Abstract

Assessing and projecting the dynamic response of glaciers on the Antarctic Peninsula to changed atmospheric and oceanic forcing requires high-resolution ice thickness data as an essential geometric constraint for ice flow models. Here, we derive a complete bedrock data set for the Antarctic Peninsula north of 70° S on a 100 m grid. We calculate distributed ice thickness based on surface topography and simple ice dynamic modelling. Our approach is constrained with all available thickness measurements from Operation IceBridge and gridded ice flow speeds for the entire study region. The new data set resolves the rugged subglacial topography in great detail, indicates deeply incised troughs, and shows that 34 % of the ice volume is grounded below sea level. The Antarctic Peninsula has the potential to raise global sea level by 71 ± 5 mm. In comparison to Bedmap2, covering all Antarctica on a 1 km grid, a significantly higher mean ice thickness (+48 %) is found.

1 Introduction

Glaciers of the Antarctic Peninsula strongly differ from the rest of Antarctica regarding their topographical and climatological characteristics and their sensitivity to climate change. The recent collapse of several ice shelves around the Peninsula and the subsequent speed up and mass loss of glaciers feeding them (Rignot et al., 2004; Scambos et al., 2004; Pritchard and Vaughan, 2007; Glasser et al., 2011; Rott et al., 2011) demonstrated the high vulnerability of the region to climate change. Over the last decades, glacier retreat in the region was considerable (Cook et al., 2005) and the Antarctic Peninsula and its surroundings are reported to have contributed by almost 30 % to the cryospheric component of sea-level rise since 1960 (Hock et al., 2009). Strong atmospheric warming trends in recent years (Vaughan et al., 2003; Barrand et al., 2013b) and changed oceanic conditions (Meredith and King, 2005) are likely to be the main triggers of the dynamic glacier mass loss.

[Title Page](#)[Abstract](#)[Introduction](#)[Conclusions](#)[References](#)[Tables](#)[Figures](#)[Back](#)[Close](#)[Full Screen / Esc](#)[Printer-friendly Version](#)[Interactive Discussion](#)

Ice shelf disintegration and wide-spread surface lowering in coastal areas as observed on the Antarctic Peninsula are also relevant at larger scales for both the Greenland and the Antarctic ice sheet (Pritchard et al., 2009, 2012). Understanding the related processes is crucial for improved projections. However, ice flow modelling requires accurate and spatially distributed bedrock data. Despite major advances in airborne radio-echo sounding of ice thickness in polar regions, the uncertainty in gridded bedrock data still limits the application of state-of-the-art flow models for detailed process studies.

For the Antarctic Peninsula, a large number of ice thickness observations is provided by the repeated surveys of Operation IceBridge (OIB) (e.g., Allen, 2013). Ground-based thickness measurements are still relatively scarce and are only available for a few individual glaciers (e.g., Farinotti et al., 2013, 2014).

The glaciers of the Antarctic Peninsula are covered by the first complete bedrock data set for Antarctica (BEDMAP, Lythe and Vaughan, 2001). Le Brocq et al. (2010) enhanced BEDMAP by including additional thickness measurements and refined interpolation techniques. However, the grid spacing of both data sets is only 5 km which is too coarse for resolving the mountain topography of the Peninsula with its narrow subglacial valleys and a high spatial ice thickness variability. With the rapid increase in the coverage of thickness measurements, new initiatives have recently contributed to updated bedrock maps for both Greenland (Bamber et al., 2013), and Antarctica (Fretwell et al., 2013) at 1 km resolution. For the Peninsula, Bedmap2 is a big step forward. Fretwell et al. (2013) interpolated all available bedrock data supported by synthetic ice thicknesses estimated from a simple relation with surface slope.

Whereas for large-scale ice sheet modelling the spatial resolution provided by Bedmap2 is sufficient, detailed considerations of mass balance, ice flow and grounding-line dynamics necessitate the application of models that are able to cope with the high spatial variability of the governing processes. Thus, for advancing the development of ice flow models used for predicting the future response of Antarctic Peninsula glaciers

to climate change and/or ice shelf break-up, a high-resolution bedrock topography is required as an essential geometric constraint.

Over the last years, several methods for indirectly inferring ice thickness by combining information contained in surface topography with ice dynamic modelling have been developed and applied. Some studies have focused on thickness distribution of individual glaciers in alpine environments (Farinotti et al., 2009; McNabb et al., 2012; Michel et al., 2013), and have also been applied at the mountain-range scale (Clarke et al., 2013). Other papers have addressed the bedrock topography of a part of Antarctica (Roberts et al., 2011), or for outlet glaciers of the Greenland ice sheet (Morlighem et al., 2011, 2013a). Huss and Farinotti (2012) have presented a data set of ice thickness distribution for each of the world's roughly 200 000 glaciers outside of the two ice sheets. The benefit of including flow speed data into the calculation of ice thickness distribution has been demonstrated in a few papers recently (e.g., Morlighem et al., 2011; McNabb et al., 2012) but has so far not been exploited at the regional scale.

