Abstract

To quantify the ablation processes on a debris covered glacier, a simple distributed ablation model has been developed and applied to a selected glacier. For this purpose, a bundle of field measurements was carried out to collect empirical data. A morphometric analysis of the glacier surface enables us to statistically capture the areal distribution of topographic features that influence debris thickness and consequently ablation. Remote sensing techniques, using high resolution satellite imagery, were used to extrapolate the ground truth results to the whole ablation area and to map and classify melt-relevant surface types. As a result, a practically applicable method is presented, that allows the estimation of ablation on a debris covered glacier by combining field data and remote sensing information. The sub-debris ice ablation accounts for about 19% of the entire ice ablation, while the percentage of the moraine covered area accounts for approximately 32% of the entire glacierized area. Although the ice cliffs occupy only 1.7% of the debris covered area the melt amount accounts for approximately 15% of the total sub-debris ablation and 2.7% of the total ablation respectively. Our study highlights the influence of debris cover on the response of the glacier terminus to climate warming. Due to the fact that melt rates beyond 0.1 m of moraine cover are highly restricted the shielding effect of the debris cover dominates over the temperature- and elevation dependence of the ablation in the bare ice case.

1 Introduction

Debris covered glaciers are a prominent feature in high relief mountain ranges like the Tien Shan, the Himalaya or the Karakoram. These glaciers are characterized by the presence of supraglacial debris mantles in the ablation zones that can originate from various sources, such as thrusting of subglacial material, melt-out of englacial debris bands, channel fill material, rockfall from mountain sides and meltwater bursts through the crevasse and conduit system or aeolian deposition directly on the glacier surface

Interactive Discussion

(Schomacker, 2008). Several studies concentrated on the relationship between debris cover thickness and sub-debris ice melt rates since the fundamental contribution of Østrem (1959). When solar radiation is present, very thin layers of debris or small single grains absorb more heat than ice, due to their lower albedo. The transfer of this energy into the underlying ice increases ablation rates. Thicker supraglacial debris covers act as a protecting carapace, which insulates the underlying ice and significantly reduces ablation (Østrem, 1959). The response of debris covered glaciers to climate change and therefore the prediction of future water availability are the subject of current research (e.g. Scherler et al., 2011; Benn et al., 2012; Bolch et al., 2012). Several physically based models that calculate sub-debris melt rates based on meteorological variables and debris thermal properties have been developed during the recent past (Nicholson and Benn, 2006; Reid and Brock, 2010). However, these physically based models require a wide range of input data whose determination is difficult, time consuming and expensive, especially for larger areas. They are important for process studies at point locations, but the application for large glaciers or even basin wide calculations remains difficult. To determine the ablation of a whole debris covered glacier, robust conceptual approaches with empirically derived functions have been proven to produce realistic results.

Apart from the natural debris coverage also ice cliffs and supraglacial lakes are important features of debris covered glaciers: they are widely recognized as spots of enhanced melting (Sakai et al., 2002, 2000). The exposed areas of steeply inclined ice are normally covered with a very thin layer of dust or sand, leading to higher absorption of shortwave radiation due to the low albedo compared to clean ice. Sakai et al. (2000) also states that supraglacial lakes produce internal ablation in the conduit system that leads to a positive feedback process, accelerating the ablation rate of debris covered glaciers. Caused by the collapse of water channels new ice cliffs and ponds are created.

To quantify these complex physical melt processes on a debris covered glacier, this study applies a distributed ablation model to a selected glacier.

2 Study area

Field observations have been carried out on the moraine covered ablation area of the Koxkar glacier, located in the Xinjiang Uyghur Autonomous Region of northwestern China (41.76° N, 80.11° E; Fig. 1).

5 The glacier is situated in the Central Tien Shan, one of the largest mountain ranges in Central Asia. Melt water, originating from the glaciers in this region feeds the Tarim river and is required in the surrounding lowlands for agriculture and drinking water (Hagg et al., 2007). The prevailing climate can be described as continental and is characterized by low winter precipitation and convective rainfall events in summer (Aizen
10 et al., 1997). The glacier reaches from 3060 to 6432 m a.s.l. with a length of 25 km and an area of 84 km² (Haidong et al., 2010). Debris thickness ranges from less than 0.01 m on the upper reach of the ablation area and on ice-cliff slopes to more than 3 m near the glacier terminus (Haidong et al., 2006; Wu and Liu, 2012). According to
15 Yong et al. (2006) the glacier has an ablation zone of about 30.6 km², with 60 % of the area covered by debris. The Equilibrium Line Altitude is 4300 m a.s.l. and the maximum glacier area is situated at the elevation band between 4600 and 4800 m a.s.l. (Haidong et al., 2010).

