## Abstract

Long-term climate records are rare at high elevations in Southern Europe. Here, we reconstructed the evolution of Ossoue Glacier (42°46' N, 0.45 km<sup>2</sup>), located in the Pyrenees (3404 m a.s.l.), since the Little Ice Age (LIA). Glacier length, area, thickness and mass changes indicators were generated from historical datasets, topographic surveys, glaciological measurements (2001–2013), a GPR survey (2006) and stereoscopic satellite images (2013). The glacier has receded considerably since the end of the LIA, losing 40 % of its length and 60 % of its area. Three periods of marked ice depletion can be identified: 1850–1890, 1928–1950 and 1983–2013, as well as two periods of stabilization or slightly growth: 1905–1928 and 1950–1983; these agree with climatic datasets (air temperature, precipitation, North Atlantic Oscillation, Atlantic Multidecadal Oscillation). In the early 2000s, the area of the glacier dropped below 50 % of its area at the end of the LIA. Geodetic mass balance measurements over 1983–2013 indicated  $-30.1 \pm 1.7$  m w.e. ( $-1$  m w.e. yr<sup>-1</sup>) whereas glaciological mass balance measurements show  $-17.36 \pm 2.9$  m w.e. ( $-1.45$  m w.e. yr<sup>-1</sup>) over 2001–2013, resulting in a doubling of the ablation rate in the last decade. In 2013 the maximum ice thickness was  $59 \pm 10.3$  m. Assuming that the current ablation rate stays constant, Ossoue Glacier will disappear midway through the 21st century.

## 1 Introduction

Southern Europe is projected to be a hotspot of climate change over the 21st century, with increasing temperatures and decreasing precipitation (IPCC, 2013). Among other consequences, water resources, including snowmelt from mountain areas, could be affected while water demand should will likely increase (EEA, 2012; IPCC, 2013).

The Pyrenees are a mountain range in southwestern Europe spanning ~ 430 km from the Bay of Biscay (Atlantic Ocean) to the Mediterranean Sea. According to regional climate model projections, the thickness and duration of its snowpack could de-

cline over the 21st century (López-Moreno et al., 2009). However, analysis of snow depth observations over 1985–1999 in the Spanish Pyrenees showed contrasting trends, with increasing snow depth above 2200 m elevation and decreasing snow depth below 2200 m (López-Moreno, 2005). Tree-ring time series from living trees and in situ relict samples, collected at elevations of 2200–2450 m a.s.l., have allowed the reconstruction of 1260–2005 summer temperatures in the Pyrenees. The data confirmed the twentieth century warming (Büntgen et al., 2008). The longest meteorological time series in the French Pyrenees began in 1882 at an astronomical observatory located on the Pic du Midi (2862 m a.s.l.). A mean annual temperature increase of 0.83 °C has been observed over 1882–1970 with a significant decrease in the mean annual diurnal temperature range (2.89 °C per century) (Bücher and Dessens, 1991; Dessens and Bücher, 1995). Recent work on data homogenization within the framework of the Pyrenean Climate Change Observatory depicts a uniform warming at the massif scale over the last sixty years, and highlights a significant warming signal from the 1980s (Soubeyroux et al., 2011; Camberlin and Yves, 2014)

Due to the paucity of meteorological measurements, Pyrenean climate proxy records are crucial to reconstruct past climate fluctuations at secular scales and high altitudes. Glaciers are considered robust climate proxies (WGMS, 2008; Zemp et al., 2009). The Pyrenees hosts the European southernmost glaciers in Europe, all below the 43° N latitude. Their small sizes (< 1 km<sup>2</sup>), relatively low elevations, and southern locations make them particularly vulnerable to climate warming (Grunewald and Scheithauer, 2010). Pyrenean glaciers are strongly out of balance with regional climate and are retreating quickly (Chueca et al., 2007).

The Ossoue Glacier (42°46′ N, 0.45 km<sup>2</sup>) is the second largest glacier in the Pyrenees. In comparison with that of other pyrenean glaciers, the evolution of Ossoue Glacier is well documented, with observations starting at the end of the 19th century. These include historical datasets, topographic maps, aerial images and stakes measurements. The objective of this paper is to reconstruct the evolution of Ossoue Glacier

based on these data to provide further information on the Pyrenean climate since the end of the Little Ice Age (LIA).

The first section gives a brief review of glaciers studies in the Pyrenees (Sect. 2). After describing the site of Ossoue Glacier (Sect. 3), we propose a reconstruction of various indicators including glacier length, area and mass balance of Ossoue Glacier (Sects. 4 and 5). We use ground penetrating radar (GPR) measurements collected in 2006 to estimate the ice depth in the upper part of the glacier. The combination of these indicators allows us to depict a consistent evolution of the glacier since the LIA for the first time. Finally, we discuss the response of the glacier to past climatic changes (temperature, precipitation) and a possible connection with the North Atlantic Oscillation (NAO) and the Atlantic Multidecadal Oscillation (AMO) (Sect. 6).

## 2 Glaciers studies in the Pyrenees

The last favorable period to glacier development in the Pyrenees was the Little Ice Age (LIA), which occurred between the 14th and 19th centuries (Grove, 2004). LIA climate cooling in the Pyrenees led to the formation and advance of glaciers in fifteen massifs where there are up to one hundred cirques (Trueba et al., 2008). In the middle of the 19th century, after advance and recession phases, the Pyrenean glacier fronts reached positions close to their maximum LIA extent. At that time, the area of Pyrenean glaciers is estimated to be slightly over 20 km<sup>2</sup> (Chueca et al., 2007). Since then, their area covered 8 km<sup>2</sup> in 1984 (Serrat-Ventura, 1988), 6 km<sup>2</sup> in 2004 (Chueca et al., 2004) and approximately 3 km<sup>2</sup> in 2013 (René, 2014).

Due to their remote locations and small sizes, Pyrenean glaciers have not benefited from long-term glaciological studies (Grove, 2004). Early topographic measurements were made by “Pyreneists”, alpinists who became enthusiasts in the exploration and observation of the Pyrenees (de Carbonnières, 1801; von Charpentier, 1823; Trutat Eugène, 1876; Schrader, 1895). The *Commission Internationale des Glaciers* (CIG) was created in 1894 in Zürich and led thereafter to the present-day International Asso-

ciation of Cryospheric Sciences (IACS) (Radok, 1997; Jones, 2008). Its first president, the Swiss François-Alphonse Forel, promoted the organized monitoring of glaciers in the Pyrenees for comparison to the evolution of the glaciers in the Alps (Forel, 1887; Gellatly et al., 1994). Prince Roland Bonaparte established and communicated to the Commission the first regular observations of glacier frontal variations between 1874 and 1895 (Bonaparte, 1892). Next, Gaurier monitored the glaciers over the period 1904–1927, which was interrupted by World War I (Gaurier, 1921). On the French side of the Pyrenees, *Eaux et Forêts*, the French national agency in charge of forest and water management, took over the measurements in year 1932, and after World War II, during the period 1945–1956 (Mercanton, 1956). At the end of the 1970s, under the initiative of François Valla from the *Centre Technique du Génie Rural et des Eaux et Fôrets* and the support of the *Parc National des Pyrénées*, the first mass balance measurements in the Pyrenees to our knowledge were performed at Ossoue Glacier between 1978 and 1984 (with only qualitative data taken in 1983 and 1984) (Pont and Valla, 1980; Pont, 1985). This initiative led to the creation of the *Groupe d'Etudes des Glaciers des Pyrénées* (GEGP), a collaborative group comprising the *Institut National de l'Information Géographique et Forestière* (IGN) and researchers at Pau University. Two topographic maps dated from 1948 and 1983 and shown below were produced by the GEGP (Cazenave-Piarrot et al., 1987). However, this group lasted only a few years, so that between 1957 and 2001, only raw terrestrial and aerial images are available for reconstructing glacier front and area variations. Since 2001, a group of volunteer glaciologists called the *Association Moraine* have performed regular glaciological field measurements (René, 2014). On the Spanish side, the institutional program *Evaluación de Recursos Hídricos Procedentes de Innivación* (EHRIN) has monitored Spanish glaciers since the 1990s. Since 1991, this program has collected an uninterrupted glaciological mass balance time series of the Maladeta Glacier (still ongoing WGMS, 2008). The ablation stake measurement protocol in Spain and France was established in collaboration with glaciologists from the *Laboratoire de Glaciologie et Géophysique*

*de l'Environnement* (Grenoble, France), which facilitates comparison between glaciers fluctuations in the Pyrenees and Alps.