Here, we derive a new high-resolution ice thickness and bedrock data set for all glaciers of the Antarctic Peninsula. We further develop the approach proposed by Huss and Farinotti (2012) and invert local glacier thickness from surface topography based on the principles of ice flow dynamics. The results are constrained by a large number of direct ice thickness measurements from Operation IceBridge (Allen, 2013) and gridded surface velocities (Rignot et al., 2011). We present the ice thickness distribution of the Antarctic Peninsula on a 100 m grid, discuss the implications for potential sea-level rise and compare the data set to Bedmap2 (Fretwell et al., 2013).

2 Data

Our approach to derive highly resolved ice thickness makes use of a variety of data sets including surface topography, glacier outlines, surface mass balance, ice thickness and surface flow speed measurements. The study addresses the Antarctic Peninsula north of 70° S (Fig. 1).

Interactive Discussion

A 100 m Digital Elevation Model (DEM) for the Antarctic Peninsula (63–70° S) is provided by Cook et al. (2012) based on the Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER). Several ASTER scenes acquired over the last decade were stacked and artifacts were corrected resulting in a consistent, smooth and void-filled terrain model for the entire study region. The accuracy of the DEM in comparison to ICESat is quantified as ± 25 m (Cook et al., 2012).

Based on this high-quality DEM, Cook et al. (2014) derived ice-flow catchments for 1606 glacier entities. The catchments delimit dynamically connected regions from the highest point of the basin to the calving front or to the grounding line (Fig. 1). We do not consider floating ice in the present study. Catchment areas range between 0.3 km² and 7000 km². By intersecting the basin outlines with a detailed vector data set of rock outcrop boundaries retrieved from the SCAR Antarctic Digital Database Version 6.0 (www.add.scar.org) we obtain an ice mask for each individual glacier.

Lenaerts et al. (2012) provide average mass balance for the period 1979–2010 based on simulations with the Regional Atmospheric Climate Model (RACMO) on a 27 km grid. RACMO was driven by ERA-interim data and validated against in-situ mass balance measurements. The Peninsula is identified as the region with highest accumulation rates of the Antarctic continent (> 1500 mm yr⁻¹). However, only very few direct mass balance observations (e.g., Turner et al., 2002) are available for validation in the study region (Fig. 1).

Between 2002 and present numerous flight campaigns from NASA's Operation Ice-Bridge (Allen, 2013) covered the Antarctic Peninsula collecting radar-sounding data at 150 MHz using the Multichannel Coherent Radar Depth Sounder (MCoRDS) (see also, Shi et al., 2010). OIB provides direct measurements of local ice thickness for 238 individual glaciers on the Peninsula (15% of the total number). Almost 500 000 individual point observations are available along 8500 km of continuous tracks (Fig. 1). The OIB data yield ice thickness and bed elevation with a nominal accuracy of 10 m (Gogineni et al., 2001). Actual data accuracy depends on location, quality of bed reflections and uncertainties in the dielectric properties of the ice. Based on cross-over analysis of OIB

Interactive Discussion

flight lines on Russell Glacier, Greenland, Morlighem et al. (2013a) found a standard ice thickness error of 31 m. Similar accuracies were confirmed through cross-validation with terrestrial ground-penetrating radar (GPR) on Starbuck Glacier, Antarctic Peninsula (Farinotti et al., 2014). A maximal deviation of 44 m (11 % of local ice thickness) was found. In addition to OIB data, this study also makes use of ice thickness measurements for Flask and Starbuck Glacier (Fig. 1) based on air-borne and ground-based GPR (Farinotti et al., 2013, 2014).

A comprehensive data set of annual ice flow speed on a 450 m grid for the entire Antarctic Peninsula is provided by Rignot et al. (2011). Surface velocities have been derived based on satellite radar interferometry using fall 2007 and 2008 imagery from the Advanced Land Observing Satellite (ALOS) PALSAR sensor. The uncertainty in inferred surface speed is estimated at 3–10 m yr⁻¹ for the Peninsula (Rignot et al., 2011).

3 Methods

The basic approach to derive a bedrock data set covering the entire Antarctic Peninsula on a fine grid (100 m resolution) is the constraining of a simple model for ice dynamics with a variety of observational data. We invert local ice thickness from surface topography, supported by comprehensive data sets of (i) surface mass balance, (ii) point ice thickness, and (iii) ice flow velocity. We thus follow recent studies (see e.g., Clarke et al., 2013; Morlighem et al., 2013a; van Pelt et al., 2013) that have proposed similar techniques for inferring distributed ice thickness.

3.1 Modelling approach

The methodology applied in this study is based on the approach by Huss and Farinotti (2012) which is further developed and adapted to glaciers on the Antarctic Peninsula (see also, Farinotti et al., 2014). Based on surface mass balance, ice volume fluxes

along the glacier are determined and are used to compute ice thickness based on Glen (1955)'s flow law for ice deformation and assumptions on basal sliding. As described in Huss and Farinotti (2012), all calculations are performed for a simplified two-dimensional shape of each individual glacier which is obtained by evaluating glacier characteristics (area, surface slope, length, width) for 10 m elevation bands of ice surface topography.

