Abstract. The El Niño/Southern Oscillation (ENSO) is a major driver of climate variability in the tropical Andes, where recent Niño and Niña events left an observable footprint on glacier mass balance. The nature and strength of the relationship between ENSO and glacier mass balance, however, varies between regions and time periods, leaving several unanswered questions about its exact mechanisms. The starting point of this study is a four-year long time series of distributed surface energy and mass balance (SEB/SMB) calculated using a process-based model driven by observations at Shallap Glacier (Cordillera Blanca, Peru). These data are used to calibrate a regression-based downscaling model that links the local SEB/SMB fluxes to atmospheric reanalysis variables on a monthly basis, allowing an unprecedented quantification of the ENSO influence on the SEB/SMB at climatological time scales (1980–2013, ERA-Interim period). We find a stronger and steadier anti-correlation between Pacific sea surface temperature (SST) and glacier mass balance than previously reported. This relationship is most pronounced during the wet season (December–May) and at low altitudes where Niño (Niña) events are accompanied with a snowfall deficit (excess) and a higher (lower) radiation energy input. We detect a weaker but significant ENSO anti-correlation with total precipitation (Niño dry signal) and positive correlation with the sensible heat flux, but find no ENSO influence on sublimation. Sensitivity analyses comparing several downscaling methods and reanalysis datasets resulted in stable mass balance correlations with Pacific SST but also revealed large uncertainties in computing the mass balance trend of the last decades. The newly introduced open-source downscaling tool can be applied easily to other glaciers in the tropics, opening new research possibilities on even longer time scales.

1 Introduction

The climate of the Cordillera Blanca in the Peruvian Andes is characterized by a wet season from October to April followed by a dry season with little or no precipitation. These dry and wet periods can be modified during El Niño and La Niña events, the *El Niño Southern Oscillation* (ENSO) being an important driver of climate variability in the region (e.g. Garreaud et al., 2009). In this particular setting, the glaciers of the Cordillera Blanca are of great economical, environmental and scientific importance. They are not only important suppliers of fresh-water during the dry periods (e.g. Chevallier et al., 2011), but they also act as sensitive indicators of climate variability and climate change, as evidenced by the glacier shrinkage observed since the Little Ice Age (Kaser et al., 1990; Georges, 2004; Racoviteanu et al., 2008; Schauwecker et al., 2014).

The response of tropical glaciers to climate variations differs from their mid-latitude counterparts (e.g. Kaser, 1999) and has been studied extensively, in Africa (e.g. Kaser et al., 2004; Nicholson et al., 2013) and in South-America (e.g. Hastenrath, 1978; Kaser et al., 1990; Francou et al., 2000 and references herein; see Vuille et al., 2008a and Rabatel et al., 2013 for a review). At low latitudes the annual cycle of temperature is small and humidity becomes an important driver of mass balance seasonality by its control on precipitation, net radiation, and sublimation (Wagnon et al., 1999; Kaser, 2001; Winkler et al., 2009; Sicart et al., 2011). By determining the phase of precipitation and thus the surface albedo, changes in temperature can have a significant impact on mass balance inter-annual variability (e.g. Favier et al., 2004; Gurgiser et al., 2013). The physical basis of tropical glaciers' response to various atmospheric forcings is therefore best studied with process-based models that aim at the full decomposition of the Surface Energy and Mass Balance (SEB/SMB) (e.g. Wagnon et al., 2003; Mölg et al., 2008). Since SEB/SMB models require high quality, high resolution glacio-meteorological observations for calibration and validation, the available time-series are short and unsuitable for long-term studies of glacier-climate interactions.

The starting point of this study is a four-year long time series of distributed SEB/SMB fluxes at Shallap Glacier, Cordillera Blanca, obtained using a process-based model (Gurgiser et al., 2013). Our first objective is to extend the length of these time series while still preserving the advantages of the decomposition into individual SEB/SMB components. The SEB/SMB variability is tied to large scale driven weather conditions, and we hypothesize that by using atmospheric reanalysis data we can compute (downscale) the energy fluxes with sufficient accuracy to determine the atmospheric drivers of SEB/SMB variability on longer time-scales. This hypothesis is the foundation of any empirical statistical retrieval of glacier climatic mass balance (MB), no matter of which complexity.