In spite of all these efforts, observations of the Pyrenean glaciers remain scarce and irregular. Hence, there are few available reconstructions of glacier evolution since the LIA, and quantitative studies are even rarer. A brief review of Pyrenean glacier evolution is given in Chueca and Julian (2004). On the Spanish side of the Pyrenees, the ice-covered area decreased by 74 % since the end of the LIA (Chueca et al., 2008). In comparison, the area of glaciers in the European Alps decreased by 35 % (Hoelzle et al., 2007). Field measurements completed by early maps, paintings, terrestrial and aerials photographs have allowed the reconstruction of the fluctuations of the Tailon, Maladeta and Coronas Glaciers throughout the 20th century (Gellatly et al., 1994; Chueca et al., 2003; Cía et al., 2005; Chueca et al., 2007). The results of these studies are consistent with a general glacier recession since the LIA. Each glacier experienced alternating periods of strong recession and periods of stability or limited readvance. In particular, there seems to be a common period of strong recession after 1850, a period of readvance or stability between 1960 and 1980, and a period of strong recession from the mid-1980s until now.

The main driver of these glacier changes since the LIA is the regional temperature increase (Grunewald and Scheithauer, 2010). Periods of low precipitation were identified without evident trends. Investigation into potential connections to larger-scale atmospheric patterns has been less common. The NAO controlled the snow accumulation in the Pyrenees during the second half of the 20th century, in particular at high-elevation (López-Moreno et al., 2007, 2011). The AMO was more recently identified as a possible driver of multi-decadal variations in river flow and precipitation in southwest France including the Pyrenees (Giuntoli et al., 2013; Boé and Habets, 2014).

Local topo-climatic effects such as avalanching, wind-drifted snow or shading may significantly influence accumulation and ablation processes. In the Pyrenees, these local influences are expected to have introduced spatial disparities in ice shrinkage,

promoting in particular steep north and northeast glacier cirques, located below the highest summits (Chueca et al., 2007, 2008).

### 3 Study site

Ossoue Glacier (42°46'15" N, 0°08'40" W) is located in the central part of the Pyrenees, beneath the border pass of Cerbillona. It belongs to the Vignemale Massif, which owes its name to the eponymous highest peak of the French Pyrenees (3298 m a.s.l.) (Fig. 1). It is an east-facing cirque glacier. Its main characteristics are given in Table 1. The bedrock comprises metamorphic limestone ridges and quartzite rocks of Devonian age.

Ossoue Glacier is the largest glacier of the French Pyrenees and had an area of 0.45 km<sup>2</sup> in 2011. It is characterized by a large plateau on the upper part (mean elevation 3105 m a.s.l., elevation range 3030–3200 m). The plateau constitutes two thirds of the overall area and is located on a gentle slope (8°). The lower part of the glacier has a steeper slope (> 20°). Therefore, the elevation distribution along the 455 m elevation range is characterized by a relatively high median value (3076 m a.s.l. in 2013; Tab 3). Ossoue Glacier has a typical “alpine morphology”, being significantly longer (1400 m) than wider (400 m) and terminating in a double tongue.

Ossoue Glacier is 150 km from the Atlantic coast and is thus under the influence of the North Atlantic westerlies, which bring abundant precipitation (Chueca et al., 2008). The mean annual precipitation at the closest meteorological station (Gavarnie, 11 km, 1380 m a.s.l.) is 1450 mm yr<sup>-1</sup> over 1992–2012. The glacier is fed mainly during winter by direct precipitation and wind-blown snow. Avalanching is most likely not a significant source of nourishment for the Ossoue Glacier. The surrounding crest walls exhibit limited superficies for snow interception. Thus, Ossoue Glacier carries little debris on its surface, and topographic shading is quite limited. Dust particles are frequently observed on the snow surface, which likely affects glacier albedo and snowmelt in summer. The first day of the local hydrological year is fixed to 1 October (Cogley et al.,

2011). The melting period extends generally from the end of May to the beginning of October. We thus consider the hydrological summer (JJAS). Moulins are often observed during that period in the glacier upper area.

Ossoue Glacier was irregularly monitored throughout the 20th century, but has been quite well monitored since 2001 (Tab. 2).

## 4 Data sets and methods

### 4.1 Topographic surveys

#### 4.1.1 Early sources

As is usual in glacier reconstructions, our data come from various sources (Tab. 2). Distances between the glacier snout and reference points (spits, marks) on specific dates were measured in situ or from photographs or aerial images. Moraines allow us to determine the glacier extent at dates estimated to be close to the end the LIA. The testimony of Henri Passet establishes that the glacier reached the summit of the left lateral moraine in 1865 (Grove, 2004). A photograph taken in 1885 by Joseph Vallot provides evidence that Ossoue Glacier was still close to its moraines at this date. The Etat-Major map edited in 1851 by the French army also provides similar evidence. The map has an estimated accuracy of 15 m in planimetry. Two elevation points located on the front of the glacier are marked at 2458 and 2471 m a.s.l. Currently, both points are located on the glacier moraine. At these locations, the present elevations are 2447 and 2491 m a.s.l. It is remarkable that the difference in elevations are only 11 and 20 m, which gives us further confidence in the fact that the glacier front was actually in contact with its moraine at the middle of the 19th century, i.e., at the estimated end of the LIA in the Pyrenees (Grove, 2004; Trueba et al., 2008).

Interactive Discussion

The Villa Russell is a cave accessible from the glacier at 3201 m a.s.l. It was extruded by Henry Russell and his employees in 1881 (Fig. 4, Tab. 2). Vertical measurements between the glacier surface and the cave threshold were made beginning in 1882.

We collected three paper topographic maps from 1924, 1948 and 1983 (Fig. 5 and Tab. 2). The map dated from 1924 is a 1 : 20 000 scale topographic map with 20 m contour lines. It was created by Alphonse Meillon, a pyrenean topograph-alpinist from the *Club Alpin Français* and Etienne de Larminat, a military cartographer (Meillon and de Larminat, 1933). Its implementation involved both field measurements and triangulation from photographs. Most of the photographs were terrestrial photographs, but military aerial photographs were also used to fill the gaps in a unique collaboration framework (Guilhot, 2005). The maps from 1948 and 1983 feature 2 m contour lines maps and were drafted by GEGP (Sect. 2). Elevation contour lines were generated by manual restitution from stereoscopic airborne photographs (Cazenave-Piarrot et al., 1987). Both maps have a 1 : 2500 scale and were projected in Lambert 3 (the official French coordinate projection system until 2001). We digitized these maps at 1270 dpi.

We also collected summer aerial photographs dated from 1924, 1948 and 1983 available in the IGN in digital format. The latter two photographs exhibit crevasses features matching the aforementioned topographic maps, which indicates that they were used as stereoscopic images to generate the contour lines. We used these photographs to delineate the glacier outline and compute the glacier area, because we found that the glacier outline on the topographic maps was either incomplete or inaccurate. We also used the Etat-Major map (dated 1851) to compute the glacier area. We preferred the outline derived from the moraine position to that from this map to determine the glacier outline in and around the 1850s.

Orthorectification, photointerpreation, length and area measurements (based on graphical or digital sources) were performed in GIS (ArcGis 10.2 from Esri®).

Because there was no projection information available for 1924, the map was georeferenced by extracting GCPs from a digital reference map at 1 : 25 000 scale (IGN Scan 25). For the 1948 and 1983 maps, the coordinates of the graticule intersections

registered on the paper map allowed a direct geo-referencing of the scanned maps. The estimated accuracy in planimetry is 5 m for the 1924 map and 2 m for the 1948 and 1983 maps.