Surface mass balance distribution is taken from the RACMO-based data set by Lenaerts et al. (2012). We perform a spatial downscaling of the RACMO results from their coarse grid (27 km) to 100 m resolution by deriving a local, elevation-dependent mass balance function and applying the relation to our fine grid using the DEM by Cook et al. (2012). This function is obtained from linear regression of mass balance vs. surface elevation of the RACMO grid. For every location, the parameters of the regression are estimated through ordinary least-square fits considering a box of 10 × 10 RACMO cells.

According to mass conservation, ice volume flux along the glacier can be derived by combining information on local surface mass balance b with the elevation change rate $\partial h / \partial t$. From these variables we calculate an apparent mass balance \tilde{b} (Farinotti et al., 2009) as

$$\tilde{b} = b \cdot f_{\text{RACMO}} - \rho \cdot \frac{\partial h}{\partial t}, \quad (1)$$

with ρ the ice density and f_{RACMO} a dimensionless factor accounting for a potential bias in RACMO mass balances. f_{RACMO} is treated as a calibration parameter. Whereas glaciers of the Antarctic Peninsula showed moderately negative values of $\partial h / \partial t$ before the year 2000 (Kunz et al., 2012), ice mass loss strongly increased in the 21st century for glaciers flowing into the embayment of the former Larsen A and B ice shelves (e.g., Berthier et al., 2012). Unfortunately, no complete and distributed data set documenting recent surface elevation changes on the Peninsula is yet available. Motivated by results of several studies (Scambos et al., 2004; Pritchard et al., 2009; Berthier et al., 2012; Kunz et al., 2012), we thus roughly parameterize surface elevation changes by

prescribing a linear decrease of $\partial h/\partial t$ from 0 myr^{-1} at an elevation of 700 m a.s.l. to -10 myr^{-1} at the calving front for glaciers flowing into the Larsen A and B embayment, and to -1 myr^{-1} for all other glaciers. The effect of these poorly constrained assumptions on calculated thickness is assessed in sensitivity tests (see Sect. 4).

By integrating \tilde{b} from the maximum glacier altitude to the terminus or the grounding line we obtain ice volume flux q_{tot} for each glacier (Fig. 2a). In the case of an invariant position of the glacier terminus or the grounding line, this also yields frontal ablation (calving, marine melting, flux into ice shelf). By applying an integrated form of Glen (1955)'s flow law the ice thickness h_i for every elevation band i is calculated (see also, Huss and Farinotti, 2012) as

$$h_i = \sqrt[n+2]{\frac{q_{d,i}}{2A_f} \cdot \frac{n+2}{(F_{s,i}\rho g \sin \bar{\alpha}_i)^n}}, \quad (2)$$

with $q_{d,i}$ the deformational component of total ice flux normalized by glacier width w , $n = 3$ the exponent of the flow law, g the acceleration of gravity, $\bar{\alpha}_i$ the elevation band average of surface slope, and $F_{s,i} = w_i/(2h_i + w_i)$ a valley shape factor (Nye, 1965). As h enters the calculation of F_s , Eq. (2) is solved iteratively. The flow rate factor A_f shows a strong dependence on englacial temperatures (e.g. Cuffey and Paterson, 2010), and is used as a second calibration parameter.

The deformational component q_d of the total ice flux q_{tot} for each elevation band i is computed by prescribing a fraction of basal sliding f_{sl} relative to surface velocity as

$$q_{d,i} = q_{\text{tot},i} - q_{b,i} = q_{\text{tot},i} \cdot \left(1 - \frac{f_{sl,i}}{(1-r) \cdot f_{sl,i} + r}\right), \quad (3)$$

where q_b is the ice flux due to basal sliding, and $r = (n+1)/(n+2) = 0.8$ is the ratio between average deformational flow speed of an ice column and surface velocity (see e.g., Cuffey and Paterson, 2010).

Interactive Discussion

The fraction of basal sliding f_{sl} exerts an important control on ice dynamics in our approach. Parts of Antarctica are known to be warm-based and exhibit significant basal motion (e.g., Kamb, 2001; Joughin et al., 2009). Related to comparably maritime climate conditions, glaciers on the Antarctic Peninsula can be assumed to show considerable basal sliding close to their grounding line, but no or limited basal melting and englacial temperatures of -10 to -15 °C in their accumulation areas (Zagorodnov et al., 2012). For the region of interest, Morlighem et al. (2013b) inferred fractions of basal sliding relative to surface flow speed of between about 50 and 90% based on modelling. Relying on these findings, we prescribe $f_{sl} = 0.5$ above the median glacier elevation, and parameterize f_{sl} as a linear function with altitude increasing to $f_{sl} = 0.9$ at the calving front or the grounding line. The impact of these assumptions on calculated thickness and volume is assessed with sensitivity tests (Sect. 4).

Kamb and Echelmeyer (1986) recommend smoothing the basal shear stress $\tau_i = F_{s,i} \rho g \sin \bar{\alpha}_i$ over a distance of about 10 times the local ice thickness for accounting for the influence of longitudinal stress gradients on ice flow. We smooth τ accordingly and reintroduce it into Eq. (2). Convergence for h , F_s and τ is reached after about five iterations providing mean glacier thickness in 10 m surface elevation bands along a longitudinal glacier profile (Fig. 2b).