“Temperature index” or “positive degree day” models (e.g. Braithwaite, 1995; Hock, 2003) are probably the simplest example of seeking statistical relationships between glacier MB and local climate variables (in this case temperature and precipitation). Extensions of temperature-based models include so-called “semi-empirical” models that incorporate further explanatory variables and/or physical processes while still relying on observational data for calibration (e.g. Kaser, 2001; Juen

et al., 2007; Pellicciotti et al., 2008). Another approach is to use observed relations between the MB and atmospheric variables or global circulation indexes in order to build statistical models that predict glacier MB (see Hoinkes, 1968, for a probably very first attempt in this direction). Several variations of this method have been applied to glaciers in Northern Europe (Mernild et al., 2014; Trachsel and Nesje, 2015), northern America (Hodge et al., 1998; Shea and Marshall, 2007) and in the Tropics (Manciati et al., 2014). All these studies use the MB as the predicted variable and do not use the terminology of “downscaling”, that is extensively used in climate research. Statistical downscaling studies that target glaciological applications often focus on one or more meteorological variables at the glacier surface (Hofer et al., 2010, 2012) for use in a subsequent MB model for example (Jarosch et al., 2010; Weidemann et al., 2013).

Here we follow the general idea that, in principle, *any* target variable can be downscaled from large-scale atmospheric fields – as long as there is a physical reason for the local- and large-scale variables to be related (Benestad, 2004; Maraun et al., 2010). We present a new open-source tool (*DownGlacier*) developed especially to retrieve glacier SEB/SMB fluxes from large-scale atmospheric data. Inspired from existing software packages (Wilby et al., 2002; Hessami et al., 2008), it is a semi-automated, regression-based statistical downscaling tool (see Sect. 2.2).

The second and main objective of this study is to quantitatively assess the impact of ENSO on the SEB/SMB of the Shallap Glacier. The influence of ENSO in the tropical and central Andes can be roughly summarized with prevailing warmer and drier conditions during El Niño phases, while colder and wetter conditions prevail during La Niña phases. As a result, studies dealing with ENSO’s influence on tropical Andean glaciers reported a significant anti-correlation between Pacific Sea Surface Temperature Anomalies (SSTA) and MB (Arnaud et al., 2001; Francou et al., 2004; Vuille et al., 2008b; Veetil et al., 2014). The extreme 1997/98 Niño year, for example, caused exceptional glacier melt in the outer tropics (Wagnon et al., 2001; Francou et al., 2003). Favier et al. (2004) advanced that glaciers in the outer and inner tropics react similarly to El Niño events, mainly because of a precipitation deficit in the outer tropics and a temperature increase in the inner tropics, both leading to a rise in snowline altitude.

However, ENSO influences are neither spatially nor temporally coherent, especially in regions of complex terrain between the outer and inner tropics (Vuille and Keimig, 2004; Garreaud et al., 2009). Several studies in the Zongo valley (Bolivia, $\sim 16^\circ$ S; Ronchail and Gallaire, 2006) or in the Cordillera Vilcanota ($\sim 14^\circ$ S; Perry et al., 2014; Salzmann et al., 2013) report less strong or even opposite (“Niño/wet, Niña/dry”) local ENSO effects. The related studies of Kaser et al. (2003) and Vuille et al. (2008b) are the only reports of ENSO influence in the Cordillera Blanca ($\sim 9^\circ$ S) to date. Based on a hydrological reconstruction of glacier MB for the period 1953–1993 (Kaser et al., 2003), they found a significant anti-correlation between annual MB and October to April Pacific SSTA, supporting the expected “Niño \rightarrow negative MB, Niña \rightarrow positive MB” pattern. This relationship

however did not hold true during at least three individual years after the the mid-1970's, leading the
95 authors to conclude that ENSO characteristics may have undergone changes in recent decades.

Here we use *DownGlacier* to retrieve monthly SEB/SMB fluxes at Shallap Glacier from atmo-
spheric reanalysis data. This allows a first time assessment of the influence of ENSO on the individ-
ual components of the SEB/SMB during a longer climatological period (1980–2013). The seasonal
variations of the ENSO signal and its varying impact with altitude will be of particular interest.
100 The rest of the paper is organized as follows. In Sect. 2, we present the study region, describe the
DownGlacier tool and the data used. In Sect. 3, we present the downscaling results for the ablation
area of the glacier where the glacio-meteorological measurements took place. In Sect. 4, we apply
the downscaling procedure to the entire glacier area and discuss the strengths and limitations of our
method. We assess the robustness of our results in Sect. 5 by using several sensitivity analyses. The
105 influence of ENSO will be analysed and discussed for each of these steps before concluding our
study in Sect. 6.

