situated in southwest Greenland (Fig. 1), is one of the largest fjord systems in the world. The fjord is ca. 190 km long, 4–8 km wide, and up to 625 m deep and covers an area of ca. 2013 km². The fjord has several sills; the main one is located at the mouth of the fjord at ca. 170 m water depth, with smaller sills in the side branches of the fjord (Mortensen et al., 2011). The fjord hydrography is influenced by ocean forcing (governed largely by the West Greenland Current, WGC) and both tidal and wind mixing (Juul-Pedersen et al., 2015), and the combination of atmosphere–ocean–ice forcing makes the fjord particularly sensitive to

climatic changes. The main fjord branch, Nuup Kangerlua, is heavily influenced by glacial discharge and acts as a gateway for iceberg outflow, while the three side branches, Kapisillit Kangerluat, Qoornup Sullua, and Ummannap Sullua, do not house large outlet glaciers and are not directly influenced by glacial discharge (Fig. 1). The average yearly freshwater runoff between 2015 and 2019 was ca. 20.9 Gt yr^{-1} , and solid ice discharge was ca. 8.1 Gt yr^{-1} (Mankoff et al., 2020). The fjord system is heavily impacted by meltwater, especially during summer, which lowers the surface salinities (Meire et al., 2017). However, icebergs also have a significant role in the freshwater flux as they can produce up to ca. one-quarter of the total meltwater (Van As et al., 2014). The fjord receives freshwater and sediment discharge from three marine-terminating glaciers (Kangiata Nunaata Sermia, KNS; Akullersuup Sermia, AS; and Narsap Sermia, NS) and three land-terminating glaciers (Qamanaarsuup Sermia, QS; Kangilinnuata Sermia, KS; and Saqqap Sermia, SS), of which SS drains into the lake Tasersuaq, while the others drain into the fjord (Fig. 1). The turbid meltwater reduces light penetration in the inner fjord close to the outlet point of Tasersuaq, creating a large spatial contrast across the fjord (Fig. 1; Meire et al., 2017). The inner part of the fjord is annually covered by sea ice from November to May, whereas the outer part stays ice-free for most of the year. A large interannual environmental gradient exists inside the fjord as the inner part receives ice, freshwater, and sediments especially in the spring and late summer, creating salinity, temperature, and productivity gradients (Mortensen et al., 2013; Krawczyk et al., 2015b, 2018; Meire et al., 2016b, 2017).

Present-day total annual primary production in Nuup Kangerlua is generally high ($84.6\text{--}139.1 \text{ g C m}^{-2} \text{ yr}^{-1}$), and it is maintained by diverse pelagic and benthic protist communities (Juul-Pedersen et al., 2015; Krawczyk et al., 2015a, b, 2018). Two phytoplankton blooms of a similar magnitude occur each year with the first bloom taking place during the spring in April–May and the second during the summer in July–August (Juul-Pedersen et al., 2015). The spring bloom plays a major role in Nuup Kangerlua, accounting for 50 %–60 % of the annual production, and it is highly relevant for fuelling the marine food web by starting the annual productive season (Hodal et al., 2012; Meire et al., 2016b). During recent decades, phytoplankton spring blooms in the Arctic have become markedly longer and occur earlier due to sea-ice retreat (Kahru et al., 2011). However, in Arctic fjords, increased freshwater discharge has been suggested to be one of the main factors enhancing the phytoplankton spring bloom (Meire et al., 2016b). In Nuup Kangerlua, the timing, intensity, and location of the modern spring bloom is also controlled by a combination of sea-ice cover, upwelling of nutrient-rich waters, and wind forcing (Juul-Pedersen et al., 2015; Meire et al., 2015, 2016b). The spring bloom is typically dominated by pennate diatoms (that form silicified frustules), and thus the input of dissolved silica (DSi) from the GrIS is one of the critical components driving the pri-

Figure 1. mary production. Meltwater runoff is suggested to be tightly linked to DSi input to the fjord, with surface runoff contributing 79 %, subglacial discharge 12 %, and solid ice discharge 9 % of the total silica input to Nuup Kangerlua (Meire et al., 2016a). Together, these three mechanisms sustain a high silica concentration and primary production 30–80 km downstream of the marine-terminating glaciers, with the highest production at ca. ~ 50 km off the glacier termini (Meire et al., 2016a, 2017).

Diatoms are one of the principal contributors to marine primary production in polar and sub-polar regions. The silicified frustules of diatoms sink to the seabed and, over time, become archived in sedimentary records (Hasle and Syvertsen, 1996). While diatoms are widely distributed and abundant as a group, many species have narrow ecological preferences

in terms of hydrographic conditions (e.g. salinity, temperature, and light availability), which makes them an excellent tool for reconstructing past environmental and productivity changes (Hasle and Syvertsen, 1996; von Quillfeldt, 2000, 2004; Krawczyk et al., 2018; Oksman et al., 2019; Weckström et al., 2020). In Nuup Kangerlua, diatom assemblages have been shown to respond mainly to physical conditions in the water column (temperature and salinity) rather than to biogeochemical properties (e.g. nutrients), and especially glacial discharge appears to favour diatoms more than other protist groups (Krawczyk et al., 2015b, 2018).

Recent studies on primary production around Greenland have focused either on process-level understanding, characterizing dynamics during the productive season, or on the annual cycle of species succession (e.g. Arendt et al., 2016; Meire et al., 2016b; Krawczyk et al., 2015a, b, 2018; Holding et al., 2019; Luostarinen et al., 2020). Although some marine and coastal studies have focused on longer timescales (e.g. Limoges et al., 2020; Saini et al., 2020), records of decadal to centennial fjord productivity and particularly its response to increased freshwater discharge are poorly documented. As underlined by the Intergovernmental Panel on Climate Change (IPCC), long-term variations in fjord primary productivity remain poorly constrained, and thus we lack solid knowledge of past productivity responses to cryosphere changes that can be used as a base for future projections (Bindoff et al., 2019).

The aim of this study is to assess the impacts of freshwater runoff from the GrIS on primary productivity in the Nuup Kangerlua fjord system since the late 19th century (from ca. 1890 to the present day). We chose Nuup Kangerlua as a suitable glaciated fjord system due to its high productivity and magnitude of modern glacial discharge and because the fjord has been monitored since 2008 and is a key site for the GEM. We extracted basin-wide freshwater runoff estimates between 1900 and 2019 from model hindcasts and reconstructed trends in primary production from four dated sediment records following a multiproxy approach including diatom fluxes and assemblage composition, biogenic silica (BSi) content, composition and origin of organic matter (total organic carbon, TOC; C/N ratio; carbon and nitrogen isotopes – $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$), and grain-size analysis. Alongside the freshwater runoff estimates, we interpret spatial and temporal trends in our proxy data against historical records of regional air and sea-surface temperature and changes in the front position of glaciers feeding into the fjord. Our combined records of freshwater runoff and primary production span more than a century and provide a novel insight into historical and recent changes and their spatial variability.

2 Material and methods

2.1 Sediment core material

A total of four sediment core records were included in this study, retrieved during three campaigns that took place between 2008 and 2013 (Fig. 1). During the campaigns, coring sites were carefully selected based on shallow seismic records and multibeam bathymetry data from previous research cruises (Harff et al., 2016; Jensen and Rasch, 2008; Mikkelsen et al., 2012; Seidenkrantz et al., 2014). The studied sediment cores were chosen based on their location and temporal resolution. Core SA12-ST8-1 (503 m water depth, 153 cm long; 64°16.416' N, 51°19.777' W) was retrieved from the side branch Qoornup Sullua in May 2012 (Mikkelsen et al., 2012), and core SA13-ST6-36R (398 m water depth, 96 cm long; 64°29.076' N, 50°42.553' W) was retrieved from the side branch Kapisillit Kangerluat in 2013 (Seidenkrantz et al., 2014). Both cores were collected on board the Greenlandic research vessel (RV) *Sanna* using a Rumohr lot. Cores DANA08-ST17 (575 m water depth, 40 cm long; 64°37.277' N, 50°56.938' W) and DANA08-ST20 (496 m water depth; 45 cm long; 64°41.927' N, 50°21.566' W) were recovered with a multicorer from the main branch of Nuup Kangerlua in 2008, on board the Danish RV *Dana*. This fjord branch is heavily influenced by glacial discharge as ice floes and icebergs travel through this channel to exit the fjord (Fig. 1). All sediment cores were stored in cold (4–7 °C) and dark conditions until opened. Sediment core sub-samples were frozen at –20 °C and freeze-dried before further processing. Sediment core records are hereafter referred to by their site numbers as sites 8 (SA12-ST8-1), 6 (SA13-ST6-36R), 17 (DANA08-ST17), and 20 (DANA08-ST20) and are presented in the figures following an outer-fjord–inner-fjord gradient (8, 6, 17, and 20) (Fig. 1).

2.2 Geochronology

The activity of ^{210}Pb , ^{226}Ra , and ^{137}Cs was analysed from all studied cores by gamma spectrometry at the Gamma Dating Centre at the University of Copenhagen. From selected depth intervals, ca. 2 g of freeze-dried sediment was measured per sample using Canberra ultralow-background Ge detectors. The ^{210}Pb was measured via its gamma peak at 46.5 keV, ^{226}Ra via the granddaughter ^{214}Pb (peaks at 295 and 352 keV), and ^{137}Cs via its peak at 661 keV. Chronologies for each site were obtained using a modified constant rate of supply (CRS) model (Andersen, 2017), where the activity below the lowermost sample was calculated based on a regression of activity versus accumulated mass depth for the upper part of the core. The obtained chronologies were validated by ^{137}Cs data.