We then extrapolate calculated mean elevation band thickness from the simplified 2-D shape of the glacier (Fig. 2b) to the 100 m grid by inversely weighting the distance to the closest rock outcrop, and including surface slope α of each grid cell proportional to $(\sin \alpha)^{-n/(n+2)}$ (based on Eq. 2). Local slopes are filtered with a threshold $\alpha_{cutoff} = 1.5^\circ$ because $\sin \alpha$ tends to infinity for small values. Furthermore, unrealistic ice thicknesses h larger than $h_{max} = \frac{z}{(\rho_w - \rho)/\rho_w}$ with z the surface elevation according to the DEM and ρ_w the density of sea water, are corrected to h_{max} . We thus assume the entire glacier to be grounded within the catchment boundary. Gridded ice thickness is finally smoothed to remove local noise due to surface roughness. The extrapolation procedure results in a fully distributed estimate of ice thickness for each individual glacier catchment (see Fig. 2c, for an example).

3.2 Model calibration and validation

To validate model results against observed surface flow velocities we solve Eq. (2) for q_d and derivate it. This yields average flow speed u_i for each glacier elevation band i as

$$5 \quad u_i = \frac{2A_f}{n+1} \cdot (F_{s,i} \rho g \sin \bar{\alpha}_i)^n h_i^{n+1} + u_{b,i}, \quad (4)$$

with $u_{b,i}$ the basal velocity obtained from the prescribed fraction of basal sliding $f_{sl,i}$. Annual surface motion of each grid cell is then approximated by redistributing u_i based on local thickness and slope proportionally to $(\rho g \sin \alpha)^n h^{n+1}$ (based on Eq. 4).

10 The parameters f_{RACMO} (Eq. 1) and A_f (Eq. 2) are calibrated to optimally match all point observations of OIB ice thickness available for the Antarctic Peninsula, and distributed surface flow velocity. Both parameters are poorly constrained a priori and are thus suitable to tune the model. Whereas lowering f_{RACMO} results in reduced mass turnover and smaller ice thickness, lower values for A_f lead to stiffer ice and increase calculated thickness. Hence, similar results regarding mean thickness could
15 be achieved with various combinations of the two parameters. It is therefore essential to utilize two independent sets of measured data to unambiguously determine physically meaningful values for f_{RACMO} and A_f .

We vary f_{RACMO} in the range [0.1, 1.0], and A_f within [0.005, 0.075] $\text{bar}^{-3} \text{yr}^{-1}$ and calculate ice thickness distribution for each of the 1606 glacier catchments of the Antarctic Peninsula with 285 combinations of the two parameters. Point OIB measured and calculated thicknesses are then compared and the mean misfit over all data is evaluated. Calculated surface velocity is resampled to the 450 m grid of the observations and a point-to-point comparison is performed for catchments $> 25 \text{ km}^2$ and ice surface elevations $> 100 \text{ m a.s.l.}$ We do not integrate small glaciers into this evaluation due to
25 possible uncertainties in measured flow speeds, and exclude areas close to sea level as we do not judge our simple approach as suitable to reproduce flow speeds determined by grounding line dynamics.

Interactive Discussion

Average misfits close to zero are found for several parameter combinations when considering OIB thickness data or measured ice flow speeds alone (Fig. 3). For the two observational variables, error fields in the parameter space are however almost perpendicular to each other resulting in a unique optimal combination of $f_{\text{RACMO}} = 0.71$ and $A_f = 0.025 \text{ bar}^{-3} \text{ yr}^{-1}$. This combination matches the average ice thickness for all OIB data points as well as the spatially distributed flow velocity (Fig. 3). The parameters are assumed to be constant for the entire study region.

The plausibility of the inferred values of f_{RACMO} and A_f is verified by considering independent data sets. Depoorter et al. (2013) estimate annual mass losses in the Larsen C embayment due to calving and marine melting of about 43 Gtyr^{-1} (average over 2003–2009). By summing up frontal mass fluxes of all contributing glaciers and including RACMO-based accumulation on the shelf (corrected with f_{RACMO}) we find a total flux of 57 Gtyr^{-1} , overcompensating estimated ablation by about one third. Without correcting the RACMO mass balance field ($f_{\text{RACMO}} = 1.0$) accumulation in the Larsen C embayment would be much higher (79 Gtyr^{-1}) which would result in a strongly positive mass budget when combined with the mass loss data by Depoorter et al. (2013). A tendency towards a positive bias of RACMO for the Antarctic Peninsula is also indicated by comparison to the sparse in-situ accumulation observations (see compilation in Turner et al., 2002). Due to inconsistencies at the temporal and spatial scale a direct comparison is however difficult.

According to Cuffey and Paterson (2010), our calibrated value for A_f corresponds to the viscosity of ice at temperatures of between -5 to -10°C which is conceivable compared to the direct measurements by Zagorodnov et al. (2012). These rather rough considerations do not prove the validity of the calibrated parameter values but indicate that they are in a reasonable range, and that our assumptions on basal sliding (f_{sl} , cf. Morlighem et al., 2013b) are appropriate.