Topographic maps and georeferenced orthoimages (outlines) were assessed in planimetry using a 2010 aerial image orthorectified by the IGN as reference. We associated a random error to outline positions due to glacier margin interpretation, resolution or scale of the documents. From these errors, we generated buffers to estimate random errors in area, most likely resulting in error overestimations (Hoffman et al., 2007). We estimated the random errors in cave height with respect to the glacier surface and in glacier front position based on a subjective assessment of the reliability of the observations as reported in the historical documents (Tab. 2). We calculated total random errors in length, area and height (Villa-Russell) variations registered between two dates  $t_1$  and  $t_2$  by calculating the root sum of squares of each random errors:

$$\sigma_{\text{indicator.total.PoR}} = \sqrt{\sigma_{\text{indicator}.t_1}^2 + \sigma_{\text{indicator}.t_2}^2} \quad (1)$$

To scale the error to an annualized value of a  $N$ -years period of record (with  $N = t_2 - t_1$ ), we considered two cases: (i) if the indicator value at  $t_2$  was deduced from the indicator value at  $t_1$ , then we divided by  $\sqrt{N}$  (e.g., in the case of the field measurements on the glacier front), or (ii) if both indicator values were calculated independently, we divided by  $N$  (e.g., in areas variations based on diachronic aerial images).

On the three digitized maps, contour lines were sampled densely to generate close elevation points. Two m DEMs were generated by an interpolation method, based on a discretized thin plate spline technique (Anudem 5.3, Wahba, 1990; Hutchinson, 2011).

#### 4.1.2 Recent surveys

The length, area and height (Villa-Russell) measurements have been continued in the 2000s.

Interactive Discussion

To complete the historic DEMs time series, two DGPS surveys (DGPS receivers Trimble GEO XH 2008 and 6000) were performed on 3 September 2011 and 6 October 2013 (Tab. 2). Post-corrections based on a 40-km-distant base from the French geodetic permanent network (RGP) were applied. Two m DEMs were generated from the elevation point canvas applying the same interpolation method previously mentioned. The estimated random error on the DGPS DEM is 0.6 m.

A Pléiades stereo pair was acquired over Ossoue Glacier on 23 September 2013. We generated a 2 m horizontal resolution DEM with 1 m vertical resolution and 1.8 m vertical accuracy (GeoView©software 6.6, Marti et al., 2014). In this study, the Pléiades DEM was used to generate the surface elevation of the deglaciated margin between 1983 and 2013. To map the differences in surface elevation on the glacier between 1983 and 2013, the DGPS surface elevation was used because it was acquired closer to the end of the summer.

### 4.2 Geodetic mass balances

The DEMs generated for 1924, 1948, 1983, 2011 and 2013 allowed us to establish a geodetic mass balance over an 89 year period. Consecutive DEMs were subtracted on a pixel by pixel basis. Volume changes derived by differencing DEMs is based on the following equation (Zemp et al., 2013):

$$\Delta V = r^2 \sum_{k=1}^K \Delta h_k \quad (2)$$

where  $K$  is the number of pixels covering the glacier at the maximum extent,  $\Delta h_k$  is the elevation difference at pixel  $k$ , and  $r$  is the pixel size (2 m in this study).

We have very little information on the generation of the maps based on terrestrial (1924) or aerial photogrammetry (1948, 1983). DEMs were assessed on stable terrain following the technical recommendations given in Racoviteanu et al. (2010). A GCPs dataset was generated from DGPS points collected on 23 October 2013 on the frontal

margin of the glacier, i.e., on a snow and ice free bedrock surface. DEMs were not horizontally shifted given the good absolute localization of the sources (5 m for 1924, 2 m for 1948 and 1983), and the limited superficies covered outside the glacier to perform such an adjustment.

The differences between the DEM and the DGPS elevation values were normally distributed for 1948, 1983 and 2013. The mean elevation difference found for each DEM was noted as  $e_{\text{bias}}$  ( $e_{\text{bias.1948}} = -1.8$  m,  $e_{\text{bias.1983}} = -1.4$  m, and  $e_{\text{bias.2013.P}} = -1.37$  m for the 2013 Pléiades DEM) and was uniformly added to all the elevation values. For the 1924 DEM, the elevation differences did not follow a normal distribution and it was not possible to determine the elevation bias (noted as  $e_{\text{bias.1924}}$ ). Hence, no correction was applied to this DEM. The SD of the elevation difference values on stable areas was considered as to be a representative value of the vertical random error and was noted as  $\sigma_{\text{bias}}$ . The random error term due to the interpolation process was calculated to be 0.5 m for 2011 and 2013 DGPS data. The geodetic mass balance  $B_{\text{geod}}$  was calculated through the following formula:

$$B_{\text{geod}} = \rho \left( \frac{\Delta V_{\text{gla}}}{A_{\text{gla}}} + \frac{\Delta V_{\text{marg.gain}}}{A_{\text{marg.gain}}} + \frac{\Delta V_{\text{marg.loss}}}{A_{\text{marg.loss}}} \right) \quad (3)$$

where  $\rho$  is the mean density (see detail below).  $A_{\text{gla}}$  is the area that is glaciated in both DEMs.  $A_{\text{marg.loss}}$  is the deglaciated area;  $A_{\text{marg.gain}}$  is the area where the glacier advanced. The mean density was assumed to be  $900 \text{ kg m}^{-3}$  between 1924 and 1948, and between 1983 and 2013, because the firn zone was nearly absent during those periods. We neglected the errors associated with this density assumption. In 1983, because a firn zone was likely present, we used a mean density of  $850 \text{ kg m}^{-3}$  with an uncertainty range of  $\pm 50 \text{ kg m}^{-3}$  (Huss, 2013). For that period, we calculated an error term  $\sigma_{\text{dc}}$  associated with the uncertainty range due to density conversion. For every period, we considered an additional systematic error term  $e_t$  due to the time lag between the raw data acquisition date and the first day of the next hydrological year, fixed to 1 October (when the elevation surface is expected to reach its annual minimum).

The error  $\epsilon_t$  was computed by multiplying the mean ablation rate observed during this period of the year over 2001–2013 (from stake measurements) by the duration of the time lag. At this stage we preferred to keep this term as an error rather than correcting the mass balance value, using a floating-date system (Cogley et al., 2011).

Following Zemp et al. (2013) the mean annual systematic error may be expressed as:

$$\overline{\epsilon_{\text{geod.total.a}}} = \frac{\epsilon_{\text{geod.total.PoR}}}{N} = \frac{\epsilon_{\text{geod.DEM.PoR}}}{N} \quad (4)$$

$$= \frac{\epsilon_{\text{bias}} + \epsilon_t}{N} \quad (5)$$

where PoR is period of record and  $N$  is the number of years in the PoR. After co-registration  $\epsilon_{\text{bias}}$  is assumed to be 0, and therefore:

$$\overline{\epsilon_{\text{geod.total.a}}} = \frac{\epsilon_t}{N} \quad (6)$$

The mean annual random error may be expressed following (Zemp et al., 2013):

$$\overline{\sigma_{\text{geod.total.a}}} = \frac{\sigma_{\text{geod.total.PoR}}}{N} = \frac{\sqrt{\sigma_{\text{geod.DEM.PoR}}^2}}{N} \quad (7)$$

$$= \frac{\sqrt{\sigma_{\text{bias}}^2 + \sigma_{\text{dc}}^2}}{N} \quad (8)$$

Note that for scaling random errors at annual time steps, division is by the number of years (Zemp et al., 2013). The values of  $\epsilon_{\text{bias}}$ ,  $\epsilon_t$ ,  $\sigma_{\text{bias}}$ ,  $\sigma_{\text{dc}}$  and the resulting errors in DEM differences are given in Table 3. Annualized systematic and random errors are presented in Table 10.

### 4.3 Glaciological mass balances

Since 2001, Ossoue Glacier has been monitored by systematic winter and summer mass balance measurements performed by Association Moraine. These are available on the WGMS website (Id: 2867). The direct glaciological method was used here (Ostrem-Brugman, 1991; Cuffey and Paterson, 2010). The protocol was similar to that used for Saint-Sorlin and Argentière Glaciers in the Alps (Gerbaux et al., 2005; Vincent, 2002) and followed the technical recommendations of the GLACIOCLIM observation network (GLACIOCLIM, 2001; René, 2013). At eight sites (Fig. 4), the winter and annual mass balances were determined by two specific methods: (1) the end of winter snow depth with respect to the previous summer surface was measured using snow probes and the near-surface snow density was calculated by drilling and weighting calibrated cores; and (2) the annual mass balance was determined by inserting 10 m ablation stakes (five 2 m sections) into the ice. Summer ablation measurements were repeated once a month until a date close to the beginning of the next hydrological year, according to the floating-date system (Cogley et al., 2011).