3 Data compilation

3.1 Ablation measurements

20 From 10 August to 29 August 2010 a series of ablation measurements were performed on the Koxkar glacier. Ablation stakes were installed at locations with varying debris thicknesses and preferably horizontal surfaces. Ablation was also measured at several ice cliffs of different expositions. To find out how the slope angles of the cliffs evolve, stakes have been placed orthogonal to the ice surface in the upper and the lower part
25 of the ice cliffs. Debris cover thickness was measured at each stake during installation.

Interactive Discussion

Additionally moraine thickness along a longitudinal profile was measured in summer 2011 by scientists from the Cold and Arid Regions Environmental and Engineering Research Institute (CAREERI).

3.2 Meteorological measurements

5 An automatic weather station (AWS) operated by CAREERI provides the required temperature record for the model. The AWS is located near the glacier terminus at an elevation of 3009 m a.s.l. (Fig. 1). The respective air temperature sensor is a HMP45C, Campbell Scientific Inc., mounted 2 m above ground surface. It is connected to a datalogger (CR1000, Campbell Scientific Inc.) which provides hourly records (Haidong et al., 2010).
10

3.3 Remote sensing

High resolution images from the Ikonos satellite have been used to generate a digital elevation model (DEM) from the entire Koxkar glacier catchment. Ikonos provides panchromatic images with 1 m resolution and multispectral imagery with 4 m resolution (Table 1). A cloud-free Ikonos image was acquired on 30 April 2009, 13:32 LT. The solar elevation was 60.1° and the solar azimuth was 149.6°.
15

An ASTER (Advanced Spaceborne Thermal Emission and Reflection Radiometer) Level 1B granule was processed to obtain land surface temperature (LST) following the approach by Pu et al. (2006). The observation date is 10 April 2007, the local observation time is 13:39 and the spatial resolution of the thermal infrared channel, which is used to obtain LST, is 90 m. The ASTER scene was selected, because no snow or clouds are present over the debris covered area in the acquired image.

4 Methods

4.1 Ablation model design

To compare ablation rates of several locations and time spans, mean degree day factors for each stake were calculated from the air temperature record (Braithwaite, 1995). The temperature data was extrapolated to higher elevations using a lapse rate of $-0.008\text{ }^{\circ}\text{C km}^{-1}$ (from 3000 to 3700 m a.s.l.) and $-0.004\text{ }^{\circ}\text{C km}^{-1}$ (from 3700 m a.s.l. and above) respectively. These lapse rates have been determined by Haidong et al. (2008) on the basis of measured air temperature at two different AWS located on the glacier (short term observation in 2003 and 2004) and the AWS in vicinity to the glacier described above (long term observation). Haidong et al. (2008) state that the drastic change in temperature lapse rate at an elevation of 3700 m a.s.l. is because of the transition from a broad supraglacial debris cover in the lower parts to a debris free ice surface in the middle and upper parts of the glacier. Ablation rates and their relation to debris thickness are determined empirically, to obtain an equation that represents the connection from debris cover thickness to degree day factor (Hagg et al., 2008).

Different curve fittings were tested, but a power law regression provides the most reliable equation because of the asymptotic approximation to the x-axis. To take account of the fact that the degree day factor for very thin layers of debris cover is enhanced compared to bare ice, a linear equation is used for moraine thicknesses smaller than 0.014 m. Considering the simplicity of the equation, there is good agreement between the measurements and the regression equation with a coefficient of determination of 0.92 (Fig. 2). In the case of the ice cliffs, degree day factors for north facing, south facing and east/west facing cliffs were calculated and applied within the model. Because the ice cliff area is measured in the horizontal projection from an orthophoto, the actual area of the cliffs was determined using a standard slope angle of 45° according to Haidong et al. (2010) which represents a reasonable mean value for the observed cliff slopes. During the observation period in the ablation season 2010 no change in inclination was determined. The slope angle of the observed cliffs was in

between 40° and 50° and fits well with the determined mean value. For supraglacial lakes the melt rates at the lake bottom are estimated using the same degree day factor – debris cover thickness regression. But instead of calculating the sum of positive degree days based on the air temperature record, the overlying water is assumed to have a constant temperature of 4 °C. This assumption is supported by the work of Xin et al. (2012), who monitored the thermal regime of a supraglacial lake during ablation season at the Koxkar glacier in 2008. One drawback of the present model is that the lateral melting in the ponds is not included, because the dynamic evolution of the debris mantle is not incorporated.

The mapping and area calculation of supraglacial lakes and steep ice cliffs were carried out with the stereo image data provided by the Ikonos product (Fig. 3).