2 Study region, data and methods

2.1 Study region and meteorological data

The Shallap Glacier ($9^{\circ}20' S$, $77^{\circ}20' W$, cf. Fig. 1) lies in the Cordillera Blanca, which hosts nearly
110 a quarter of all tropical glaciers by area (Kaser, 1999). Precipitation in the region is essentially of con-
vective nature and is tied to the moisture originating from the Amazonian Basin (Vuille and Keimig,
2004; Perry et al., 2014). The Andes mountain chain (reaching > 6700 m a.s.l. in the Cordillera
Blanca) divides the wet Amazonian climate in the east from the dry coastal areas in the west (e.g.
Kaser and Osmaston, 2002). The map in Fig. 1 illustrates the control of topography on triggering
115 precipitation and the pronounced changes occurring within short distances.

The Shallap Glacier has been the subject of an intensive field program in recent years. Two auto-
matic weather stations were operated over two distinct and partly overlapping periods: at the glacier
surface (July 2010–September 2012, with several gaps) and on the southern moraine (2002–2009
and July 2011 to February 2012). Here, we used the southern moraine data from October 2005 to
120 September 2009 (longest period with complete data coverage). The *Unidad de Glaciología y Recur-*
sos Hidricos (UGRH) of the Peruvian *Autoridad Nacional de Agua* (ANA) started surface height
change measurements in the ablation zone of the glacier in 2003. From August 2006 to August 2008
(end of data collection), additional measurement points are available (20 ablation stakes in total) with
a reading frequency of 14 to 64 days. The average altitudes of the stake points as measured by the
125 UGRH in August 2006 and August 2009 ranges between 4758 and 4824 m a.s.l. For a geographic
overview of the stations and stakes see Gurgiser et al. (2013) (their Fig. 1).

2.2 DownGlacier

DownGlacier is an open-source tool programmed in the Python language. It relies on the statistical libraries Scikit-learn (Pedregosa et al., 2012) and Statsmodels (Seabold and Perktold, 2010) for the regression models, and adds specific SEB/SMB and uncertainty assessment tools. The project repository (<https://bitbucket.org/fmaussion/downglacier>) contains the source code, some usage examples and all data and scripts used to generate the plots presented in this paper.

2.2.1 Surface energy and mass balance

The function of *DownGlacier* is to compute the glacier SEB equation as resolved by most process-based melt models (e.g. Mölg et al., 2012):

$$SW_{in} + SW_{out} + LW_{in} + LW_{out} + QS + QL + QC + QPS = F \quad (1)$$

where SW_{in} and SW_{out} are the incoming and outgoing shortwave radiation, LW_{in} and LW_{out} the incoming and outgoing longwave radiation, QS and QL the turbulent sensible and latent heat fluxes, QC the conductive heat flux inside snow or ice, and QPS the penetrating shortwave radiation. An energy flux ($W m^{-2}$) has a positive (negative) sign when it induces an energy gain (loss) at the surface. The sum of these fluxes yields a resulting flux F , which represents the available energy for melting QM if the glacier surface temperature is at the melting point ($0^\circ C$). This energy is then converted to melt and added to the other mass fluxes ($kg m^{-2}$) to compute the climatic mass balance MB:

$$MB = PRCP_{Solid} - \underbrace{QM/l_{melt}}_{M_{Melt}} - \underbrace{QL/l_{subli}}_{M_{Subli}} + M_{Subs} \quad (2)$$

where $PRCP_{Solid}$ is solid precipitation, l_{melt} and l_{subli} the latent heats of melting and vaporisation/sublimation/deposition, and M_{Subs} the subsurface mass fluxes (subsurface melt largely due to QPS and refrozen melt water in snow or at the ice surface).

SW_{in} , SW_{out} , LW_{in} , LW_{out} , QS , QL , QC , QPS , $PRCP_{Solid}$, M_{Subs} in Eqs. (1) and (2) are the fluxes that are *downscaled* based on calibration time series provided by the process-based model (see Sect. 2.2.3). The other variables are called *diagnostic variables* and are computed from the downscaled fluxes. Note that Eqs. (1) and (2) are valid at any instant, but not for averaged time periods. To compute the SEB/SMB from monthly averaged fluxes we assume that F is always equal to QM and that l_{subli} is equal to the enthalpy of sublimation (and not vaporisation). The effect of these approximations is generally small and depends on temperature and therefore on altitude (see Appendix A1 for details and Sect. 4 where we present a method to mitigate the errors related to these assumptions).