2.3 Grain-size analysis

The grain-size distribution of the sediment records was analysed on 28, 19, 20, and 23 samples from sites 8, 6, 17, and 20, respectively, using two complementary methods: wet sieving and laser diffraction. For wet sieving, a minimum of 2 g of freeze-dried sediment was used to obtain the percentages of clay and silt (< 63 µm), fine sand (63–150 µm), and coarse sand (> 150 µm). The laser diffraction analyses were performed on a Malvern Mastersizer E/2000 to obtain the distribution of clay (< 2 µm) and silt (2–63 µm). Before laser diffraction measurements, samples of ca. 0.2 g of sediment were treated with a sodium pyrophosphate decahydrate solution and ultrasonicated once for 2 min to separate aggregates.

2.4 Biogeochemical analysis

The total organic carbon (TOC) content of the sediments was measured at the Geological Survey of Denmark and Greenland using a LECO CS-200 instrument on sub-samples (1 g of freeze-dried sediment). TOC was measured in a total of 72 samples: 19 from site 8, 10 from site 6, 20 from site 17, and 23 from site 20. The inorganic carbon fraction was removed by treating the samples with HCl before measuring their TOC content. Sources of the organic material (terrestrial versus marine) were further investigated from 13 (site 8) and 10 (site 6) samples by measuring the isotopic composition of bulk organic carbon ($\delta^{13}\text{C}$) and nitrogen ($\delta^{15}\text{N}$). The isotopic composition analyses were performed at the Department of Geosciences and Natural Resources Management, University of Copenhagen. Approximately 20–30 mg of each sample was homogenized before its carbon and nitrogen content and isotopic ratios were measured by Dumas combustion (1700 °C) on an elemental analyser (EA; CE 1110, Thermo Electron, Milan, Italy, or Flash 2000, Thermo Scientific, Bremen, Germany). The EA was coupled in continuous-flow mode to a Finnigan MAT Delta plus or Thermo Delta V Advantage isotope ratio mass spectrometer (Thermo Scientific, Bremen, Germany).

Biogenic silica was measured at the Geological Survey of Denmark and Greenland according to the 5 h Na_2CO_3 extraction method (DeMaster, 1991) in a total of 100 samples: 40, 17, 20, and 23 samples from sites 8, 6, 17, and 20, respectively. Samples of 30 ± 1 mg of freeze-dried sediment were leached using 40 mL of 1 % sodium carbonate (Na_2CO_3) in an 85 °C water bath for 5 h. Sub-samples (1 mL) were taken after 3, 4, and 5 h of extraction and measured with a spectrophotometer Jenway 7305 using the blue ammonium-molybdate method (Mullin and Riley, 1955). Final biogenic silica concentrations were calculated and corrected for mineral dissolution using the intercept of a linear regression line through 3, 4, and 5 h sub-samples under the assumption that all biogenic silica dissolved during the first 2 h, whereas minerogenic silica dissolves slowly at a constant rate throughout the extraction (Barão et al., 2015).

2.5 Diatoms

Diatom microscopy slides were prepared according to Battarbee et al. (2001) at the Geological Survey of Denmark and Greenland from 48, 21, and 20 samples from sites 8, 6, and 17, respectively. Approximately 0.1 g of sediment per sample was treated with 10 % hydrochloric acid (HCl) and 30 % hydrogen peroxide (H_2O_2) in an 80 °C water bath for 4 h to remove carbonates and organic material. Afterwards, samples were rinsed with distilled water and spiked with 0.1 mL of a microsphere solution of 6.13×10^6 spheres mL^{-1} . Slides were then mounted using Naphrax[®] with a refractive index of 1.73. Diatom slides were analysed with an Olympus BX51 light microscope using phase contrast optics at 1000 \times magnification, and a minimum of 300 valves were counted (excluding *Chaetoceros*). Diatom concentrations (valves g^{-1} dry sediment) were calculated using the sum of microspheres counted per total diatom sum and the number of microspheres added in the diatom sample. The non-linear ordination method of correspondence analysis (CA) was utilized using the program PAST version 4.02 (Hammer et al., 2001) to detect ecological shifts and the major patterns of variation in the diatom assemblages. CA was run on relative abundance data for all taxa representing > 1 %, and the resulting sample eigenvalues give a measure of the variance accounted for by the corresponding eigenvectors. To test correlation between CA axis scores, diatom taxa, grain size, geochemical parameters, and environmental variables (runoff, air and sea-surface temperatures), a Pearson product-moment correlation coefficient and the associated level of statistical significance ($p < 0.05$) were used on the 5-year running mean average for each time series.

2.6 Freshwater runoff 1900–2019

We used regional climate model data to obtain runoff estimates for the period 1900–2019. For the period 1979–2019, we used the Greenland liquid water runoff dataset (Mankoff et al., 2020). This dataset is based on MAR v3.11, which is driven by the most recent reanalysis data ERA5 (Delhasse et al., 2020). For the period prior to 1979, we used MAR v3.5 (Fettweis et al., 2017), which is based on 20CRv2c reanalysis (Compo et al., 2011). The runoff data from the Greenland liquid water discharge dataset are considered to be more accurate than the MAR v3.5 dataset, and thus, the latter data series was calibrated prior to merging of the two datasets. Modelled runoff from both ice and tundra surfaces were extracted for the Nuup Kangerlua basin partitioned into three regions (Fig. 1) – inner, outer, and southern part of the fjord – in order to investigate spatial differences between the four sediment core sites.

2.7 Glacier front position

To assess temporal changes in the front positions of the outlet glaciers feeding into Nuup Kangerlua, we use historical aerial and satellite imagery. The historic imagery consists of oblique and vertical images from the Danish Agency for Data and Infrastructure, supplemented with CORONA imagery from the 1960s and satellite data from different Landsat missions retrieved from <http://earthexplorer.usgs.gov> (last access: 30 November 2021). All imagery was georeferenced relative to a 2 m ortho-photo mosaic (Korsgaard et al., 2016), which in this area of Greenland is based on aerial stereophotogrammetric imagery from summer 1985. The georeferencing is based on the method outlined by Bjørk et al. (2012).

3 Results

3.1 Geochronology

The relatively high sedimentation rates since the late 19th century allowed for obtaining fjord records with a sub-decadal resolution for all the cores (average sample resolution between 2 and 6 years).

For site 8, the ^{210}Pb -based chronology indicates that the upper 55 cm of the record covers the period between ca. 1890 and 2012 (Fig. 2), resulting in an average sample resolution of 2 years. Sedimentation rates are relatively high at site 8 and vary between 0.33 and 0.67 cm yr^{-1} , with a mean of $0.45 \pm 0.1 \text{ cm yr}^{-1}$ (Fig. 3).

For site 6, the topmost 21 cm of the sediment core used in this study represents the period from ca. 1890 to 2013, thus giving an average sample resolution of ca. 6 years (Fig. 2). Sedimentation rates are thus lower at site 6 than site 8 and vary between 0.13 and 0.25 cm yr^{-1} , with a mean of $0.18 \pm 0.03 \text{ cm yr}^{-1}$ (Fig. 3).

The cores from sites 17 and 20 cover shorter time intervals, from 1930 to 2008 and from 1956 to 2008, respectively (Fig. 2). Sedimentation rates are higher in these glacier-proximal sites and vary between 0.24 and 1.18 cm yr^{-1} at site 17 (mean $0.57 \pm 0.2 \text{ cm yr}^{-1}$) and between 0.46 and 2.33 cm yr^{-1} (mean $1.10 \pm 0.6 \text{ cm yr}^{-1}$) at site 20 (Fig. 3). The sediment cores from sites 17 and 20 were analysed at 4-year and 2-year resolutions, respectively.

3.2 Grain-size distribution analysis

All the sediment cores consisted mostly of clay and silt (Fig. 3). This < 63 μm fraction of the sediment varied from 90.7 % to 98.2 % (mean $96.6 \pm 1.4 \%$) at site 8, from 28.2 % to 93.0 % at site 6 (mean $76.7 \pm 14.7 \%$), from 87.3 % to 99.0 % (mean $94.2 \pm 3.2 \%$) at site 17, and from 88.5 % to 99.6 % (mean $96.7 \pm 2.8 \%$) at site 20 (Fig. 3). More detailed distribution between silt (2–63 μm) and clay (< 2 μm) grains is presented in Fig. 3. The fraction of coarse material > 63 μm is widely used as a proxy for ice-rafted debris