For this purpose a digital elevation model (DEM) with a spatial resolution of 6 m was generated utilizing stereo satellite image data. The orthorectified multispectral images in combination with the derived elevation model were used to detect surfaces like ice, water or ice cliffs semi-automatically. For the lake detection the normalized difference water index (NDWI) developed by Huggel et al. (2002) was used. Two spectral channels with maximum reflectance difference for water (blue- and near infrared-channel) were utilized. In the case of the ice cliffs a combination of the slope, derived from the DEM, and a grayscale filter applied on the panchromatic image yields to the best result. Unfortunately a large number of ice cliffs are not recognized by this approach because of their small size. The method is limited to features that are larger than the pixel size of the fundamental DEM. Therefore these features were picked manually with the aid of the semi-automatic method.

To estimate debris cover thickness from thermal satellite imagery an empirical approach was used. Mihalcea et al. (2008) showed the strong correlation between ASTER-derived LST and debris thickness. To obtain a map of moraine thickness distribution we investigated the relation between those two parameters (Fig. 4).

For 22 pixels of the ASTER image one or more debris thickness measurements were available. For pixels with more than one measurement the mean value of moraine

Interactive Discussion

thickness was used for the regression. Three different regressions were tested: (a) an exponential regression (b) a linear regression through the origin and (c) a power law regression. The exponential regression is leading to very thick debris covers for high temperatures, but when compared to debris cover thickness from Wu and Liu (2012) it seems to be the most realistic and therefore is used as the default choice in the following figures. The linear regression through the origin is based on the assumption that the surface temperature of melting ice is 0°C and if there would be debris present the LST would be higher. The power law regression represents a compromise of the previous regressions. This empirical relationship can now be used to derive debris cover thickness from ASTER LST. To find out how sensitive the model responds to different moraine patterns the three different regressions shown in Fig. 4 were tested. The ASTER image was resampled to a pixel size of $10\text{ m} \times 10\text{ m}$ so that the ablation model is able to resolve small features like ice cliffs. The resulting debris cover thickness distribution maps are shown in Fig. 5.

The total debris cover volume can now be calculated by accumulating the pixel values of the entire debris covered area of the corresponding map. The resulting mean debris thicknesses are shown in Fig. 5. The patterns of the three debris cover thickness distributions are very similar, although the resulting thicknesses differ, especially in the tongue area where the highest values can be assumed.

5 Results and discussion

5.1 Areal distribution of features

The analysis of the satellite data reveals the areal distribution of features that are relevant for the ablation model (Table 2).

The statistic shows that more than 32 % of the entire glacierized area is covered with debris. The areas of ice cliffs occupy 1.70 %, the area of the supraglacial lakes 0.36 % of the debris covered area.

5.2 Role of the spatial distribution of debris thickness patterns

In Fig. 6 the modelled ice ablation for the time span of 1 May 2010 to 31 October 2010 is shown. This period covers the entire ablation season, before and after this time period no temperatures above 0°C were measured at the AWS.

To compare the total ice melt of the different regressions for the debris thickness inversion the calculated ablation is presented in Fig. 7.

The bare ice ablation, the ice cliff ablation and the sub debris ice ablation beneath supraglacial debris is the same for all of the three regressions due to the model structure. The features are all on the same location and their degree day factors are constant. Therefore the only difference in total ice ablation arises from debris cover thickness that has an effect on the sub debris ice ablation. The sub-debris ice ablation accounts for 16.9% in the case of the exponential regression, for 17.4% in the case of the linear regression and for 19.9% in the case of the power law regression of the entire ice ablation. Although the ice cliffs are relatively small in area (1.7% of the debris covered area) the melt amount accounts for 13–16% of the total sub-debris ablation and 2.6–2.7% of the total ablation respectively (Table 3).

These results are not in line with the findings of Sakai et al. (1998), who states that the ice cliff melt amount reaches 69% of the total ablation at the debris covered area, although the area of ice cliffs occupies less than 2% of the debris covered area on Lirung glacier in Nepal. Despite the analogy in the fraction of ice cliffs of the debris covered area the ice cliff melt amount differs significantly. The discrepancy can be explained by the fact that Sakai et al. (1998) used an average melt rate for the entire debris covered area and therefore did not account for the spatial distribution of debris thickness.

5.3 Influence of debris cover on the response of the glacier terminus

It is stated by several authors that debris covered glaciers respond differently to climate change than bare ice glaciers (Bolch et al., 2008; Sorg et al., 2012; Scherler