2.2.2 Downscaling strategy

The purpose of the downscaling procedure is to find a function f such as:

$$160 \quad Y = f(X) + \varepsilon \quad (3)$$

where Y is the variable to be predicted (predictand), $X = X_1, X_2, \dots, X_p$ are the explanatory variables (predictors), and ε is a random error term¹. In principle, the downscaling process is similar to any statistical learning problem (Hastie et al., 2009). The term *downscaling* refers to the fact that, in this case, the predictors X are extracted from large-scale atmospheric data (reanalysis data of atmospheric model output, representative of a large space) and the predicted variables Y are the glacier
165 SEB/SMB fluxes, representative of a local state (Benestad, 2004).

DownGlacier proposes several options to define f but for this study we use the so-called Lasso (“least absolute shrinkage and selection operator”, Tibshirani, 1996) which performed best in our cross-validation tests. The Lasso is a shrinkage method developed to overcome some of the problems
170 of least-squares regression such as over-fitting and the high sensitivity to the predictor subset. By penalizing the fitting of the regression coefficients by a factor λ , it shrinks some coefficients and sets others to zero (Tibshirani, 1996; Hastie et al., 2009). The resulting model is still a linear combination of multiple predictors (as for stepwise regression), but the chosen coefficients are not the same as with standard least-squares. Lasso is widely used in statistical learning problems across disciplines
175 but it is not (yet) used much in climate downscaling studies despite of encouraging results (e.g. Hammami et al., 2012; Gao et al., 2014). Due to the novelty of this approach in a glaciological context, we provide more elements about Lasso in Appendix A2.

2.2.3 Calibration SEB/SMB data

The SEB/SMB data used to calibrate and validate the downscaling model was generated using an
180 updated version of the process-based model developed and described by Mölg et al. (2008, 2009, 2012) previously applied at Shallap glacier by Gurgiser et al. (2013). Air temperature, humidity, wind speed, global radiation and total precipitation measured at the southern glacier moraine serve as model input for the period October 2005 to September 2009. The model calculates the SEB/SMB as formulated in Eqs. (1) and (2) at hourly time steps and for the entire glacier surface on a 50 m × 50 m
185 grid.

The distributed SEB/SMB time series are aggregated to monthly values and averaged spatially over altitude slices of 50 m height (the altitude slice at 4750 m a.s.l. for example being the average of the grid points in the 4750–4800 m range). The uncertainty associated with this reference data has to be assessed independently using the measurements at the ablation stakes: the annual RMSE of
190 the reference MB was estimated to 0.76 m w.e. (water equivalent) for the year 2007 and 0.88 m w.e.

¹ ε comprises an *irreducible* error (the part of variability in Y which cannot be explained by X) and a *reducible* error (originating from the error made when approximating f).

for the year 2008. We kept the more conservative estimate of 0.88 m w.e. and scaled it by a factor of $1/\sqrt{12}$ (following the normality assumption) to obtain a monthly RMSE of 0.25 m w.e. month⁻¹. This value will be taken into account and added to the downscaling error when analysing our results at 4750 m a.s.l. (where most ablation stakes are located). For other altitudes and for the intermediate
195 SEB variables no uncertainty assessment can be realized: this is discussed in more detail in Sect. 4.

2.2.4 Atmospheric predictors

The selection of the predictor set is crucial for the accuracy and stability of the downscaled time series (e.g. Maraun et al., 2010; Fowler et al., 2007; Sauter and Venema, 2011). For this study, we chose to select the predictors out of the nearest grid point of the atmospheric reanalysis dataset,
200 which is a common approach in downscaling studies (e.g. Gutiérrez et al., 2013; Hofer et al., 2012, 2015). It prevents dubious correlations with remote indices and ensures that the local glacier features are indeed related to the local atmospheric state (from the coarse dataset perspective). Another more practical advantage of this procedure is its systematic and objective aspect.

In a first step, we chose to use ERA-Interim reanalysis data (Dee et al., 2011) provided by the
205 European Centre for Medium-range Weather Forecasts (ECMWF), which proved to be most accurate for downscaling purposes in the region (Hofer et al., 2012). We chose to follow a similar approach as in Hofer et al. (2012) and previously smoothed the ERA-interim fields using a spatial gaussian filter with $\sigma = 1$ (approximately a 3×3 box average), reducing the noise related to arbitrary choice of the nearest grid-point. The starting predictor set consists of 27 predictors at the surface and at selected
210 pressure levels in the atmosphere (Table 1). The sensitivity of our results on the chosen predictor set and the reanalysis dataset is assessed in Sects. 5.2 and 5.3.