These point observations were spatially integrated using an area extrapolation method. The glacier surface was divided into eight polygons centered at each ablation stake. The polygon borders were determined through empirical considerations based on field observations, elevation, aspect and mean slope (Tab. 4, Fig. 4). The winter mass balance at a specific site  $k$  can be expressed as:

$$b_{w,k} = \rho_{\text{snow},k} h_{\text{snow},k} \quad (9)$$

where  $\rho_{\text{snow},k}$  is the density calculated at site  $k$  and  $h_{\text{snow},k}$  the snow depth accumulated during winter on the previous summer surface.

The glacier-wide winter mass balance  $B_w$  was obtained by summing the contribution from each polygon:

$$B_w = \sum_k b_{w,k} W_k \quad (10)$$

Interactive Discussion

where  $W_k$  is the fractional surface area of the polygon  $k$  within the glacier (Tab. 4). The  $W_k$  values were updated in 2006 and 2011 to reflect the evolution of the glacier geometry.

The annual mass balance was calculated using the same spatial integration method.

If the field operator noted the disappearance of the winter snow layer, and the presence of older firn from a previous year, a density of  $600 \text{ kg m}^{-3}$  was applied to that layer. If ice was observed, a constant density  $\rho_{\text{ice}} = 900 \text{ kg m}^{-3}$  was used. Lower densities values were not used because of the continuous glacier shrinkage observed since the 1980s.

These glaciological mass balance terms can be expressed in the following equation (Cogley et al., 2011):

$$B_{\text{glac.a}} = B_w + B_s \quad (11)$$

where  $B_{\text{glac.a}}$ ,  $B_w$  and  $B_s$  designate the glacier-wide annual, winter and summer mass balances, respectively.

The summer balance  $B_s$  was calculated as the difference between the two measured mass balance terms.

Annual systematic and random errors in the glaciological data series can be expressed as follows (Zemp et al., 2013):

$$\overline{\epsilon}_{\text{glac.total.a}} = \frac{\epsilon_{\text{glac.PoR}}}{N} \quad (12)$$

$$\overline{\sigma}_{\text{glac.total.a}} = \frac{\sum_{t=1}^N \sigma_{\text{glac.a.PoR}}}{\sqrt{N}} = \frac{\sqrt{\sum_{t=1}^N \sigma_{\text{glac.point.t}}^2 + \sigma_{\text{glac.spatial.t}}^2 + \sigma_{\text{glac.ref.t}}^2}}{\sqrt{N}} \quad (13)$$

where PoR indicates the period of record,  $N$  is number of years in the PoR and point refers to the field measurement at the location point, spatial to spatial integration, and ref to the changing glacier area over time.

The value of  $\overline{\epsilon}_{\text{glac.total.a}}$  was computed from the DPGS surveys performed in 2006 and 2011 as follows: (i) we calculated the mean elevation difference between both DEMs

Interactive Discussion

over polygons 1 to 4 (only these sectors were covered in 2006); and (ii) we calculated a mean geodetic mass balance assuming a density of  $900 \text{ kg m}^{-3}$ . We compared this geodetic mass balance to the corresponding glaciological mass balance. We obtained a difference of  $-0.68 \text{ m w.e.}$  for  $N = 5$  years, which gives  $e_{\text{gla.total.a}} = +0.14 \text{ m w.e.}$

We estimated random errors due to the field measurements following the guidelines provided by Gerbaux et al. (2005). Given that only three occurrences of positive mass balance were observed over the whole period of record (88 measurements), the entire glacier was considered as an ablation zone over this period for the estimation of the errors (i.e we neglected the errors associated with the residual snow from the previous year). The mean annual error in the specific mass balance is  $\sigma_{\text{glac.point.a}} = 0.15 \text{ m w.e.}$  The specific mean winter mass balance error is  $\sigma_{\text{glac.point.w}} = 0.35 \text{ m w.e.}$  (Tab. 5).

Next, we estimated the random error due to the spatial integration  $\sigma_{\text{glac.spatial.a}}$  to compute the glacier-wide glaciological mass balance from the specific mass balances. This was done using the DEMs made from the DGPS surveys performed in 2011 and 2012. For every polygon 1 to 6 (only these polygons were surveyed), we calculated the variance of the differences between both DEMs. The six variances values were aggregated based on Eq. (10), after rescaling the area weights. We obtained a mean value of  $0.88 \text{ m w.e.}$  However, this error value is likely too high, because, in part, it propagates the errors included in the DGPS DEMs. Therefore, we took  $\sigma_{\text{glac.spatial.a}} = 0.7 \text{ m w.e.}$  We neglected the error term  $\sigma_{\text{glac.ref.a}}$  due the changes in glacier area (Zemp et al., 2013). In sum, we estimated an annual total random error of  $\sigma_{\text{glac.total.a}} = 0.85 \text{ m w.e.}$

The stake measurements performed from 1979 to 1985 followed similar protocol as that described above, except that the glacier was divided into 5 longitudinal sectors (Pont, 1985). We used the same annual total random error as for 2001–2013.

#### 4.4 Glacier indicators combination

The Ossoue Glacier indicators mentioned above were pieced together to create a coherent time-line of glacier fluctuations. We defined five threshold values to classify variations in each glacier indicator over the period of record. We defined classes of

markedly positive variations, positive variations, markedly negative variations, negative variations and a class of “no significant variation”. Classification in a positive or a negative class was based on whether the absolute annualized variation was equal or greater than the annualized random error (Tab. 6). If this condition was not fulfilled, the variation was classified as not significant for the period of record. From this classification, we qualitatively determined periods of stable-positive or negative evolution.

#### 4.5 Geophysical surveys

A ground penetrating radar (GPR) survey was performed on 30–31 of August 2006 in the upper area of Ossoue Glacier. The GPR apparatus used was a PulseEkko 100 (Sensors and Software Inc.) with 50 MHz unshielded antennas. Three longitudinal profiles (W–E) running from the top to the slope transition of the glacier and four transverse profiles (N–S) were surveyed. The horizontal step was 0.5 m. The topography was acquired in real-time using a Leica DGNSS. In the radargrams strong reflectors identified at long two-way traveltimes were assumed to be the glacier bed. Hyperbolic features were used for electromagnetic (EM) velocity determination. An EM velocity of  $0.16 \text{ m ns}^{-1}$  was determined for the ice and was used to migrate the data. The thickness of the glacier was determined along the profiles at an horizontal resolution of 10 m. At the glacier margins the thickness was assumed to be zero (Saintenoy et al., 2013). The glacier thickness and surface elevation in 2006 were interpolated by ordinary kriging after second order trend removal (ESRI ArcGIS<sup>®</sup>, Geostatistical Analyst tool). Subsequently a map of the subglacial bedrock elevation was generated. Based on the standard error map associated with kriging, we excluded the area in the prediction map where the kriging error was greater than  $\sigma_{\text{krig}} = 10 \text{ m}$ . From the 2013 glacier DEM and the bedrock map, we generated a 2013 glacier ice thickness map (Fig. 12). The mean random error for the subglacial elevation was calculated as follows:

$$\sigma_{\text{subglacial.total}} = \sqrt{\sigma_{\text{GPR}}^2 + \sigma_{\text{krig}}^2 + \sigma_{\text{bias.2006}}^2} \quad (14)$$

mate and have been successfully used in glacier-climate linkages (Six et al., 2001; Huss et al., 2010; Thibert et al., 2013).

- For the NAO we used a winter (DJFM) index based on the monthly 1850–1999 Climate Reasarch Unit (CRU) dataset, completed by Tim Osborn’s 2000–2013 NAO Update (Jones et al., 1997; Osborn, 2006). We applied a 5 yr moving average filter to smooth the signal.
- For the AMO we used the monthly index calculated from the Kaplan sea surface temperature dataset over 1861–2009 (Enfield et al., 2001).