We compare the point-to-point average of calculated ice thicknesses and surface flow speeds for each glacier individually to observations (Fig. 4). Although this is not a real validation as the bulk data have been used for constraining the model parame-

ters (Fig. 3), valuable information on the performance of our approach at the spatially distributed scale is provided. Average single glacier thickness is predicted with a mean relative error of 19% and a root-mean square error (RMSE) of 102 m (Fig. 4a). The agreement of calculated glacier-specific flow speed with observations is relatively poor (mean relative error of 50%). However, if averaged over glacier size classes, mean surface velocities are well captured (Fig. 4b). This indicates that our approach reproduces the general flow field but shows a lesser performance at the local scale.

Furthermore, observed and simulated thickness are also compared locally. The RMSE over all OIB point measurements is 255 m. There is a tendency of the model to overestimate measured thicknesses of < 500 m and to underestimate thickness at locations with > 1000 m of ice (Fig. 5). The relative errors decrease with ice thickness.

3.3 Incorporating Operation IceBridge data

OIB thickness data represent the best and most direct information on bedrock elevation. Despite the generally good agreement of measured and modelled point thicknesses at the glacier-specific scale (Fig. 4a), the model results may deviate by several 100 m from observations for certain OIB flight lines (Figs. 5 and 6a). We thus incorporate the local OIB data into the ice thickness distribution given by the calibrated model (Fig. 2c). Following Farinotti et al. (2014) the point-based misfit is spatially interpolated for each glacier with OIB data using an inverse distance averaging scheme that results in a two-dimensional correction field (Fig. 6b). This spatial correction map is then superimposed on the initially modelled thickness distribution. Although this final adjustment can only be performed for 15% of the glaciers, the areal coverage in terms of catchment area is high (71%) as OIB data are available for most of the large glaciers.

As a final step, the corrected ice thickness distributions of all individual glaciers are combined into a single high-resolution grid. As the glacier-specific calculations are independent from each other, results do not necessarily agree at the ice divides. We therefore apply a moving window that averages ice thickness smoothly for 1 km wide bands along the ice divides and corrects local thickness differences. The bedrock to-

pography is then obtained by subtracting calculated thickness from the surface DEM. After publication, ice thickness and bedrock will be available on a 100 m grid to the scientific community from public archives.

4 Uncertainty analysis

The uncertainty in inferred ice thickness distribution and bedrock topography is composed of several elements. These are separately assessed and combined in order to provide an estimate of (1) the overall uncertainty in ice volume and sea-level equivalent, and (2) the gridcell-based local uncertainty.

The two calibration parameters were determined as the optimal combination to match OIB thickness and surface flow velocity data (Fig. 3). For investigating the robustness of the parameter set to reduced data availability and its validity for different sub-regions of the Peninsula we divided the study area into four sectors separated by the main topographical divide into a western/eastern part, and the circle of 66° S latitude into a northern/southern part. We then re-calibrated f_{RACMO} and A_f only using thickness and velocity data from one of the four sectors (NW, NE, SW, SE) with the same approach as described in Sects. 3.2 and 3.3. The so determined parameters are optimal for the respective sector but their performance is inferior when applied to the entire study area. By re-calculating the complete bedrock topography with the sectorally calibrated parameters we obtained a range of the overall ice volume due to parameter estimation uncertainty and the spatial representativeness of the data used for calibration. Based on the same procedure, we also included an estimation uncertainty for (i) basal sliding by varying $f_{\text{sl},i}$ (Eq. 3) by $\pm 20\%$, and (ii) increasing/decreasing $\partial h/\partial t$ (Eq. 1) by a factor of 2.

By statistically evaluating the results of these experiments we find an uncertainty in calculated total ice volume of $\sigma = \pm 9.7\%$. Parameter combinations obtained by calibration solely on the northern/southern sectors indicate slightly smaller/bigger thicknesses. The sensitivity of overall ice volume on the assumptions on basal sliding is

Interactive Discussion

relatively small ($\pm 1.2\%$), and the dependence on the tested range of $\partial h/\partial t$ is minor ($\pm 0.3\%$). The modest impact of assumptions on basal sliding on total volume is attributed to the fact that changes in f_{sl} are partly compensated by the re-calibrated flow rate factor A_f .

For estimating the local uncertainty in calculated ice thickness two approaches are combined. (i) We statistically evaluate the skill of the reference result to reproduce point OIB data based on the optimal parameters. Uncertainty (± 1 standard deviation σ) is calculated for 100 m classes of modelled thickness. σ is between 46 and 41 % of local thickness providing a first order uncertainty estimate at an arbitrary unmeasured location. (ii) As we include direct information from OIB data into our final result, the accuracy of inferred thickness will be higher in the vicinity of OIB flight lines. Farinotti et al. (2014) accounted for this fact by constructing a distance-dependent uncertainty function, derived from resampling experiments of GPR data from Starbuck Glacier. Here, we adopt this function in normalized form, assuming it to be representative for the entire study region.

Whereas approach (i) yields an uncertainty relative to local ice thickness, approach (ii) provides a correction function for this estimate with values in the range $[0, 1]$ being small close to OIB measurement locations and maximal at distances of 15 km or more from the next thickness sounding. By multiplying the uncertainty grids from the approaches (i) and (ii), an error map for the entire study region is created providing information on local ice thickness and bedrock uncertainty (Fig. 7). On average, the local thickness uncertainty is ± 95 m but values for deep troughs with no nearby OIB measurements can reach ± 500 m. Fortunately, some direct data are available for many large glaciers considerably reducing the total uncertainty (Fig. 7).