2.2.5 Uncertainty analysis

The uncertainty associated with our method has two major sources: the calibration of the SEB/SMB time series (see Sect. 2.2.3) and the downscaling procedure itself. To a certain extent, the later can
215 be assessed using cross-validation (e.g. Michaelsen, 1987). Here we use a variant of the leave-one-out cross-validation in which a five-elements window is removed iteratively from the calibration set. The model selection and calibration procedure is repeated 48 times (one for each month), providing new “penalized” time series obtained by 48 different models, each of them unaware of the 5 months period surrounding each data point. The period of ± 2 months was chosen based on the predictands
220 properties: the lag-3 autocorrelation values of the predictands at 4750 m a.s.l. were all close to 0, the highest being M_{Subs} with an r^2 of 0.08. Refer to Appendix A3 for more details about the cross-validation procedure.

For the evaluation of the model skill we used standard metrics computed from the cross-validation: coefficient of determination r^2 , root mean square error RMSE, and the Brier Skill Score BSS, defined

225 as:

$$\text{BSS} = 1 - \frac{\text{MSE}_{\text{ds}}}{\text{MSE}_{\text{ref}}} \quad (4)$$

with MSE_{ds} and MSE_{ref} being the mean square error of the downscaling and of the reference model, respectively. The reference model is the leave-one-out monthly average of the calibration time series (i.e. the value for June 2007 is the average of the June values in 2006, 2008 and 2009). A positive
230 BSS evaluates the capacity of the downscaling model to make better predictions than taking the “climatology” (a perfect model having a BSS of 1).

2.3 ENSO classification

For the ENSO events classification we use the sea surface temperature anomalies (SSTA, relative to the base period 1981–2010) in the Niño 3.4 region obtained from the National Oceanic and At-
235 mospheric Administration (NOAA) Climate Prediction Center (CPC). We follow the classification recommended by Trenberth (1997): El Niño (La Niña) occurs if the 5 month running average of Niño 3.4 SSTA exceeds 0.4 K (falls below -0.4 K) for 6 months or more (Fig. 2). This results in 192 neutral (47%), 95 Niño (23%) and 121 Niña months (30%). The same index was also chosen by Vuille et al. (2008b) and Francou et al. (2004) for similar purposes. In addition, we shifted the
240 SSTA time series by three months (as suggested by Francou et al. (2004) and confirmed by our own correlation analyses) to account for the lagged response of the MB anomalies at Shallap glacier. We assess the sensitivity of our results to the choice of other ENSO indexes and lag values in Sect. 5.4.

3 Results

Shallap Glacier spans the altitude range 4700–5800 m a.s.l. We first present the results of the down-
245 scaling at the 4750–4800 m a.s.l. altitude slice which is located in the ablation area of the glacier. Here we have the highest confidence in the calibration time series and in their uncertainty estimates. From now on we use the term “year” as replacement for “hydrological years” (1998 for example referring to the period October 1997 to September 1998). For simplicity, we refer to the 4750–4800 m a.s.l. altitude slice with the shorter “4750 m a.s.l.” and add a ₄₇₅₀ subscript to the MB
250 variable name wherever judged necessary to avoid ambiguities.

3.1 Downscaling results

3.1.1 Validation

A summary of the cross-validation results is presented in Table 2. All downscaled variables have a positive BSS, the highest (0.81) for Temp and the lowest (0.21) for $\text{PRCP}_{\text{Total}}$. The most deter-
255 minant variables for MB_{4750} are the short-wave variables SW_{in} and SW_{out} as well as $\text{PRCP}_{\text{Solid}}$. Their scores are generally lower than those of other variables but they are satisfying considering the

complex nature of the precipitation and surface albedo processes. We discuss the conditions for the successful downscaling of SW_{out} in Sect. 4.

260 The example of $PRCP_{Total}$ illustrates the importance of considering all scores when assessing the model results. $RMSE_{\sigma}$ of $PRCP_{Total}$ is lower than that of $PRCP_{Solid}$, meaning that the model is working satisfyingly. However, the inter-annual variability of $PRCP_{Total}$ is smaller and results in an efficient reference model that penalises the BSS. $PRCP_{Solid}$, in turn, has a higher inter-annual variability (tied to the temperature variations, see Fig. 3) better caught by the downscaling model than by the reference climatology.