## 5 Results

### 5.1 Front, outlines and area variations

Our reconstruction of the Ossoue Glacier front and area shows significant glacier retreat since the LIA, with intermittent stationary phases (Fig. 9).

From 1850 to 1889, the Ossoue Glacier front retreated by 346 m ( $-8.8 \text{ myr}^{-1}$ ). During the following fifteen years (1889–1904), the front position was quite stationary, retreating by 11 m between 1892 and 1893 and by only 9 m between 1899 and 1904. In the year 1904–1905, however the Ossoue Glacier front retreated by 23 m. The following periods were characterized by stability (1905–1911) and progression (1911–1927). In our dataset, the glacier reached its most position of greatest 20th century advance in 1927 (Tab. 7).

The area of Ossoue Glacier at the end of the LIA, based on moraines locations, was  $112.6 \pm 10$  ha. The glacier area extracted from the “Etat Major” map (dated near 1851) is  $115 \pm 20$  ha. Between the end of the LIA and 1924, the area of Ossoue Glacier decreased by 20 %. The area decreased by a further 10 % over the period 1924–1948. During the period 1948–1983 the front retreated by 315 m until 1963 and then advanced by 156 m, although the changes in area over this period were low ( $-3$  %). Over

Interactive Discussion

1983–2002 the area decreased by 17% with a notable width reduction on the slope transition. In the early 2000s, the area of Ossoue Glacier was less than 50% of the its area at the end of the LIA (Tab. 8).

Changes in glacier geometry mainly occurred in the lower part of the glacier. In the upper part, the glacier shape remained almost unchanged until 1983. From 1983 to 2013, glacier width reduced dramatically at the slope transition between the plateau and the tongue of the glacier.

## 5.2 Mass changes and ice thickness

Since 1924, Ossoue Glacier has lost a mean of 59 m.w.e. over the current glacier area (Fig. 9). The two periods of marked ice depletion, 1924–1948 and 1983–2013, were interrupted by a stable period between 1948 and 1983.

Between 1924 and 1948, the glacier lost  $-33.5 \pm 8.8$  m.w.e. ( $-1.39$  m.w.e.  $\text{yr}^{-1}$ ) over the 1948 glacier area and  $-25.5 \pm 8.8$  m.w.e. over the deglaciated margin. The ice depletion signal was strongest in the central part of the glacier (Fig. 7).

The period 1948–1983 is the only period with observed positive geodetic mass balance variation, with a cumulative value of  $+5.8 \pm 2.6$  m.w.e. over the 1983 glacier area ( $+0.16$  m.w.e.  $\text{yr}^{-1}$ ). However, a notable depletion was observed on the tongue (Fig. 7). On the deglaciated margin, depletion was  $-7.9 \pm 2.6$  m.w.e. The glacier advanced over a very small area (1 ha) with a mean ice growth of 6.5 m.w.e. An area of higher accumulation is localized on the lower part of the glacier, below the slope transition (Fig. 7). At the end of that period, using ablation stakes, François Valla and Henri Pont measured mass gains of +0.81 m.w.e. in 1978, +0.26 m.w.e. in 1979, +0.17 m.w.e. in 1980, and 0 m.w.e. in 1981 and 1982. In 1983 and 1984, they considered the mass balances to be “negative” but did not provide quantitative information (Pont, 1985).

Over 1983–2013 the glacier lost  $-30.1 \pm 1.7$  m.w.e. over the 2013 glacier area ( $-1$  m.w.e.  $\text{yr}^{-1}$ ) and  $-22.6 \pm 1.7$  m.w.e. over the deglaciated margin. A marked pattern of ice depletion occurs along a longitudinal profile on the upper part of the glacier

Interactive Discussion

(Fig. 7). This phenomenon increases glacier convexity in that zone, which was once named as *Plateau des Neiges* in older maps.

If we consider the 2013 glacier area as a common integration area for all the periods, the absolute value of the geodetic mass balance increased over 1924–1948 (–35 m w.e.) and 1948–1983 (+6.1 m w.e.).

Between 2001 and 2013, superficial mass loss on Ossoue Glacier given by the glaciological method is  $17.36 \pm 2.9$  m w.e. ( $-1.45$  m w.e. yr<sup>-1</sup>) (Fig. 8). The strongest mass losses were registered at the lowest elevated stakes (stakes 7 and 8). The mass balance was negative every year since the stake measurements began except in 2012–2013 with a value of +0.22 m w.e. (René et al., 2014). In 2008 the mass balance was only slightly negative.

In 2006, the estimated mean ice thickness was  $29.3 \pm 6.3$  m (max.  $74.8 \pm 10.2$  m), giving an estimate of  $25 \pm 6.5$  m (max.  $59 \pm 10.3$  m) in 2013 (Fig. 12). In 2011, another GRP survey (Del Rio et al., 2012) indicated a maximum depth of 45 m and an average depth of 30 m. Despite the discrepancies in ice thickness, both studies suggest similar bedrock morphologies. As a verification of these data, we provide here the depth of the main moulins that have been measured regularly since 2004 by glacial speleologists: 30 m in 2004, 38 m in 2005, 36.5 m in 2006 and 41.5 m in 2009. However, these values should be considered minimum estimates of the glacier thickness because they do not necessarily reach the bedrock.

### 5.3 Trends observed from glacier indicators

Taken together, all indicators suggest a clear retreat of Ossoue Glacier since the end of the LIA (Fig. 10). We identified three periods of marked ice depletion, when these indicators consistently indicate a negative trend: 1850–1890, 1928–1950 and 1983–2013. By the same reasoning, two periods are characterized by stability or slightly growth: 1905–1928 and 1950–1983.

## 5.4 Linkage with climate

Correlations between the Ossoue Glacier mass balances time series (2001–2013) indicate that the annual mass balance is mainly dependent on the summer mass balance and that the winter mass balance has less influence (Spearman's  $\rho = 0.84$  for summer mass balance and  $\rho = 0.65$  for winter mass balance).

The link between ablation and air temperature is verified at Ossoue Glacier through the high and significant ( $p$  value  $< 0.05$ ) correlations between monthly summer ablation and monthly air temperature time series over 2002–2013 ( $\rho = -0.81$  for Gavarnie valley station,  $\rho = -0.74$  for Pic du Midi station, which is located farther from the glacier, and  $\rho = -0.8$  for the regional CRU time series). Mean summer air temperature and summer-wide mass balance  $B_s$  (June–September) are also correlated, although only significantly with the Gavarnie dataset ( $\rho = -0.72$  for Gavarnie,  $\rho = -0.52$  for Pic du Midi and  $\rho = -0.66$  for the CRU time series). The high correlation between the different time series over the common period of records ( $\rho > 0.96$ ,  $p$  values  $< 0.05$ ) give us confidence that the mean summer temperature at Pic du Midi is related to  $B_s$ .

The link between annual mass balance and mean annual temperature is weaker in the Pic du Midi time series than in the CRU time series ( $\rho = -0.45$  for Pic du Midi and  $\rho = -0.74$  for the CRU time series). The correlation is only significant with the CRU dataset. This may due to the use of raw data in the Pic du Midi time series starting from 2011 or to the limited period of record of glaciological mass balance (annual mass balance measurements only began in 2001). However, due to the good correlation between the CRU and the Pic du Midi temperature datasets, we also considered that the mean annual temperature at Pic du Midi is linked to  $B_{\text{glac.a}}$  over the longer period 1890–2013. The elevation of the Pic du Midi station (2874 m a.s.l.) is close to that of the Ossoue Glacier front (2755 m a.s.l.); thus, we used principally this dataset to identify temperature trends over historical periods.

Precipitations records at Gavarnie and Tarbes are significantly correlated with the winter mass balances ( $\rho = 0.71$  for Gavarnie,  $\rho = 0.69$  for Tarbes, which is located far-

Interactive Discussion

ther from the glacier). The link between annual mass balance and annual precipitation is significant in the Tarbes dataset ( $\rho = 0.66$ ). Thus, we conclude that the Tarbes time series can be used to identify trends in precipitation that are linked with Ossoue Glacier fluctuations.