5 Results and Discussion

Our high-resolution bedrock for the Antarctic Peninsula reveals complex subglacial structures with deeply incised troughs and a high ice thickness variability at short spa-

tial scales (Fig. 8). Despite the steep mountain relief a considerable fraction of the ice is grounded below sea level: $23\,300\text{ km}^2$ (24 % of the total) in terms of surface area, and $12\,000 \pm 2600\text{ km}^3$ (34 %) in terms of ice volume (Table 1). According to our data set the mean ice thickness of the Antarctic Peninsula north of 70° S is $364 \pm 35\text{ m}$. For some outlet glaciers, thicknesses of more than 1500 m are found (e.g. Crane, Flask, Lurabee, Fig. 1) and the bedrock is partly located up to 1000 m below sea level (see also Fig. 6a). The total ice volume in the study area is $35\,100 \pm 3400\text{ km}^3$ (Table 1).

For evaluating the potential sea-level rise contribution of the Antarctic Peninsula we use an ocean surface of $3.62 \times 10^8\text{ km}^2$. For ice grounded a.s.l. we calculate the contributing ice mass by assuming an average glacier density of 870 kg m^{-3} thus approximately including typical firn layer thicknesses and densities for the Peninsula according to model results by Ligtenberg et al. (2011). For ice grounded below sea level only the mass between the ice-equivalent surface and the elevation corresponding to flotation level effectively contributes to sea-level rise (see also, Fretwell et al., 2013). Floating ice has a small positive effect on sea level due to dilution of ocean waters (Jenkins and Holland, 2007) which is however not accounted for here.

The Antarctic Peninsula north of 70° S has the potential to raise global sea level by $0.071 \pm 0.005\text{ m}$ which is negligible compared to the entire Antarctic ice sheet (58 m, Fretwell et al., 2013). However, considering the short response time of glaciers on the Peninsula (e.g., Barrand et al., 2013a), it needs to be taken into account in decadal-scale projections. Compared to other glacierized mountain ranges around the globe, the contribution potential of the Antarctic Peninsula is on a par with Arctic Canada and is significantly higher than that from, e.g., Alaska, the Russian Arctic, Patagonia or High Mountain Asia (Huss and Farinotti, 2012).

The regional distribution of glacier area and volume is compiled in Table 1. North of 66° S (sectors NW and NE) the Peninsula is characterized by a large number of glaciers, smaller average thicknesses and a sea-level rise contribution potential of 27 % relative to the whole study area. The largest average ice thickness is found in the southwest dominated by wide and flat glaciers (Seller/Fleming) that are based below

sea level over much of their area. Glacier catchments in the southeast have the largest average size and are still buttressed by the Larsen C ice shelf but exhibit slightly less volume related to higher average surface slopes.

In comparison to Bedmap2 (Fretwell et al., 2013) our new bedrock data for the Antarctic Peninsula provides a ten times higher resolution and significantly more details on the sub-surface topography. We capture many features of small scale variability that were lost in the 1 km grid of Bedmap2 thus opening new possibilities for ice dynamic modelling.

Fretwell et al. (2013) state a total sea-level rise potential of 0.2 m for the Peninsula which is substantially more than our estimate. Their evaluation is however based on a much larger area and is not directly comparable. We compared the new high-resolution bedrock data set to Bedmap2 for the study region by resampling our thicknesses to a 1 km grid and cropping it with the rock mask of Bedmap2. According to our data set, mean ice thickness is 124 m (+48 %) higher than for Bedmap2. Hence, the difference is beyond the error bounds of the present assessment. The larger ice thickness might be explained with extrapolation from the sparse and non-representative ice thickness observations into unmeasured regions in the creation of Bedmap2, and with the smoothing introduced by the too coarse grid resolution.

A detailed comparison of Bedmap2 with the new data set in a region characterized by several large outlet glaciers demonstrates the considerable differences at the local scale (Fig. 9). Bedmap2 correctly indicates the location of the biggest subglacial valleys as they are relatively wide (3–5 km) and covered by at least some OIB data (Fig. 9a). However, their maximum depth is often strongly underestimated, and smaller troughs, such as Starbuck Glacier with observed thicknesses of up to 1000 m (Farinotti et al., 2014), are almost completely missing (Figs. 9b and 10). Furthermore, the new bedrock map indicates systematically higher ice thickness in the interior of the Peninsula. Local differences between the data sets can reach 1000 m and show a high spatial variability (Figs. 9c and 10).