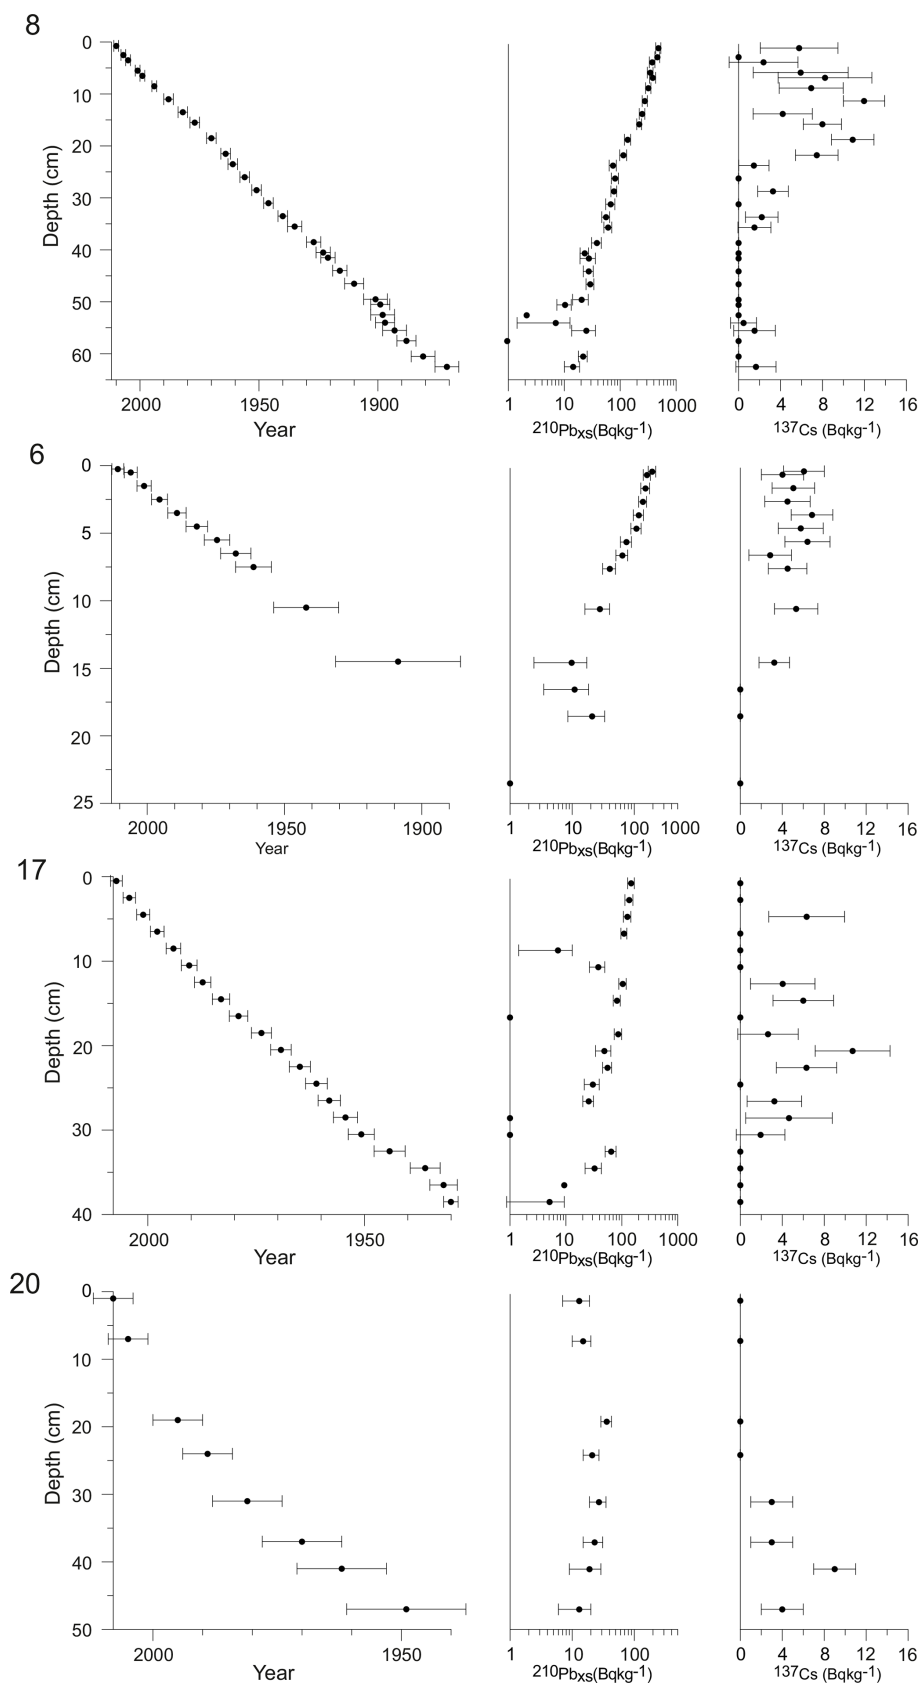

Figure 2. Age–depth models and ^{210}Pb and ^{137}Cs activities for the sediment cores SA12-ST8-1 (8), SA13-ST6-36R (6), DANA08-ST17 (17), and DANA08-ST20 (20).

(IRD) carried by icebergs that generally melt relatively close to their source. The fine-sand fraction (63–150 μm) varied between 1.2 % and 3.7 % (mean 2.2 ± 0.7 %) at site 8, between 3.8 % and 25.5 % (mean 7.5 ± 4.6 %) at site 6, between 0.6 % and 4.8 % (mean 2.1 ± 1.1 %) at site 17, and between 0.2 % and 10.8 % (mean 1.9 ± 2.4 %) at site 20, whereas the portion of the coarse-sand fraction ($> 150 \mu\text{m}$) ranged between 0.2 % and 5.8 % (mean 1.2 ± 1.0 %) at site 8, between 4.2 % and 22.2 % (mean 8.4 ± 4.4 %) at site 6, between 0.5 % and 10.9 % (mean 3.7 ± 2.4 %) at site 17, and between 0.1 % and 8.2 % (mean 1.4 ± 1.7 %) at site 20 (Fig. 3). The variations in the grain sizes between the two methods are not in full agreement when it comes to the larger fraction. This might be caused by the different sample volumes used, making the wet-sieving method more sensitive for estimating the fraction of larger grain sizes.

3.3 Biogeochemical analysis

Total organic carbon (TOC) content in sediments provides an integrated signal of production, deposition, and preservation of organic matter over time, whereas the stable carbon and nitrogen isotopes and C/N ratio can be used to infer the origin of organic matter (i.e. sourced from the terrestrial, marine, or sea-ice environments). TOC contents were highest in the most glacier-distal area (sites 8 and 6) and substantially lower at the glacier-proximal sites (17 and 20) (Table 1 and Fig. 3). Sediment C/N ratios were calculated from the sediment cores from sites 8 and 6 and show relatively low values, thus suggesting a predominantly marine origin (Table 1 and Fig. 3).

The stable nitrogen isotope composition in sediments can be used to infer nitrate (NO_3^-) supply in the euphotic zone. As phytoplankton consumes lighter nitrate, the sediment becomes enriched in the heavier ($\delta^{15}\text{N}$) nitrate, indicating increased productivity. The total nitrogen and isotopic composition of the sediments were not measured in the sediment cores from sites 17 and 20 due to the very low organic matter content (Table 1 and Fig. 3). Biogenic silica concentrations were higher in the glacier-distal sites than in the glacier-proximal sites (Table 1). However, when accounting for differences in sedimentation rates, BSi fluxes were higher in the glacier-proximal sites (Table 1 and Fig. 3).

3.4 Diatoms

Diatom assemblages were both rich and diverse at all sites except for site 20, which was virtually barren of diatoms and is discussed in Sect. 4.1. At sites 8, 6, and 17, a total of 172, 138, and 93 different taxa, respectively, were identified to the species level and 22, 21, and 10 taxa, respectively, to the genus level. Total diatom concentrations (including resting spores and vegetative forms of *Chaetoceros* spp.) in the sediment samples varied from 1.2×10^6 to 12.2×10^6 valves g^{-1} at site 8, from 2.3×10^6 to $35.8 \times$

10^6 valves g^{-1} at site 6, and from 2.8×10^6 to 30.4×10^6 valves g^{-1} at site 17 (Fig. 4). Annual diatom fluxes ranged between 0.5×10^6 and 5.1×10^6 valves $\text{cm}^{-1} \text{yr}^{-1}$ (mean $2.1 \times 10^6 \pm 1.0 \times 10^6$ valves $\text{cm}^{-1} \text{yr}^{-1}$) at site 8, 0.3×10^6 to 7.2×10^6 valves $\text{cm}^{-1} \text{yr}^{-1}$ (mean $1.6 \times 10^6 \pm 1.6 \times 10^6$ valves $\text{cm}^{-1} \text{yr}^{-1}$) at site 6 and between 0.8×10^6 and 15.8×10^6 valves $\text{cm}^{-1} \text{yr}^{-1}$ (mean $7.8 \times 10^6 \pm 4.3 \times 10^6$ valves $\text{cm}^{-1} \text{yr}^{-1}$) at site 17 (Fig. 3).

Diatom assemblage composition was relatively uniform between the three studied sites, and diatom taxa (excluding *Chaetoceros* species) were generally dominated by *Detonula confervacea* (resting spore), *Thalassiosira antarctica* var. *borealis* (resting spore), *Fragilariopsis oceanica*, *F. cylindrus*, and *T. nordenskiöldii* (Fig. 4). Diatoms were divided into five groups according to their ecological preferences: cold-water species, early-spring bloomers, benthic species, sea-ice-associated species, and freshwater species (Table 2).

Chaetoceros spp. are generally abundant in the sediment due to their good preservation and are likely to be over-represented in the assemblage and thus were left out of the diatom assemblage percentage calculations discussed here (Fig. 4). However, to estimate the concentrations of *Chaetoceros* spp. and chrysophyte cysts, we calculated flux rates (Fig. 4). *Chaetoceros* spp. (including vegetative forms and resting spores) were abundant in all the cores containing diatoms, making average flux rates of 0.4×10^6 , 0.4×10^6 , and 0.8×10^6 valves $\text{cm}^{-1} \text{yr}^{-1}$ at sites 8, 6, and 17, respectively (Fig. 4). Additionally, chrysophyte cysts were counted as this group is associated with low-salinity waters during the summer–autumn bloom (Hasle and Heimdal, 1998; Krawczyk et al., 2015b) and can thus provide additional information on past salinity changes.