5 The mean annual temperature over the hydrological year (starting 1 October) and the mean summer temperature (JJAS) over 1858–2013 are  $-1.1$  and  $5.1$  °C, respectively. The annual precipitation and the winter precipitation (NDJFMA) over 1882–2013 are 1068.2 and 556 mm, respectively. Analysis of temperature and precipitation trends over the six periods from a combination of indicators (Fig. 10) reveals four significant trends:

- 10 – The mean annual temperature over 1858–1890 may have continuously decreased. Over the same period, the mean summer temperature (JJAS) is slightly higher than the mean summer temperature over 1858–2013 ( $5.3$  °C).
- The annual precipitation trend over 1950–1982 is positive ( $\rho = 0.42$ ) and equal to the mean precipitation over 1882–2013 (1068 mm). Winter precipitation is higher than the mean recorded over 1882–2013 (586.2 mm). The annual mean temperature ( $-1.4$  °C) and mean summer temperature ( $4.8$  °C) are lower than the means over 1858–2013.
- 15 – The last period considered (1983–2013) shows positive trends in both mean annual and mean summer temperature, with the highest registered mean temperatures ( $-0.4$  °C for annual and  $6.1$  °C for summer).

## 6 Discussion

Using multiple datasets, we generated five independent time series of glacier indicators (length, area, thickness at Villa Russell, geodetic and glaciological mass balances variations) to reconstruct the evolution of Ossoue Glacier since the end of the LIA (Fig. 10).

25 The indicators give a generally consistent chronology of glacier fluctuations since the

LIA, although there are some discrepancies. We should bear in mind that the indicators do not directly reflect the same glaciological processes. The time series of frontal variations offers the best temporal resolution to of the onset of glacier changes, but these changes are strongly influenced by ice dynamics. Glacier motion is dependent on mass variations on the upper part of the glacier, but the response time is largely unknown. Areal variations depend on ice thickness at the edges only. Thickness variations registered at Villa Russell are the result of accumulation and ablation variations at the northern periphery of the glacier only, which could be prone to snow drifting. Volumetric mass changes generated by the geodetic method are mostly the result of the surface energy budget but also include internal and basal mass variations, which remain difficult to estimate. Glaciological mass balance reflects the link between energy and mass budget well, but can only be measured at a limited sample of points of the glacier surface. However, these indicators are all sensitive to the glacier mass changes, with different times scales and intensities of response. For instance, between 1948 and 1983, the mass balance was positive, but frontal variations were negative until 1963. This can likely be explained by the delay in the response time of frontal response to glacier mass changes. In the case of Ossoue Glacier, it is note-worthy that the indicators over the study period reveal a consistent signal (Fig. 10).

The evolution of Ossoue Glacier is consistent with the reconstructed evolutions of other Pyrenean glaciers. It is in good agreement with Cía et al. (2005) (Maladeta Glacier, 42.65° N, 0.64° E, northeast-oriented, 2870–3200 m altitude range and 0.27 km<sup>2</sup> area in 2011) and with Chueca et al. (2003) (Coronas Glacier, a glacieret or ice patch since the 2000s, 42.63° N, 0.65° E, southwest-oriented, 3100–3240 m and 0.02 km<sup>2</sup> in 2011) and Gellatly et al. (1994) (Taillon Glacier, 42.69° N, –0.04° E, northeast-oriented, 2530–2800 m, 0.08 km<sup>2</sup> in 2011). Considering an accuracy of ±5 years, two common stable periods could be identified (1905–1930 and 1955–1985) as well as two periods of marked ice depletion (1850–1900 and from mid-1980s until now). The evidence of strong marked ice depletion found in this study for Ossoue Glacier between 1924 and 1948 (–1.39 m m.w.eyr<sup>-1</sup>) should be considered with cau-

Interactive Discussion

tion given the high uncertainties in the altimetry restitution process. However, reconstructions of other Pyrenean glaciers over comparable periods tend to corroborate this result. Between approximately 1928 and 1957, the length of Coronas Glacier decreased from 600 to 350 m, while its area decreased from 19 to 8.6 ha and its equilibrium line altitude (ELA) increased from 3065 to 3122 m (Chueca Cía et al., 2001). During the period 1935–1957, Maladeta Glacier lost 15 ha ( $-0.68 \text{ ha yr}^{-1}$ ) and its length decreased by 80 m. This retreat is assumed to be due to a warm anomaly detected in the second half of the 1940s (Cía et al., 2005). The Maladeta Glacier mass balance time series (1991–2013) shows a good agreement with Ossoue glaciological mass balances time series over the period 2001–2013 (Fig. 9). During the 1990s, the Maladeta mass balance values were slightly negative. If we compare the Ossoue geodetic mass balance during 1983–2013 ( $-1 \text{ m w.e. yr}^{-1}$ ) and the Ossoue glaciological mass balance during 2001–2013 ( $-1.45 \text{ m w.e. yr}^{-1}$ ), we can deduce that the 1983–2001 Ossoue ablation rate was approximately  $-0.7 \text{ m w.e. yr}^{-1}$ . This result is consistent with the aforementioned variations of the Maladeta Glacier over 1991–2001 (Fig. 9).

In the French Alps, which is the nearest glaciated massif to the Pyrenees, two steady-state periods (1907–1941 and 1954–1981) and two periods of recession (1942–1953 and 1982–1999) were deduced from four glacier mass balances time series (Vincent, 2002). This further suggests that there is a common climatic driver governing fluctuations in Pyrenean and Alpine glaciers since the LIA.

Figure 11 provides insight into the possible linkage between the evolution of the Ossoue Glacier and the regional-scale climate. The period 1960–1980 is characterized by a succession of negative phases of the NAO, this coincides with a period of relative glacier growth or stability (positive variations in various glacier lengths, areas and mass balances). Ossoue Glacier seems to be anti-correlated with the NAO. Similar results were reported by Six et al. (2002) and Marzeion et al. (2014) for glaciers of the southern Alps. In addition, variations in the AMO index also appear relatively similar to variations in the combined Ossoue Glacier indicators throughout the 20th century. This result is consistent with previous studies on the influence of the multidecadal internal variability

of the North Atlantic circulation on the Northern Hemisphere climate (e.g., Enfield et al., 2001).

Variations of Ossoue Glacier indicators are in good agreements with meteorological data: periods of ice depletion are generally characterized by lower values of mean precipitation and temperatures (Tab. 13). The evolution of Ossoue Glacier may be partially explained by observed trends, with a significant positive trend in 1950–1982 precipitations (a stable period for the glacier) and a significant constant rise in mean annual and summer temperature since 1983 (a period of depletion for the glacier). The periods 1850–1890 and 1983–2013 are marked by ice depletion, although the mean air temperature time series have opposite and significant trends. Frontal variations and mean air temperature variations over the 1850–1890 interval point to a shorter period of marked ice depletion, 1850–1874, with lesser depletion over the 1874–1890 period. By the same reasoning the selected 1928–1950 period of ice depletion period may have been more pronounced in the 1937–1950 “subperiod” than over the 1928–1937 “subperiod”.

The future evolution of Ossoue Glacier depends on climatic changes, but is also constrained by the remaining ice volume. Considering the remaining ice depth in 2013 and assuming that the Ossoue Glacier mass balance follows the same trend as that recorded during 2001–2013 ( $-1.45 \text{ m.w.e. yr}^{-1}$ ), the glacier should totally disappear in 40 years. To further illustrate this, the ice thickness map (Fig. 12) was divided with thickness classes that are multiples of 1.5, i.e., a value close to the current annual mass loss rate. Thus, this map gives a rough estimation of the evolution of the glacier area every eight years. Based on this map and the past evolution of the glacier, we anticipate that the glacier may split into two parts at the slope transition (Fig. 4) in the near future. At this location the glacier may be particularly thin, and there is an abrupt change in the glacier slope. The lowest part may soon no longer be fed by the ice flow from the upper area and could thus rapidly disappear. This separation would drastically change the morphology of Ossoue Glacier from an active glacier to a glacieret or ice

patch. Such glacier fragmentation has been regularly observed on Pyrenean glaciers, e.g., the neighboring Petit Vignemale and Oulettes Glaciers.