Interactive Discussion

et al., 2011). During years of negative mass balance the position of the terminus region remains stable while the debris covered parts react by surface lowering. This downwasting behaviour is also reported for the Koxkar glacier (Pieczonka et al., 2013). The significant difference in the terminus evolution is related to the facts that moraine cover is present and the decreasing ice flow velocity due to reduction of ice thickness and surface gradient (Benn et al., 2012). The ablation model allows us to compare melt rates of the debris covered Koxkar glacier with an imaginary debris free glacier. Figure 8 shows the direct comparison of melt rates including a zoomed section of the glacier terminus. It becomes quite clear why debris covered glaciers respond differently on climate warming and negative mass balances. While the melt amount on the bare ice glacier reaches values of approximately 8 m in one ablation season, the ablation on the debris covered glacier almost comes to a standstill. The ice cliffs are the exception and can easily be spotted as melt hotspots with values up to 9 m melt on the debris covered tongue. For the supraglacial lakes a slightly inferior ablation can be observed. Another important point is the melt gradient: the modelled ablation on the bare ice tongue exhibits the temperature- and elevation dependence of the melt rates. In the case of the debris covered glacier this effect is not present. Due to the fact that the curve in Fig. 2 beyond 0.1 m levels out, no significant changes in ablation are observable along the tongue profile (Fig. 9). The shielding effect of the debris cover dominates over the vertical temperature gradient.

In Fig. 9 the longitudinal section A–A' (Fig. 1) of the tongue of the Koxkar glacier is presented. The DEM is shown as a solid grey line, the ablation of the bare ice glacier and the debris covered glacier are displayed as blue line and black line respectively. In the higher parts, where debris cover thickness is rather small, the differences are not as manifest as in the lower parts, where subdebris ablation almost ceases. Figure 9 also exhibits the influence of the ice cliffs, where the ablation reaches values beyond the bare ice case.

The substantial differences between a debris covered and a debris free glacier becomes evident when looking at the total ablation amount. Whereas for the moraine

Interactive Discussion

covered glacier the total ice ablation is in the range of $67\text{--}70 \times 10^6 \text{ m}^3$ ($67 \times 10^6 \text{ m}^3$ for the exponential regression, $68 \times 10^6 \text{ m}^3$ for the linear regression through the origin and $70 \times 10^6 \text{ m}^3$ for the power law regression), the ice melt at the debris free glacier would be $150 \times 10^6 \text{ m}^3$. Thus, it becomes clear how important the consideration of debris cover in predictions of future melt water availability really is. Our presented results do not support the statement of Kaab et al. (2012), that the insulating effect of debris layers with thicknesses exceeding a critical thickness acts on local scales of intact covers, but not in general on the spatial scale of entire glacier tongues.

6 Conclusions and outlook

The exponential regression of debris cover thickness appears to be the most realistic when compared to the multi-frequency ground penetrating radar measurements from Wu and Liu (2012), who have been able to derive a map of debris cover thickness in the lowest part of the glacier terminus.

The results regarding ablation indicate that melt on ice cliffs plays a significant role but not as substantial as stated by Sakai et al. (1998).

Our study highlights the influence of debris cover on the response of the glacier terminus to negative mass balance. Due to the fact that melt rates are highly restricted the shielding effect of the debris cover dominates over the temperature and elevation dependence of the ablation in the bare ice case. In addition the reduced melt rates highlight the serious implications with regard to runoff modelling from debris covered glaciers. The comparison of total ablation amount from a debris free and a debris covered glacier underlines the importance to include debris cover into discharge modelling.

The representation of debris covered glacier parts in hydrological models is still an unsolved problem. By implementing the presented ablation model into a conceptual runoff model, an improved version of the HBV-ETH-model (Mayr et al., 2014), capable to reproduce runoff from moraine covered glaciers will be created. Moreover, runoff scenarios for changing climate and glaciation conditions can be realised after the cali-

bration of the model has been completed for current conditions. Results from regional and local climate modelling will serve as input for the improved HBV-ETH model version, allowing to run the model with the output of sophisticated climate modelling.

Acknowledgements. The authors would like to thank Elisabeth Mayr and Liu Qiao for assisting with the fieldwork. The funding of the study by the Deutsche Forschungsgemeinschaft (MA 3347/4-1) in the context of the AKSU-TARIM project bundle (Water Resources in Western China) is gratefully acknowledged.

Studies of debris thickness patterns in an ablation model

M. Juen et al.

Table 1. Ikonos satellite sensor specifications.

Satellite	Sensor	Band number	Spectral range	Pixel resolution
Ikonos-2	Multi-spectral	1 = Blue	445–516 nm	4 m
		2 = Green	506–595 nm	
		3 = Red	632–698 nm	
		4 = NIR	757–853 nm	
	Panchromatic	Pan	526–929 nm	1 m

Table 2. Horizontally projected area of the melt relevant surface types on the Koxkar glacier derived from satellite imagery mapping.

	Feature area
Entire glacierized area	65.60 km ²
Debris covered area	21.17 km ²
Cliffs	0.36 km ²
Supraglacial lakes	0.08 km ²

**Table 3.** Percentage of ice cliff melt off total ablation and sub-debris ablation respectively.

	linear regression through the origin	exponential regression	power law regression
ice cliff ablation of the total ablation	2.71 %	2.72 %	2.62 %
ice cliff ablation of total sub debris ice ablation	15.6 %	16.06 %	13.17 %