For the diatom record from site 8, the first CA axis explains 36 % of the variation in the dataset (Fig. 4). The axis scores switch from mainly positive to mostly negative values in around the late 1940s. At site 6, the first CA axis accounts for 49.7 % of the variation in the dataset and the CA axis scores change from negative to positive in around the 1960s. At site 17, the first CA axis explains 29.5 % of the variation in the dataset. Scores for the first CA axis remain mainly negative until ca. 1985, when they shift to positive values.

3.5 Freshwater runoff

Total freshwater runoff estimates extracted from MAR were further partitioned into estimates representing inner-fjord runoff, outer-fjord runoff, and southern-fjord runoff (Fig. 5). Runoff estimates for the southern part of the fjord system (see Fig. 1 for division of the fjord regions) are excluded since they represent part of the fjord that is not investigated in this study. The estimate for the total freshwater runoff varies between 13.0 and 49.0 Gt yr^{-1} (mean 23.1 Gt yr^{-1}), for the inner-fjord runoff between 9.1 and 41.1 Gt yr^{-1} (mean 18.0 Gt yr^{-1}), and for the outer-fjord runoff between 0.7 and 2.2 Gt yr^{-1} (mean 1.3 Gt yr^{-1}) (Fig. 5). Glacial runoff makes

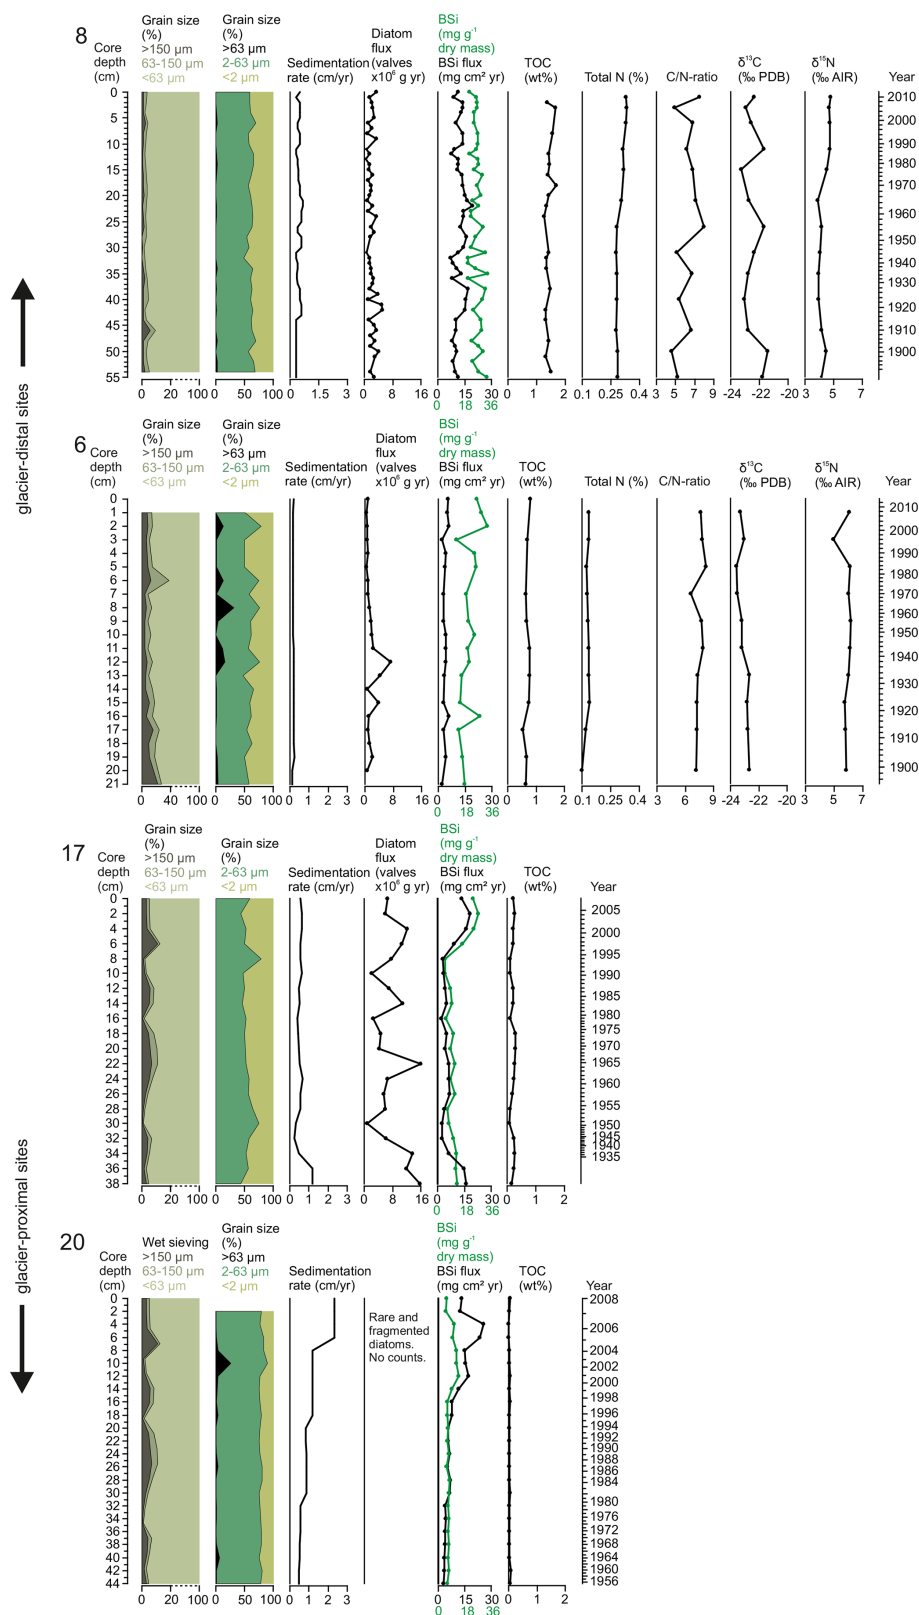

Figure 3. Sediment grain-size distribution (wet sieving and laser diffraction), sedimentation rate (cm yr^{-1}), diatom flux (valves $\times 10^6 \text{ g}^{-1} \text{ yr}^{-1}$), BSi content (mg g^{-1} dry mass; green line) and BSi flux ($\text{mg cm}^{-2} \text{ yr}^{-1}$; black line), total organic carbon (wt%), total nitrogen (%), C/N ratio, $\delta^{13}\text{C}$ (‰ Pee Dee Belemnite) and $\delta^{15}\text{N}$ (‰) in sediment cores SA12-ST8-1 (8), SA13-ST6-36R (6), DANA08-ST17 (17), and DANA08-ST20 (20).