However, future evolution of Ossoue Glacier based on interpretation of Fig. 12 was made under several strong assumptions: (i) the mass balance patterns are uniform, (ii) ice motion can be neglected, and (iii) the mass loss in the future decades will occur at the same pace as during the last decade. Our data suggest that the uniform mass balance assumption is questionable. Geodetic measurements over 1983–2013 show a clear depression in the central part of the glacier, which indicates that the glacier evolves toward a more convex topography. Stake measurements over 2001–2013 reflect the influence of the glacier topography, principally in the ablation period (Tab. 4 and Fig. 8). Accumulation processes do not show a vertical gradient, but may show a north–south gradient in the upper part, most likely driven by the accumulation of wind-blown snow. Elevation is the main factor that separates the three groups of stakes: above the glaciological mass balance (stakes 1 to 3), slightly beneath (stakes 3 and 5) and beneath (stakes 7 and 8). Stake 6 shows uncommon behavior that is most likely influenced by greater ice motion at that location. The influence of the aspect explains the discrepancy between stake 2 and stake 4, while slope seems to explain the higher melting rate at stake 3 compared to the lower-elevation stake 5. Future work is necessary to better understand the effect of local topography on the spatial variability of glacier mass balance. This influence is expected to augment in the future as the glacier retreats (López-Moreno et al., 2006a, b).

If the current ablation rate continues, Ossoue Glacier will disappear halfway through the 21st century. Its large, markedly convex plateau (two thirds of the present-day area) has allowed the accumulation of a significant amount of ice at high altitude (3105 m) during favorable periods. However, due to the limited interval range of the plateau (3030–3200 m, slope 8°), any future rise of the lower limit of the glacier (2755 m in 2013) would drastically modify the responses of the indicators of Ossoue Glacier to future climate fluctuations.

## 7 Conclusions

Ossoue Glacier is one of the southernmost glaciers in Europe. Using an exceptional archive of historical datasets and recent accurate observations, we generate consistent time series of various glacier indicators such as length, area, elevation variations, and mass changes since the LIA at high temporal resolution. The dominant trend is a retreat over the 20th century, which was interrupted by two stable periods, 1906–1924 and 1960–1983. These periods appear to be roughly in phase with hemispheric climate proxies such as the North Atlantic Oscillation and the Atlantic Multidecadal Oscillation. The 1960–1980 stable period may be partially explained by anti-correlation to the NAO index. We found that the ablation rate may have doubled in the last decade, likely as a result of the recent climate warming.

The evolution of Ossoue Glacier is in good agreement with that of other Pyrenean glacier reconstructions (Maladeta, Coronas, Taillon Glaciers) suggesting the possibility of long-term high-elevation climate reconstruction in the Pyrenees.

The time resolution of the generated indicators allows us to extract consistent glacier changes over various periods. These generally concur with climatic data, suggesting that Ossoue Glacier is a good regional climate proxy. However, it remains difficult to isolate the relative contribution of precipitation and air temperature changes to the reconstructed mass balance variations. This could be achieved with a temperature index model or a more sophisticated glacier model (e.g., Gerbaux et al., 2005).

The eastern orientation and low shading of Ossoue Glacier make it particularly vulnerable to climate fluctuations, although its relatively high elevation supports large amounts of snow accumulation. Windblown snow could also increase accumulation on some parts of the glacier.

Future studies should focus on topo-climatic drivers of Ossoue Glacier mass balance in an effort to better understand the link between its past temporal evolution and regional climate change.

Interactive Discussion

More generally, retreat of Pyrenean glaciers could affect local ecosystems by diminishing the beta diversity in Pyrenean streams (Finn et al., 2013). Natural patrimony and the visual perception of the high mountain landscape could also be irrevocably affected (EDYTEM, 2009; Moreau, 2010; René, 2013).

## Evolution of Ossoue Glacier (French Pyrenees) since the end of the Little Ice Age

R. Marti et al.

**Table 1.** Characteristics of Ossoue Glacier.

Identification	Name Ossoue Glacier Glacier d'Ossoue	Earlier names Aussoue Grand glacier de Montferrat/Vignemale	Id Inventory WGMS 2867 RGI 40-11.03864
Location	Geographic coordinates 42°46′15″	Mountain range French Pyrenees	Massif Vignemale
Glacier type	Primary class Mountain glacier	Form Cirque glacier	Frontal characteristics Double lobe, mainly clean ice
Dimension	Max. Length 1400 m	Max. width 400 m	Area 0.45 km <sup>2</sup> (2011)
Hypsometry	Elevation range 2755–3210 m a.s.l. (2013)	Elevation mean 3046 m a.s.l. (2013)	Elevation median 3076 m a.s.l. (2013)
Hydrography	Gave d'Ossoue	Gave de Pau	Adour River
Geomorphology	Nature of bedrock Limestone marble of Devonian	Moraines Visible lateral moraines out of contact	Cirque mean aspect East

## Evolution of Ossoue Glacier (French Pyrenees) since the end of the Little Ice Age

R. Marti et al.

**Table 3.** Meta-data of Ossoue Glacier volumetric measurements errors. Mean elevation bias  $\epsilon_{\text{bias}}$  and SD  $\sigma_{\text{bias}}$  are based on DGPS points surveyed on the deglaciated margin. The symbol \* means that the bias was removed from the final DEM (Sect. 4.2) and was not taken into account in the total error.  $\epsilon_t$  refers to the systematic error due to the timelag between the survey date and 1 October (Sect. 4.2). The term  $\sigma_{\text{dc}}$  refers to the density conversion error. The last columns are the sums of systematic and random errors for the period of record (PoR). The propagation law is applied for random errors (root sum of squares).

Derived 2 m-DEM $t_1 - t_2$	DEM $t_1$ ( $\epsilon_{\text{bias}}$ ; $\sigma_{\text{bias}}$ )	DEM $t_2$ ( $\epsilon_{\text{bias}}$ ; $\sigma_{\text{bias}}$ )	Errors on DEMs Differences (in m.w.e.)				
			$\epsilon_{t_1}$	$\epsilon_{t_2}$	$\sigma_{\text{dc}}$	$\epsilon_{\text{total.PoR}}$	$\sigma_{\text{total.PoR}}$
1924–1948	( $\epsilon_{\text{bias.1924}}$ ; 8.6)	(-1.8*; 2)	+1.71	+0.94	–	2.65 + $\epsilon_{\text{bias.1924}}$	8.8
1948–1983	(-1.8*; 2)	(-1.4*; 1.6)	+0.94	+1.41	0.32	2.35	2.6
1983–2013 Pléiades	(-1.4*; 1.6)	(-1.37*; 1.8)	+1.41	+0.42	–	1.83	2.4
1983–2013 DGPS	(-1.4*; 1.6)	(0; 0.6)	+1.41	0	–	1.41	1.7

**Table 5.** Errors in field measurements at specific sites for winter and annual mass balance measurements, based on estimations by Gerbaux et al. (2005). In the case of Ossoue Glacier, we have considered the entire glacier as an ablation zone, which explains the null value associated with the determination of the transition between two consecutive years.

$b_w$ measurements	Errors (in m w.e.)
Determination of surface level	0.1
Determination of transition between two consecutive years	0
Density measurements	0.05
Snow probing	0.2
<hr/>	
Total in $b_w$ measurements	0.35 m w.e.
<hr/>	
$b_{glac.a}$ measurements	Errors (in m w.e.)
Stake emergence measure	0.04
Determination of surface level	0.1
Density measurement	0.01
<hr/>	
Total in $b_{glac.a}$ measurements ( $\sigma_{glac.point}$ )	0.15 m w.e.

## Evolution of Ossoue Glacier (French Pyrenees) since the end of the Little Ice Age

R. Marti et al.

**Table 6.** Annualized threshold values to classify the change in intensity of glaciers indicators. The terms  $\sigma_{\text{len.a}}$ ,  $\sigma_{\text{area.a}}$ ,  $\sigma_{\text{VR.a}}$ ,  $\sigma_{\text{geod.a}}$ , and  $\sigma_{\text{gla.a}}$  refer to the annualized random error calculated for each glacier indicator and each period.