Interactive Discussion

A number of factors that were not included in the uncertainty assessment (Sect. 4) as their effect on calculated ice thickness is difficult to quantify, hamper the reliability of our high-resolution bedrock map to a certain degree. The model parameters are assumed to be constant over the entire study region, i.e. to not show any spatial variability depending on geographic latitude or local climate. This is, of course, a strong simplification. For example, ice temperatures, and thus the flow rate factor A_f , are likely to show variations along the glacier and to be different for the maritime northern tip of the Peninsula compared to the more continental south of the study region. Also f_{RACMO} is assumed to be the same for every glacier although the bias in the RACMO data set is poorly constrained in the spatial domain. The apparent mass balance \tilde{b} (Eq. 1) is determined by the glacier's current dynamic imbalance. $\partial h / \partial t$ shows a high spatio-temporal variability over the Antarctic Peninsula (e.g., Berthier et al., 2012) and was only crudely approximated. As the unambiguous and robust calibration of the model was only possible with reducing the degrees of freedom, the above effects were not taken into account. The regionally constrained calibration experiments however indicate that these simplifications have rather small effects on the final result.

The chosen approach strongly relies on the ice surface topography and its uncertainties, particularly regarding surface slope. According to Cook et al. (2012) the ASTER-based 100 m resolution DEM has an uncertainty of ± 25 m. Sensitivity tests for individual glaciers showed that perturbing the DEM with the stated uncertainty has a relatively small effect on calculated total ice volume (less than 3% depending on the chosen glacier). Simplifications of the three-dimensional geometry to the 2-D shape used for calculating semi-distributed ice thicknesses (see Fig. 2a) have the potential to introduce additional uncertainties in particular regarding branched glacier systems. However, quantifying the effect of this factor inherent to our approach was not possible.

The inferred ice thicknesses and bedrock elevations strongly depend on the uncertainty in the OIB data. In fact, we make the rather strong assumption that all thickness measurements are accurate, i.e. that the bedrock reflector has been correctly detected and that the uncertainties in converting travel times of the electromagnetic waves into

changes in the system such as the break-up of ice shelves. According to our results, the Antarctic Peninsula has the potential of raising global sea level by 71 ± 5 mm. In comparison to Bedmap2 we find significantly higher mean ice thicknesses (+48%). This systematic difference is attributed to the higher resolution of our new data set better rendering the shape of glacial troughs, and to the approach used to calculate thickness in regions not covered with direct measurements.

The bedrock data set derived in the present study might be useful for calculating the future response of glaciers of the Antarctic Peninsula using ice dynamic models and, hence, to better understand the processes triggering their rapid changes. Our simple but regionally implemented methodology combining data on surface topography, mass flux, ice thickness and flow speed into a distributed ice thickness map could also be applied to other polar regions. This might offer new possibilities for studying cryospheric glacier contribution to sea-level rise with state-of-the-art glacier models.

Acknowledgements. We thank A. Cook for the high-resolution DEM and the glacier catchments. Operation IceBridge is acknowledged for their many thickness measurements being one of the backbones of this study. RACMO surface mass balance data were provided by J. Lenaerts, P. Kuipers-Munneke and M. R. van den Broeke, and surface velocity data by E. Rignot. H. F. J. Corr, G. H. Gudmundsson and E. C. King from the British Antarctic Survey made unpublished ice thickness data for Flask Glacier available to us. Digital glacier outcrops and ice shelf margins were retrieved from the SCAR Antarctic Digital Database. M. Funk provided helpful comments on an earlier version of the manuscript.

A high-resolution bedrock map for the Antarctic Peninsula

M. Huss and D. Farinotti

Table 1. Number of glacier basins n , surface area A , calculated total ice volume V , volume grounded below sea level $V_{<0}$, and sea-level equivalent (SLE) for the entire Antarctic Peninsula and sub-regions west/east of the main topographic divide, and north/south of 66° S.

Reg.	n –	A (km^2)	V (10^3 km^3)	$V_{<0}$ (10^3 km^3)	SLE (mm)
NW	707	16 475	3.9 ± 0.5	1.1 ± 0.4	8.5 ± 0.8
NE	248	19 141	6.2 ± 0.8	3.0 ± 0.6	11.0 ± 1.0
SW	387	32 048	13.8 ± 1.2	5.0 ± 0.5	28.7 ± 2.1
SE	264	29 271	11.2 ± 0.9	2.9 ± 1.1	22.9 ± 1.3
Tot.	1606	96 937	35.1 ± 3.4	12.0 ± 2.6	71.0 ± 5.2