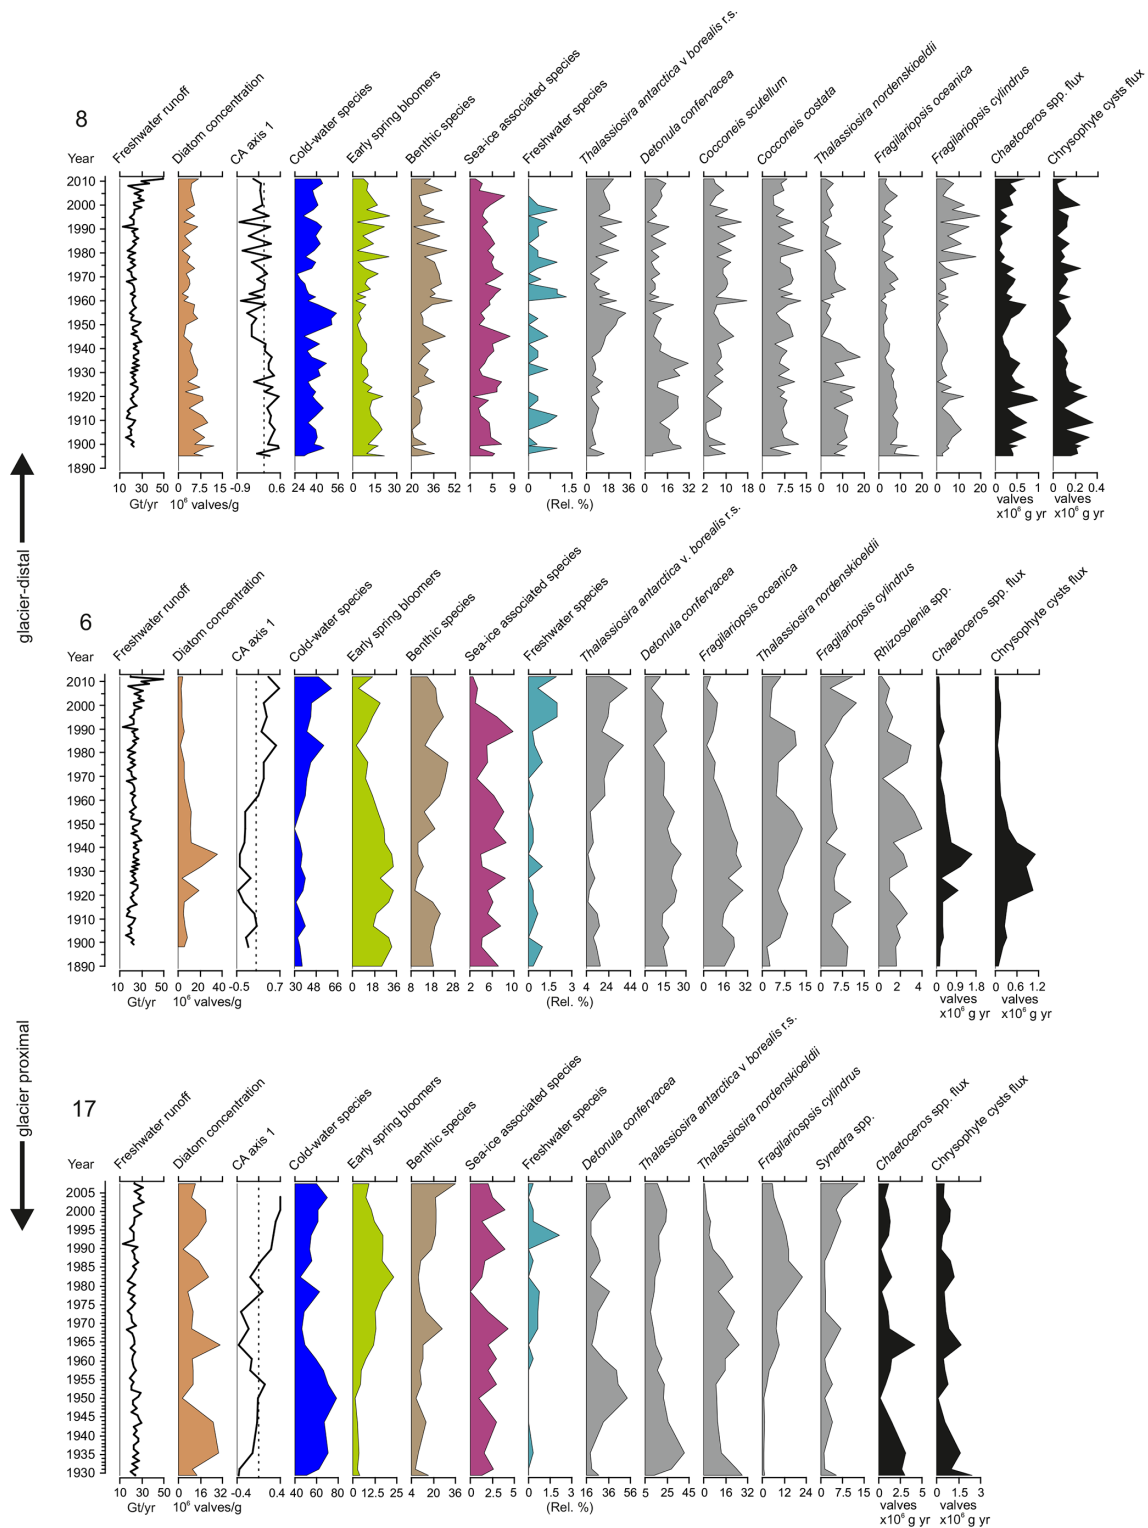

Figure 4. Total freshwater runoff (Gt yr^{-1}), diatom valve concentration (10^6 valves g^{-1} dry sediment), CA axis 1 scores (dashed lines indicate 0), relative abundance (%) of the cold-water species, early-spring bloomers, benthic species, sea-ice-associated species, freshwater species, relative percentage of the most abundant taxa in each core, *Chaetoceros* spp., and chrysophyte cyst fluxes ($\times 10^6$ valves $\text{cm}^{-1} \text{yr}^{-1}$) in sediment cores SA12-ST8-1 (8), SA13-ST6-36R (6), and DANA08-ST17 (17). DANA08-ST20 (20) was devoid of diatom valves. Diatom species are scaled on different x axes for better visualization of trends in the percentages of less abundant species.

Table 1. Results of the TOC, TN, C/N ratio, $\delta^{13}\text{C}$, $\delta^{15}\text{N}$, and BSi analyses.

Site	TOC (wt %)	TN (%)	C/N ratio	$\delta^{13}\text{C}$ (‰)	$\delta^{15}\text{N}$ (‰)	BSi (mg g ⁻¹)	BSi flux (mg cm ² yr ⁻¹)
8	1.25–1.68 (mean 1.4 ± 0.1)	0.28–0.33 (mean 0.3 ± 0.02)	4.6–8 (mean 6.3 ± 1.0)	–23.3 to –21.4 (mean –22.4 ± 0.6)	3.9–4.7 (mean 4.3 ± 0.3)	21.1–35.4 (mean 27.5 ± 3.7)	7.1–19.2 (mean 12.1 ± 2.9)
6	0.72–1.08 (mean 0.7 ± 0.08)	0.10–0.14 (mean 0.1 ± 0.01)	6.6–8.2 (mean 7.5 ± 0.4)	–23.6 to –22.7 (mean –23.1 ± 0.3)	4.9–6.2 (mean 5.9 ± 0.3)	12.8–34.5 (mean 22.2 ± 6.0)	2.1–5.8 (mean 3.9 ± 1.1)
17	0.09–0.30 (mean 0.2 ± 0.06)					5.3–28.9 (mean 12.6 ± 6.6)	2.2–18.0 (mean 7.5 ± 5.1)

Table 2. Diatom groups, species in each group, ecological preferences, and references. The abbreviations r.s. and veg denote resting spore and vegetative cell, respectively.

Group	Species	Ecology	Reference
Cold-water species	<i>Detonula confervacea</i> , <i>Thalassiosira antarctica</i> var. <i>borealis</i> (r.s. and veg), <i>Bacterosira bathyomphala</i> , <i>Thalassiosira anguste-lineata</i> , <i>Thalassiosira hyalina</i> , and <i>Shionodiscus trifultus</i>	Species preferring relatively cold waters, blooming in the late summer.	Krawczyk et al. (2015a), Oksman et al. (2019), Luostarinen et al. (2020)
Early-spring bloomers	<i>Fragilariopsis oceanica</i> , <i>Fragilariopsis cylindrus</i> , <i>Fragilariopsis reginae-jahniae</i> , and <i>Pauliella taeniata</i>	First species to bloom in the spring during and immediately after sea-ice break-up and melt.	Quillfeldt (2000, 2004), Oksman et al. (2019), Weckström et al. (2020)
Sea-ice associated	<i>Actinocyclus curvatulus</i> , <i>Coscinodiscus oculus-iridis</i> , <i>Fos-sula arctica</i> , <i>Porosira glacialis</i> , <i>Thalassiosira bulbosa</i> , <i>Rhizosolenia</i> spp., <i>Pleurosigma stuxbergii</i>	Species associated with sea-sonal and high sea-ice concentrations or produce sea-ice-related biomarkers (HBI III).	Oksman et al. (2019), Weckström et al. (2020), Belt et al. (2017)
Freshwater species	<i>Eunotia</i> spp., <i>Cymbella</i> spp., <i>Cyclotella</i> spp., <i>Tabellaria</i> spp., and <i>Pinnularia</i> spp.	Species living in freshwater environments.	Cremer (1998), Foged (1973)

up the largest proportion of the total runoff in Nuup Kangerlua, whereas the runoff from both tundra and rainfall has a smaller contribution (Fig. 5).

The relationship between the different runoff estimates and historical climate records was tested, showing a positive correlation between the total and inner-fjord runoff and the historical air temperature record ($r = 0.61$ and $r = 0.63$, respectively) as well as the sea-surface-temperature (SST) record ($r = 0.47$ and $r = 0.49$) from the Fyllas Banke oceanographic station shown in Fig. 1. In contrast, the outer-fjord runoff estimates did not have a statistically significant correlation to either air or sea-surface temperatures. All statistically significant correlations between the studied proxies and the total, inner-fjord, and outer-fjord freshwater runoff and air and sea-surface temperatures are presented in Table 3.

4 Discussion

In Arctic fjords, marine primary production is a crucial ecosystem function that sustains important ecosystem services such as fisheries and indigenous livelihoods (Berthelsen, 2014; Lydersen et al., 2014; Meire et al., 2017; Laufer-Meiser et al., 2021). Here, we present sub-decadal records of temporal and spatial changes on marine primary production (diatom fluxes, BSi, and TOC) and diatom species composition in Nuup Kangerlua since the late 19th century and discuss these changes in relation to annual freshwater runoff estimates, historical air and sea-surface temperatures, and glacier front dynamics.

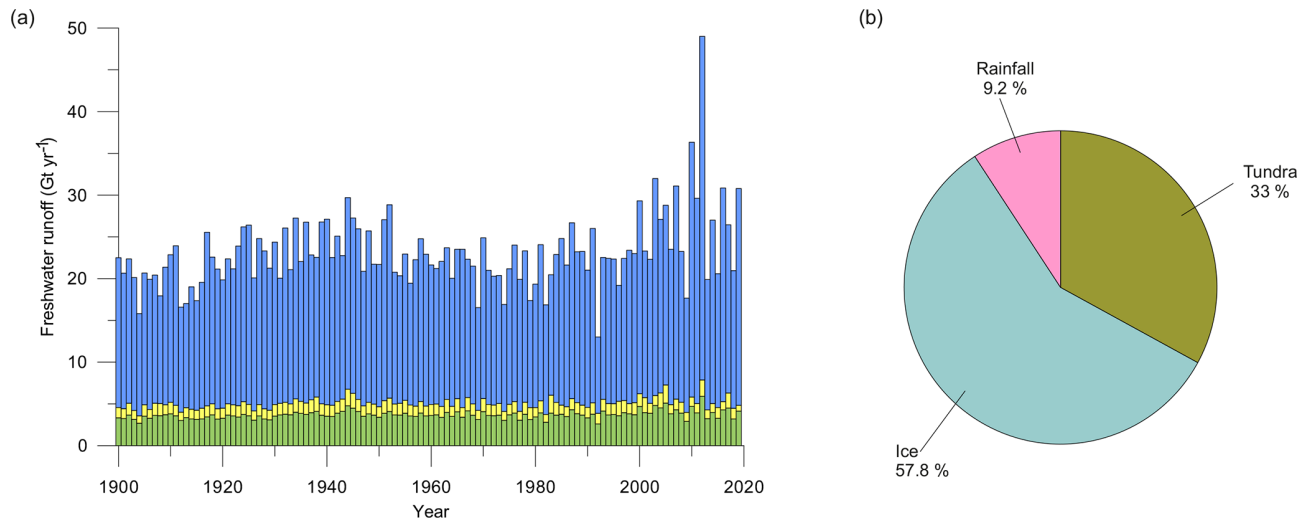

Figure 5. (a) Inner-fjord (blue), outer-fjord (yellow), and southern-fjord (green) freshwater runoff estimates (Gt yr^{-1}) for 1900–2019. For definitions of the different regions of the fjord, see red lines in Fig. 1. (b) Pie chart showing the distribution of the average runoff from ice (turquoise blue), tundra (green), and fjord rainfall (pink) between 2010–2019.