Indicators	Marked Negative	Negative	variations		
			No	Positive	Marked Positive
Length	$\leq -10$ m	$] -10; -\sigma_{\text{len.a}}]$	$\pm\sigma_{\text{len.a}}$	$[+\sigma_{\text{len.a}}; 10[$	$\geq 10$ m
Area	$\leq -1$ ha	$] -1; -\sigma_{\text{area.a}}]$	$\pm\sigma_{\text{area.a}}$	$[+\sigma_{\text{area.a}}; 1[$	$\geq 1$ ha
Elevation change at Villa Russell	$\leq -3$ m	$] -3; -\sigma_{\text{VR.a}}]$	$\pm\sigma_{\text{VR.a}}$	$[+\sigma_{\text{VR.a}}; 3[$	$\geq 3$ m
$B_{\text{geod.a}}$	$\leq -1$ m.w.e.	$] -1; -\sigma_{\text{geod.total.a}}]$	$\pm\sigma_{\text{geod.total.a}}$	$[+\sigma_{\text{geod.total.a}}; 1[$	$\geq 1$ m.w.e.
$B_{\text{glac.a}}$	$\leq -1$ m.w.e.	$] -1; -\sigma_{\text{gla.total.a}}]$	$\pm\sigma_{\text{gla.total.a}}$	$[+\sigma_{\text{gla.total.a}}; 1[$	$\geq 1$ m.w.e.

## Evolution of Ossoue Glacier (French Pyrenees) since the end of the Little Ice Age

R. Marti et al.

**Table 10.** Ossoue Glacier volumetric changes: total ice volume variation ( $\Delta V_{\text{ice}}$  in  $\text{km}^3$ ) and associated mass changes in m.w.e. ( $d = 900 \text{ kg m}^{-3}$  except for 1948–1983 where  $d = 850 \text{ kg m}^{-3}$ ) for an elementary ice-column.  $B_{\text{geod.gla}}$  and  $B_{\text{geod.marg}}$  indicate the geodetic mass balance on the glacier and on the margin, respectively. The last columns refer to the annualized rate and annualized systematic and random errors.

Period (years)	$\Delta V_{\text{ice}}$	$B_{\text{geod.gla}}$	$B_{\text{geod.marg}}$	$B_{\text{geod.error}}$	Annualized rate	$\overline{\epsilon}_{\text{geod.total.a}}$	$\overline{\sigma}_{\text{geod.total.a}}$
1924–1948 (24)	$-0.0324 \text{ km}^3$	-33.5 m.w.e.	-25.5 m.w.e.	8.8 m.w.e.	$-1.39 \text{ m.w.e. yr}^{-1}$	$0.11 + \frac{\epsilon_{\text{bias.1924}}}{24} \text{ m.w.e.}$	0.4 m.w.e.
1948–1983 (35)	$+0.0044 \text{ km}^3$	+5.5 m.w.e.	-7.9 m.w.e.	2.6 m.w.e.	$+0.16 \text{ m.w.e. yr}^{-1}$	0.06 m.w.e.	0.07 m.w.e.
1983–2013 (30)	$-0.0219 \text{ km}^3$	-30.1 m.w.e.	-20.3 m.w.e.	1.7 m.w.e.	$-1 \text{ m.w.e. yr}^{-1}$	0.05 m.w.e.	0.05 m.w.e.

## Evolution of Ossoue Glacier (French Pyrenees) since the end of the Little Ice Age

R. Marti et al.

**Table 11.** Ossoue Glacier mass balance time series measured by glaciological methods (in m.w.e.). Annual error based on field measurements is estimated to be 0.15 m.w.e.  $End_w$  and  $End_s$  refer to the end of winter and the end of summer, respectively, in the floating date system (Cogley et al., 2011).  $B_{glac.c}$  means cumulative glaciological mass balances.

	2002	2003	2004	2005	2006	2007	2008	2009	2010	2011	2012	2013	Mean
$End_w$	30 May	6 Jun.	29 May	28 May	25 May	25 May	6 Jun	30 May	29 May	28 May	26 May	7 Jun	–
$End_s$	3 Oct	27 Sep	10 Oct	25 Sep	8 Oct	20 Oct	12 Oct	12 Oct	9 Oct	9 Oct	14 Oct	6 Oct	–
$B_w$	2.09	3.23	3.55	2.58	1.95	2.66	3.24	3.15	3.01	2.12	2.36	3.79	2.81

**Table 12.** Correlation matrix (Spearman’s  $\rho_s$ ) between the meteorological time series and the Ossoue Glacier mass balances components (calculated in a fixed date system, Cogley et al., 2011). Correlation values given in parenthesis are based on the monthly mean values. Significant correlations ( $p$  values  $< 0.05$ ) are marked with asterisks. The Gavarnie time series was not complete enough to perform the correlations between the annual mass balance and the annual mean temperature and precipitation over 2002–2011; we reported a no data value (ND) in these cases.

Variables Period of record	$B_{\text{glac.a.1 Oct}}$ mass balance 2002–2013	$B_{\text{s.1 Oct}}$ mass balance 2002–2013	$B_{\text{w.31 May}}$ mass balance 2002–2013	Gavarnie 1992–2012	Pic du Midi temperature 1882–2013	CRU 1858–2013	Gavarnie precipitation 1992–2012	Tarbes precipitation 1882–2012
$B_{\text{glac.a.1 Oct}}$	1	0.84*	0.65*	ND	−0.45	−0.74*	ND	0.66*
$B_{\text{s.1 Oct}}$		1	0.2	−0.72* (−0.81*)	−0.52 (−0.74*)	−0.66 (−0.8*)	–	–
$B_{\text{w.31 May}}$			1	ND	−0.35	0.19	0.71*	0.69*

**Table 13.** Trends extracted from correlations between temperature and precipitation time series and time (Spearman's  $\rho$ ). Time structure is based on the interpretation of the glaciological indicators (Fig. 10). Significant correlations ( $p$  values  $< 0.05$ ) are marked with asterisks.

Time structure	Period	$\rho_s$ mean temperature	Mean temperature	$\rho_s$ precipitation	Mean precipitation
1858–1890 (T)	hydrological year	−0.62*	−1.37 °C	0.25	1219.2 mm
1882–1890 (P)	winter	–	–	0.17	577.8 mm
	summer	−0.36	5.3 °C	–	–
1890–1904	h. year	0.09	−1.3 °C	−0.07	1098 mm
	w.			−0.11	548.4 mm
	s.	0.14	4.8 °C	–	–
1905–1927	h. year	0.43	−1.6 °C	−0.42	1102.8 mm
	w.	–	–	−0.05	556.2 mm
	s.	0.15	4.3 °C	–	–
1928–1949	h. year	0.29	−1.2 °C	−0.2	993.6 mm
	w.	–	–	−0.19	492.6 mm
	s.	0.26	5.1 °C	–	–
1950–1982	h. year	0.16	−1.4 °C	0.42*	1068 mm
	w.			0.29	586.2 mm
	s.	0.1	4.8 °C	–	–
1983–2013	h. year	0.38*	−0.4 °C	−0.12	1041.6 mm
	w.			−0.15	567 mm
	s.	0.43*	6.1 °C	–	–

## Evolution of Ossoue Glacier (French Pyrenees) since the end of the Little Ice Age

R. Marti et al.

**Figure 1.** Top: Distribution of the present-day Pyrenean glaciers by mountain massifs: 1. Balaitous; 2. Infierno; 3. Vignemale; 4. Gavarnie-Monte-Perdido; 5. Munia; 6. Posets; 7. Perdiguère; 8. Aneto; 9. Mont-Valier. Bottom: Vignemale Glacieret: 1. Clo de la Hount. Glaciers: 2. Oulettes du Gaube; 3. Petit-Vignemale and Ossoue. Vanished glaciers: 4. Spanish Monferrat; 5. Tapou; 6. French Montferrat. We note that the vanished glaciers were oriented to the southwest and east. Clo de la Hount is northwest-oriented and its area is less than  $0.01 \text{ km}^2$  (2011). North-oriented glaciers Oulettes du Gaube,  $0.13 \text{ km}^2$  (2011), and Petit Vignemale,  $0.03 \text{ km}^2$  (2011), were one unique glacier until 1888 (Reid-Muret, 1906). Coordinate system: UTM  $31^\circ \text{ N}$ .