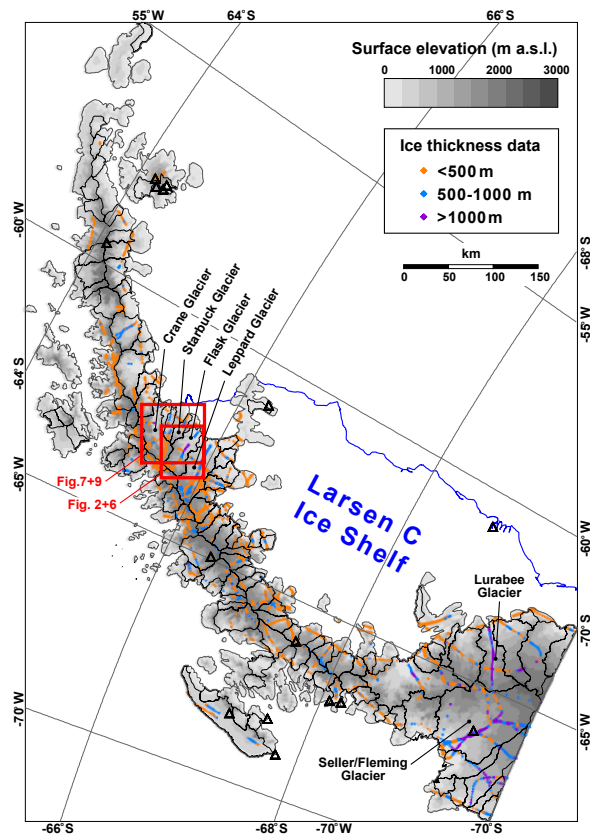

Fig. 1. Antarctic Peninsula north of 70° S. Shading refers to surface topography. Outlines of flow catchments larger than 200 km² according to Cook et al. (2014) are shown. Ice thickness measurements available from all Operation IceBridge campaigns 2002–2012 are indicated by dots colour-coded to thickness classes. Triangles show surface mass balance observations (Turner et al., 2002). Ice shelf margins are drawn according to the SCAR Antarctic Digital Database version 6.0. Red rectangles refer to detailed figures.

A high-resolution bedrock map for the Antarctic Peninsula

M. Huss and D. Farinotti

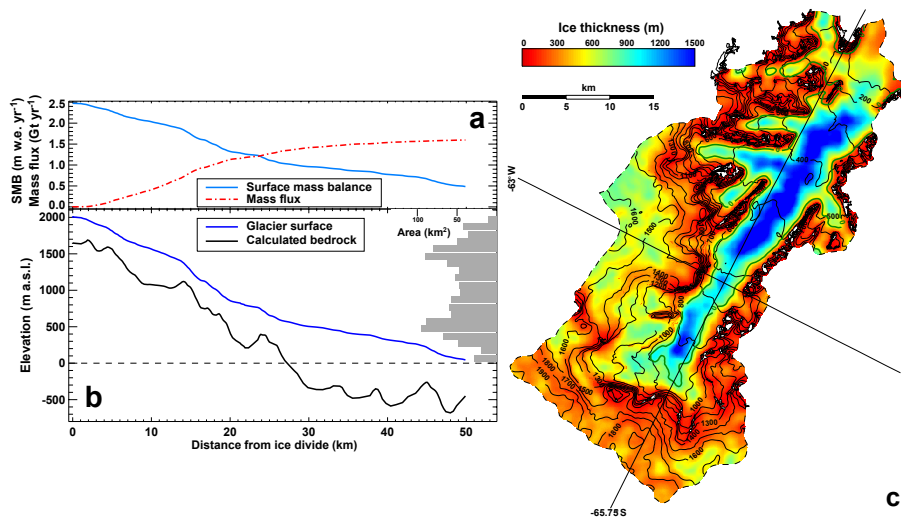

Fig. 2. (a) Surface mass balance and mass flux along Flask Glacier (see Fig. 1 for location) according to RACMO (Lenaerts et al., 2012). (b) Surface topography and calculated bedrock (mean of surface elevation bins). The glacier hypsometry is visualized by bars. (c) Calculated ice thickness distribution. The spacing of ice surface contours is 100 m. The bedrock elevation corresponding to sea level is indicated by the solid green line.

Fig. 3. Averaged absolute misfit with OIB thickness data in m (black contours and grey shading) and ice flow velocity in m yr^{-1} (red contours) for different combinations of f_{RACMO} and A_f (see Eqs. 1 and 2). The optimal parameter combination is indicated by the blue cross.

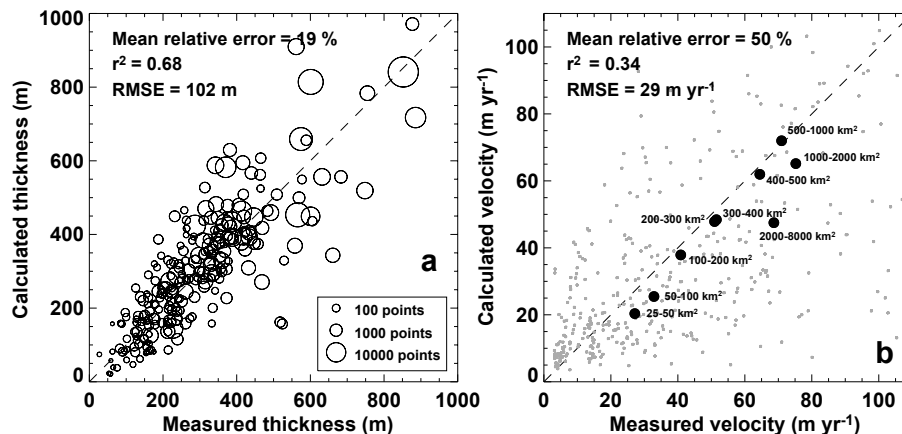

Fig. 4. Validation of calculated glacier-specific **(a)** mean ice thickness (average over all OIB data points) and **(b)** mean surface flow velocity against measurements. The mean relative error, the correlation coefficient r^2 and the root-mean square error (RMSE) are given. The size of the symbols in **(a)** is proportional to the number of measurements within the glacier catchment. Solid dots in **(b)** indicate average flow speeds for glacier size classes.