4.1 Records of marine productivity in Nuup Kangerlua since the late 19th century

Our productivity indicators (diatom fluxes, BSi, and TOC) from Nuup Kangerlua display large spatial variability between the studied sites (Fig. 3). In addition to variations in productivity between the sites, different proxies from the same core show minor dissimilarities (Fig. 3) as they do not all reflect the same productivity signal. TOC and BSi values, representing organic carbon from primary and secondary producers and the amount of biologically produced silica (Table 1), point to a relatively high productivity in Nuup Kangerlua throughout the 20th century when compared to modern values from other coastal Arctic sites, where TOC in the surface samples remains $< 1 \text{ wt } \%$ and BSi $< 10 \text{ mg g}^{-1}$ (e.g. Ribeiro et al., 2017; Limoges et al., 2018; Kumar et al., 2016; Detlef et al., 2021). Similarly, high values have been observed on the northwest Greenland shelf during the Holocene when climate conditions were favourable for high primary production (Limoges et al., 2020; Saini et al., 2020; Ribeiro et al., 2021). The modern fjord hydrography in Nuup Kangerlua has been shown to maintain productivity also in the outer fjord, as biomass and nutrients are partly advected from the inner fjord by currents and wind and tidal mixing, which, together with the warm, nutrient-rich waters carried by the WGC, can increase seasonal productivity (Juul-Pedersen et al., 2015). Also, the year-round ice-free conditions in the outer fjord may prolong the productive season, whereas glacial calving and sea-ice cover in the inner fjord shorten the productive window.

Today, spatial trends in primary production in Nuup Kangerlua are mainly controlled by sea-surface temperature and salinity gradients along with nutrient availability,

so the highest productivity rates have been reported from the inner-fjord area (Krawczyk et al., 2015a, 2018; Meire et al., 2016a, 2017). In contrast, our sediment records with the highest organic carbon content were retrieved from the outer fjord (site 8), where average TOC and BSi levels are up to 46 and 3 times higher, respectively, than in the inner-fjord area (Fig. 3). While sedimentation rates are more than 2 times higher in the inner fjord, mean BSi fluxes are still slightly higher at the outer-fjord site than at the two inner-fjord sites 17 and 20 (Table 2). Such an inner-fjord–outer-fjord gradient of increasing productivity can be found elsewhere along the Arctic coasts (Arendt et al., 2016; Kumar et al., 2016; Ribeiro et al., 2017; Limoges et al., 2018). Whereas productivity (diatom productivity, BSi, and TOC) at the outer-fjord site (8) has remained relatively stable (and high) since the late 19th century, this site records frequent low-amplitude fluctuations in biogenic silica content and diatom production occurring at a sub-decadal scale (Fig. 3).

The diatom productivity (absolute concentrations and fluxes) is highest at site 17, and this part of the Nuup Kangerlua fjord is characterized by very high rates of annual primary production (up to $120 \text{ g C m}^{-2} \text{ yr}^{-1}$) according to data from the Greenland Ecosystem Monitoring programme (Juul-Pedersen et al., 2015; Meire et al., 2015). Diatoms alone account for about 95 % of the biomass here (Arendt et al., 2011; Meire et al., 2016b). The high productivity in this part of the fjord has been suggested to be maintained by the high dissolved silica (DSi) input from surface runoff combined with upwelling of nutrient-rich deep waters (Meire et al., 2016a, 2017). The high diatom production at site 17 can be explained by its ideal location that receives freshwater discharge from both surface runoff and several marine-terminating glaciers (Fig. 1). Subglacial discharge plays a

Table 3. Statistically significant correlations ($p < 0.05$) between proxy records (diatoms, geochemistry, grain size) and environmental variables (total, inner, and outer freshwater runoff; historical air temperatures; and sea-surface temperatures, SSTs) in sediment cores SA12-ST8-1 (8), SA13-ST6-36R (6), DANA08-ST17 (17), and DANA08-ST20 (20). Correlation coefficient (r) values are presented in brackets for each correlation. Positive correlations are in bold.

key role in sustaining high productivity in this part of the fjord. Although the most glacier-proximal site (20) has a mean BSi flux of $9.2 \text{ mg cm}^{-2} \text{ yr}^{-1}$, no diatom valves were found apart from in the uppermost part of the sediment core. In general, biogenic silica contents at site 20 are significantly lower until the late 1990s, suggesting low primary production here, compared to the other sites. The major increase in BSi and appearance of diatom valve fragments in the upper part of the core indicate an increase in productivity, although this remained significantly lower than at the other sites. The absence of diatoms and low BSi values indicate, in turn, very low productivity levels. The near absence and overall poor preservation of diatom valves may also be explained by dissolution of the diatom valves in the water column or water–

sediment interface due to adverse physicochemical conditions (Ryves et al., 2006).

4.2 Sources of sedimentary organic matter in glacier-distal sites

The stable isotope carbon-13 ($\delta^{13}\text{C}$) and the carbon-to-nitrogen (C/N) ratio can be used to trace whether the organic matter in the sediment originates from marine or terrestrial sources. Autochthonous organic carbon is produced by the primary producers using the CO_2 dissolved in the seawater, whereas allochthonous organic carbon sources can be of terrestrial or marine (e.g. sea ice) origin (Bianchi et al., 2020). At sites 8 and 6, the organic matter in the sediment can

be traced to be of marine origin, as the measured $\delta^{13}\text{C}$ values (between -20‰ and -22‰) are typical of protein-rich marine phytoplankton, whereas the terrestrial organic carbon would generally be more depleted in $\delta^{13}\text{C}$ (Meyers, 1994). In our record from sites 6 and 8, we find no evidence of freshwater runoff increasing the amount of terrestrial carbon in the sediment as the variations in $\delta^{13}\text{C}$ values are minimal and show no increase in pace with the freshwater runoff dataset (Fig. 3). Despite the C/N ratio from site 6 having a positive correlation with freshwater runoff, the very low values (average of 6.3 at site 8 and average of 7.4 at site 6) further support autochthonous organic matter sources as C/N ratios above 20 would indicate terrestrial carbon sources (Meyers, 1994). In marine sediments, bound inorganic nitrogen can constitute a large portion of the total nitrogen concentration, and thus the marine organic matter might be more depleted in $\delta^{13}\text{C}$ than terrestrial organic matter (Kumar et al., 2016). However, we found no clay-bound nitrogen when C/N ratios were tested for land-derived inorganic nitrogen according to Schubert and Calvert (2001). These analyses ($\delta^{13}\text{C}$ and C/N ratio) were performed only for the glacier-distal records (8 and 6) and not for the glacier-proximal records (17 and 20) due to extremely low carbon contents in these sediments (Fig. 3). Although the sedimentary organic carbon in our records is mainly from marine sources, we found freshwater diatoms in sites 8, 6, and 17 (Fig. 4) that originate from terrestrial freshwater sources, e.g. lakes and ponds, and enter the fjord via runoff (Jensen, 2003). Overall, the relative abundance of freshwater diatoms is extremely low ($< 2\%$), but it represents a clear fingerprint of terrestrial origin as these species generally have very low to zero tolerance to saline waters and are not found in marine environments (Cremer, 1998; Foged, 1973), thus supporting the assumption that part of the organic carbon could originate from terrestrial sources. However, freshwater species were most abundant at site 6 (Fig. 4) where the C/N data suggest that the organic matter was found to originate from marine sources (Fig. 3).

4.3 Freshwater discharge positively impacts primary production in the inner fjord

Our records display a substantial increase in BSi content and fluxes at the glacier-proximal sites (17 and 20) from ca. 1995 onwards as sedimentary BSi contents increase rapidly, keeping pace with the inner-fjord freshwater runoff (Fig. 6). In modern monitoring studies the inner fjord is found to have high productivity, as upwelling of the subglacial freshwater discharge and the subsequent meltwater plume bring essential nutrients from the nutrient-rich deep water into the surface water layer for the primary producers (Meire et al., 2016a, 2017; Hopwood et al., 2018, 2020). Also, the input of dissolved silica (DSi) and its implications for increasing diatom productivity are highest in the inner part of the fjord (Meire et al., 2016a). The modern monitoring data from Nuup Kangerlua reach back to 2008 (Greenland Ecosys-

tem Monitoring); however, our long-term records suggest that the high productivity levels, prevailing at the glacier-proximal area today, had been already initiated in the 1990s. The strong positive correlation between marine productivity (BSi flux) and freshwater runoff (Table 3) shows that increased productivity in this part of the fjord is tightly associated with freshwater discharge. This positive correlation suggests that in the future, increased freshwater discharge is likely to have a positive socio-economic impact as high productivity is reflected in the higher trophic levels such as fish and marine mammals (Boye et al., 2010). For example, halibut fisheries, which are economically important for Greenland (Berthelsen, 2014), have been shown to have a positive correlation with meltwater input (Meire et al., 2017).

Although most of the freshwater originates from glacial discharge (Fig. 5), the increasing relative abundance of freshwater diatoms recorded from the 1990s (Fig. 6) indicates flushing of freshwater deposits (such as the lake Tasersuaq) into the fjord. Together with the BSi flux, coarse sediment grains ($> 63\mu\text{m}$) at site 20 display a strong positive correlation with freshwater runoff (Table 3), suggesting that freshwater input to this site originates from solid ice discharge. The coarse sediment grain size generally represents the IRD deposited by icebergs, which typically release most of the coarse grains close to the source as they melt. The melting of icebergs can cause water column vertical mixing in a similar way to subglacial discharge and thus provide more nutrients to the surface waters (Kanna et al., 2018). Also, sedimentation rates are increasing at sites 17 and 20 along with freshwater runoff (Table 3), suggesting that a large amount of sediment is being delivered to the fjord with freshwater discharge. Subglacial discharge from marine-terminating glaciers typically causes sediment suspension plumes (Fig. 1), which, by upwelling, bring nutrients from nutrient-rich deep waters to the surface for the primary producers (Meire et al., 2017; Hopwood et al., 2018, 2020). In the inner fjord, an increase in freshwater discharge, accompanied by increased sediment fluxes and upwelling, would represent a shift from clear, stratified waters to turbid, mixed waters after the 1990s. In fact, our diatom record from site 17 shows that species such as *Thalassiosira nordenskioeldii* and *Fragilariopsis cylindrus*, as well as chrysophyte cysts, which prefer low salinities and stratified waters (Hasle and Heimdal, 1998; von Quillfeldt, 2004; Krawczyk et al., 2015a, b), decrease after the 1990s (Fig. 4), while the number of benthic species, associated with water turbidity and with low-light conditions (Glud et al., 2002; Karsten et al., 2011) increases (Fig. 4). Interestingly, site 17 shows evidence of the suspension plume typically caused by the marine-terminating glaciers, whereas the record from site 20 suggests increased iceberg calving.

In contrast to the inner fjord, the record from the glacier-distal site (site 8) shows no correlation between productivity (diatom fluxes, BSi, or TOC) and freshwater runoff throughout the entire studied period, and here, freshwater runoff is

limited (Fig. 5). The diatom CA axis suggests an important change in the assemblage around the 1940s (Fig. 6), from an assemblage dominated by early-spring bloomers to an assemblage dominated by benthic species and late-summer bloomers, e.g. *Thalassiosira antarctica* var. *borealis* r.s. (resting spore; Fig. 4). This suggests an increase in water turbidity, and/or more nutrient limitation (Glud et al., 2002; Karsten et al., 2011). However, the timing of this shift in the assemblage composition is not associated with any significant changes in freshwater runoff and may therefore be caused by changes in, for example, wind strength and consequently mixing of the water column.

4.4 Freshwater discharge influences spring and summer bloom dynamics

Based on modern observations, the annual marine primary production in Nuup Kangerlua is sustained by two seasonal blooms of similar magnitude occurring during the early spring and the late summer (Juul-Pedersen et al., 2015). Our long-term perspective indicates that the dynamics and magnitude of these blooms have varied according to freshwater discharge (Fig. 6). We find that freshwater runoff leads to a stronger spring bloom signal at site 6, while it promotes late-summer bloomers at site 17 (Table 3 and Fig. 6) and vice versa during periods of lower runoff. In terms of species responses, the diatom records show that species blooming in early spring during ice melt (*Fragilariopsis* spp.) or right after ice break-up in late spring (*Thalassiosira nordenskioeldii*) (Cremer, 1998; Jensen, 2003; Oksman et al., 2019) dominate the assemblage at site 6 during periods of higher freshwater discharge, while these species at site 17 have a negative correlation with freshwater (Table 3). Yet, the species blooming during the late summer (*Detonula confervacea* and *Thalassiosira antarctica* var. *borealis* r.s.) as well as *Chaetoceros* spp., which typically follow nutrient exhaustion and represent the last stage of the productive season (Krawczyk et al., 2015b), are more common at site 17 during periods of increased freshwater runoff (Fig. 4).

Modern observations have shown that today spring and summer bloom dynamics are mainly controlled by seasonal changes in salinity and temperature as well as fjord hydrography and tidal and wind mixing (Juul-Pedersen et al., 2015; Krawczyk et al., 2015b, 2018; Meire et al., 2016b). Other environmental factors, in particular sea ice, might better explain the differences observed at the two sites as sea ice can also influence the timing and magnitude of the spring bloom (Meire et al., 2016b). At the glacier-proximal site (17), a relatively high number of sea-ice species (which have a positive correlation with freshwater runoff) and low number of early-spring bloomers suggest sea-ice presence continuing late into the spring and limiting the spring production season (Fig. 4). However, the substantially high percentage (up to 79 % in the 1950s) of late-summer bloomers alongside elevated BSi

Figure 6. and diatom flux (Fig. 3) is indicative of a productive summer season.

The spring bloom makes up a significant part of the annual primary production in Nuup Kangerlua (Juul-Pedersen et al., 2015), and increased spring production in the Arctic is a typical feature of the ongoing climatic warming, which has

been evident in the Arctic Ocean over recent decades (Renaut et al., 2018). The length of the productive season has implications for CO₂ capture as the fjords can function as carbon sinks (Meire et al., 2015; Rysgaard et al., 2012). In the future, increasing freshwater discharge is likely to extend the productive season and contribute to spatial differences in the timing of blooms occurring in different parts of the fjord system. The spring bloom is likely to occur earlier in the side branch of the fjord, whereas the magnitude of the late-summer bloom increases along the main ice flow pathway.

4.5 Freshwater impact reaching the glacier-distal side branch

Until now, the impacts of freshwater runoff on primary production have mainly been studied in the main branch of the Nuup Kangerlua fjord system (Juul-Pedersen et al., 2015; Meire et al., 2016a, b, 2017; Krawczyk et al., 2018), whereas productivity changes in the side branches are less known. Today, the upwelling of nutrients by subglacial processes in Nuup Kangerlua is suggested to affect primary production downstream, to a distance of 10–100 km along the pathway of the advected bloom (Meire et al., 2016b; Hopwood et al., 2018). Here, we show that freshwater runoff impacts primary production (BSi flux and TOC) in the glacier-distal site at the side branch of the fjord system (site 6). Here, both BSi flux and TOC strongly correlate with the freshwater runoff, despite this site being in the sheltered side branch ca. 110 km from the Kangiata Nunaata Sermia (KNS) termini and not directly on the main flow path of glacier influence (Fig. 1). The high number of early-spring bloomers at site 6 indicates an earlier seasonal ice break-up and strong inflow of freshwater into the side branch as these species thrive in cold and fresh surface waters. Diatom production was high (up to 36×10^6 valves g⁻¹ and a flux of 7.2 valves cm⁻¹ yr⁻¹) during the 1930s and the 1940s while freshwater runoff was elevated and sea-surface temperatures were relatively high (Figs. 3 and 6). The high productivity is further supported by the diatom species composition data, as the *Rhizosolenia* genus reaches the highest abundances of the record in around 1945 (Fig. 4). This genus has been linked to a nutrient-rich and stratified water column, conditions that are generally related to meltwater pulses (Kemp et al., 2006).

4.6 Long-term productivity links to atmospheric forcing

Teleconnections in the North Atlantic region, such as the North Atlantic Oscillation (NAO) and the Atlantic Multidecadal Oscillation (AMO), have been shown to drive marine primary production (Martinez et al., 2009). These decadal-scale ocean–atmosphere oscillations modulate sea-surface conditions through fluctuations in temperature, precipitation, and wind and, thus, impact ecosystem responses (Martinez et

al., 2009; Racault et al., 2017). In West Greenland, the locations of glacier termini are driven primarily by atmospheric temperatures reflecting NAO phases, and atmospheric forcing has been defined as the primary driver of KNS ice margin changes (Lea et al., 2014; Bjørk et al., 2018). NAO phases modulate the climate so that during a negative NAO phase, West Greenland experiences warmer climate and increased precipitation, whereas during the positive phase the opposite occurs (e.g. Hurrell, 1995; Bjørk et al., 2018).

In Nuup Kangerlua, most of the glacier termini responded to the warm atmospheric temperatures during the negative NAO phase between the 1930s and 1970s by retreat and mass loss (Fig. 7), with KNS having the largest retreat of ca. 8 km (Fig. 6). Our record shows increased marine productivity at site 6 during this negative NAO phase (Fig. 6), and here the TOC has a strong positive correlation with regional air temperature and freshwater runoff records. The diatom record from site 6 shows freshening of surface waters as *Chaetoceros* spp. and chrysophyte cyst fluxes are highest, together with a higher relative percentage of early-spring bloomers (Fig. 4). Together, this suggests that fjord productivity responds to decadal ocean–atmosphere oscillations. After the 1970s, the NAO phase has remained mainly positive, but interestingly since the 1990s the accelerated climate warming has overruled the NAO-modulated climate signal (Seidenkrantz et al., 2009), and both temperatures and freshwater discharge have increased substantially despite the ongoing positive NAO phase (Fig. 6). During recent decades, asynchronous behaviour of KNS and NS has primarily been attributed to subglacial melt (Motyka et al., 2017); however, both KNS and NS have retreated (Fig. 7), resulting in increased freshwater discharge and productivity in the inner-fjord sites. The accelerated warming of the recent decade may lead to substantial retreat of KNS in the future (Aschwanden et al., 2019). This can have a negative impact on productivity if the grounding depth changes significantly (reducing the fertilizing effect of nutrient upwelling) or if the ice margin retreats onto land. The retreat of marine-terminating glaciers is likely to have a strong impact on productivity due to the key role that subglacial discharge plays in sustaining high fjord productivity on both interannual (Meire et al., 2017; Hopwood et al., 2018) and multidecadal timescales as shown here.

5 Conclusions

Long-term records of marine productivity are needed to define the natural baseline against which to assess recent cryosphere and coastal ecosystem changes. More accurate baselines ultimately provide more robust projections of future changes. Here, we have combined sub-decadal records of primary productivity changes with estimates of freshwater runoff since the late 19th century to determine the impacts of

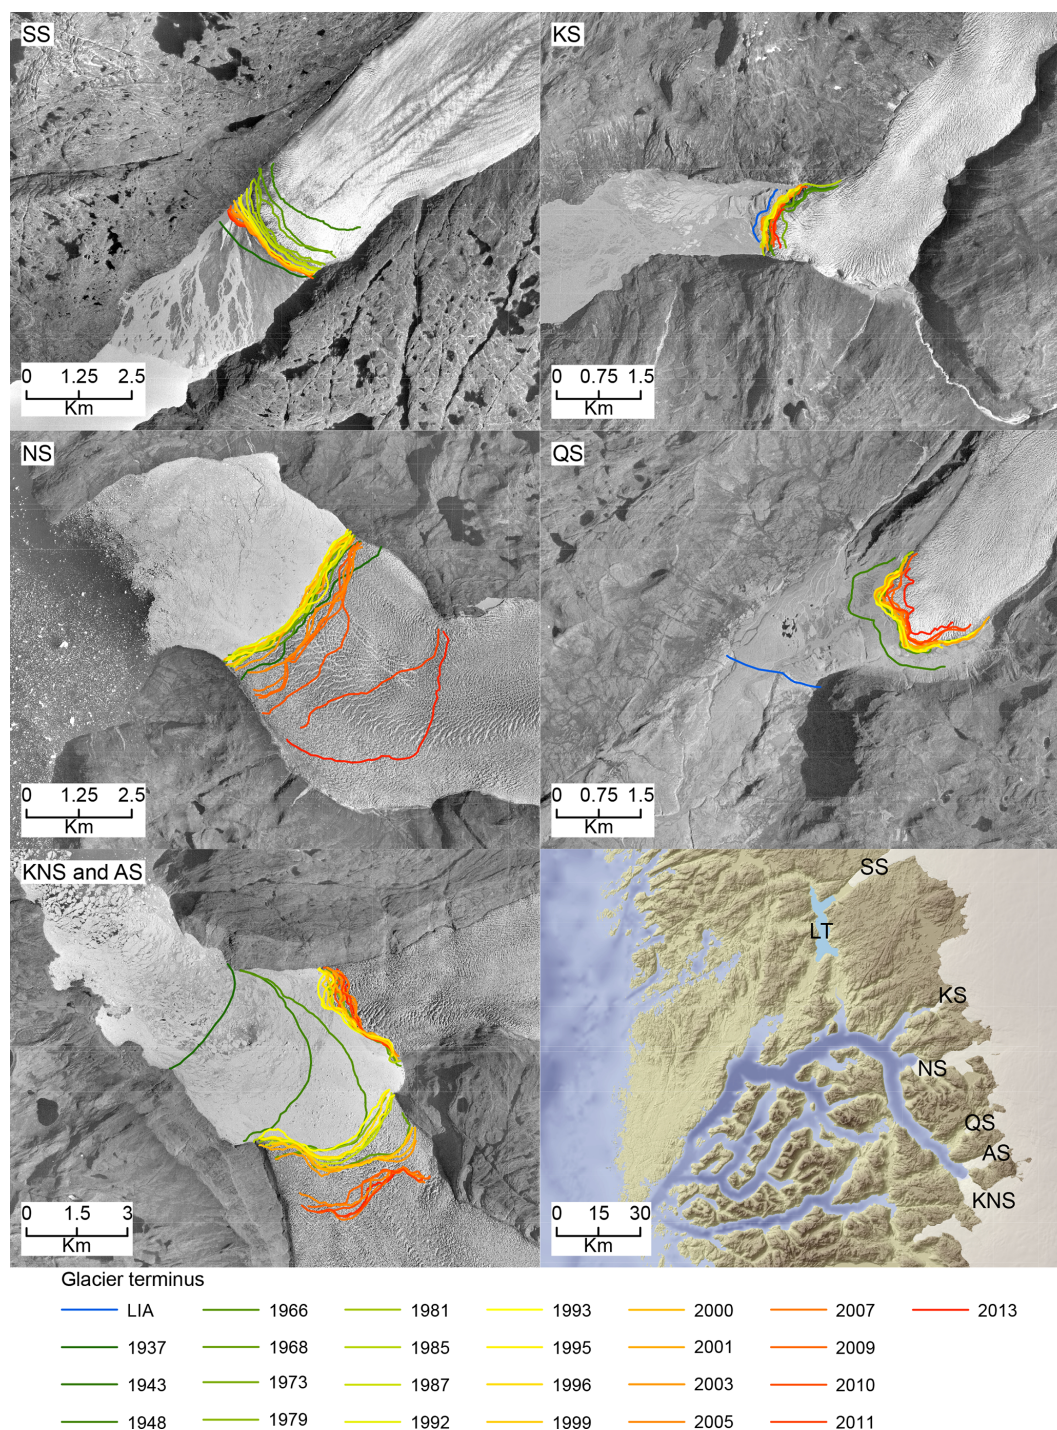

Figure 7. Glacier terminus changes in Saqqap Sermia (SS), Kangilinnguata Sermia (KS), Narsap Sermia (NS), Qamanaarsuup Sermia (QS), Kangiata Nunaata Sermia (KNS), Akullersuup Sermia (AS), and the lake Tasersuaq (LT) in a relation to their 2020 position.

freshwater on fjord productivity for Nuup Kangerlua, southern West Greenland.

We find that in the glacier-proximal area, biogenic silica fluxes are tightly associated with freshwater runoff and that freshwater imposes positive impacts on marine productivity. Our record shows non-uniform responses to freshwater inside the fjord system, which highlights the importance

of marine-terminating glaciers to marine productivity. However, we find that the impacts of freshwater discharge are wider than previously known as freshwater has a positive impact on the marine productivity in the glacier-distal side branches of the fjord away from the main discharge flow path. Further, our diatom assemblage data show that freshwater modulates the location and magnitude of the spring and late-summer blooms, and these blooms are not synchronous inside the fjord. Freshening of the inner fjord prolongs the late-spring sea-ice conditions, leading to more extensive spring bloom in the side branch, while summer bloom becomes larger in the inner fjord. Overall, however, we conclude that productivity is higher today than at any other time since the late 19th century. A substantial increase in productivity that was initiated in the 1990s in the inner fjord is co-incident with local cryosphere changes (retreat of the glacier terminus and subglacial freshwater input to the fjord) that are associated with acceleration in climate warming.

In the future, freshwater runoff is expected to increase and will likely result in higher marine productivity in Nuup Kangerlua, with positive influence on Greenlandic fisheries and other harvestable marine resources. It is likely that, in a warmer near-term future with more ice-sheet melt, the fjord system with marine-terminating glaciers that have not retreated beyond their grounding line may become a greater CO₂ sink as increasing freshwater runoff is related to increasing marine production and a prolonged annual productive season due to increased nutrient availability. Ultimately, the future productivity of this system will be tightly linked to the fate of its marine-terminating glaciers.

Data availability. The data presented in this paper are archived in the GEUS Dataverse and can be accessed through the following link: <https://doi.org/10.22008/FK2/ICURNP> (Oksman, 2022).

Author contributions. MO planned the study together with SR. SR designed the project (GreenShift) and provided sediment core material together with NNP, MSS, and NM. MO conducted diatom, grain-size, and BSi analysis, and ABK assisted with BSi and grain-size analyses. TJA carried out ²¹⁰Pb measurements. SHL and WC provided freshwater runoff calculations for 1900–2010 together with KDM, who provided freshwater runoff data. KKK provided data for the ice margin position. MO wrote the manuscript with input from all the co-authors.

Competing interests. The contact author has declared that neither they nor their co-authors have any competing interests.

Disclaimer. Publisher's note: Copernicus Publications remains neutral with regard to jurisdictional claims in published maps and institutional affiliations.

Acknowledgements. We thank Ida Sofie Mikaelssdóttir Olsson, Annette Ryge, and Charlotte Olsen for help with biogenic silica analysis and diatom slide preparation. Finally, we thank Thomas Juul-Pedersen and Ann Lennert for supporting our sediment coring activities during the Greenland Ecosystem Monitoring cruise with RV *Sanna* in 2012.

Financial support. This research has been supported by the Geo-center Denmark (project GreenShift, grant no. 2018-5 to Sofia Ribeiro) and by the Independent Research Fund Denmark (grant no. 9064-00039B to Sofia Ribeiro). Marit-Solveig Seidenkrantz was funded by the Danish Council for Independent Research (grant no. 7014-00113B (project G-Ice) and 0135-00165B (project Green-Shelf)) with additional funding from the European Union's Horizon research and innovation programme (grant no. 869383 (project ECOTIP)). The 2013 cruise with RV *Sanna* was funded by the Arctic Research Centre of Aarhus University, Denmark.

Review statement. This paper was edited by Elizabeth Bagshaw and reviewed by two anonymous referees.