265 Figure 3 shows a comparison between the reference and modelled time series of Temp, SW_{net} , $PRCP_{Solid}$ and MB_{4750} . As expected, the full-model time series are closer to the reference than the cross-validation time series. However, the differences between the two are small, which indicates that the chosen predictors and their coefficients are stable regardless of the calibration period. The inter-annual variability is well caught by the model: the MB_{4750} of the two last years is less negative
270 due to lower air temperatures, higher snowfall and lower short-wave radiation input, for both the reference and the downscaled model. This raises a question: are the downscaled variables consistent with the glacier surface processes and can we interpret them in the same way as we would do it with a physical model?

3.1.2 Physical consistency of the downscaled variables

275 Albedo (ratio SW_{out}/SW_{in}) for example is strongly related to solid precipitation (Fig. 4e). The downscaled fields reproduce the expected relationship and the spread (related to other factors such as snowfall frequency) but some issues arise: in rare cases (6%) the downscaled precipitation is slightly negative and for two cases the albedo is close to the high value of 1. This is due to the linear nature of the downscaling algorithm and is a known issue of statistical models, which are not aware of the
280 physical properties of the downscaled variables. In *DownGlacier* the precipitation values are clipped to zero but we decided to leave the short-wave variables unchanged, since the occurrence of extreme low/high albedo are rare and correspond to a realistic atmospheric forcing (low/high solid precipitation). For other expected relationships such as the relation between the turbulent fluxes QS and QL with wind-speed and vapour pressure (Fig. 4a and c), the downscaling produces realistic fields as
285 well. Since monthly air temperature is always close to 0° and therefore close to the surface temperature, the sensible heat flux is more dependent on wind speed than on air temperature (Fig. 4d). The latent heat flux is also well correlated with wind speed (Fig. 4e), but this is also due to the peculiar conditions at Shallap glacier, where wind speed and vapor pressure are well correlated (not shown).

The physical consistency of the MB with the downscaled fluxes is ensured by the computation
290 of the SEB/SMB budget (Eqs. 1 and 2) and is an advantage of *DownGlacier* over other approaches downscaling the MB only. Interestingly, the direct downscaling of MB_{4750} is slightly less accurate than the diagnostic method (BSS of 0.65 instead of 0.69) but we obtain a downscaled MB_{Down}

extremely close to the diagnostic MB_{Diag} (Fig. 4f). Two reasons can explain this encouraging result. First, while the SEB/SMB equations are additive in nature, the non-linear processes are resolved
295 beforehand by the process-based model and then mimicked by the downscaling procedure. Second, this result can be seen as an implicit confirmation that the downscaling procedure has “caught” all the SEB/SMB variability that can be explained by the large scale atmospheric fields. The remaining uncertainty is related either to missing information and errors in the large-scale atmospheric data or to the simplifying nature of the downscaling functions. In Appendix A4, we describe these functions
300 and discuss their interpretation.

3.2 Influence of ENSO on the SEB/SMB fluxes

The downscaled monthly MB_{4750} is mostly negative for the period 1980–2013 and displays a pronounced intra- and inter-annual variability (Fig. 5). A few months have a positive MB_{4750} , all of them occurring during Niña periods. Inversely, the most negative events occur during Niño periods.
305 We will now investigate if we can detect a systematic pattern by building composites of the Niño and Niña periods.

3.2.1 Niño/Niña composites

The annual cycles of MB_{4750} , temperature, snowfall and total precipitation for each of the seven Niña and eight Niño periods are shown in Fig. 6. Despite of a large spread between individual
310 years we distinguish a clear signal with below (above) average MB_{4750} during Niño (Niña) periods, confirming the findings of previous studies (e.g. Francou et al., 2004; Favier et al., 2004; Vuille et al., 2008b). The largest differences between Niño and Niña occur between December and May, although the ENSO signal remains visible towards the end of the year for both MB_{4750} and temperature. Temperature displays a larger spread for Niño than for Niña years, with temperature anomalies up to
315 +2 K for extreme months. We also distinguish a Niño → dry/Niña → wet signal in total precipitation during the wet season but it is less pronounced, with at least two wetter than average Niño years. Snowfall displays a clearer tendency, all Niña years being above the average from December to May and several Niño years having almost no snowfall at 4750 m a.s.l. during the same period. Due to this large spread it would be difficult to define a “typical” Niño or Niña period. In fact, our attempts
320 to go beyond the visual interpretation by testing the statistical significance of these differences were unfruitful because of the large standard deviation between years, the small number of composites, and the variables’ RMSEs.

As for most glaciers, the energy budget at the ablation area of Shallap is dominated by the radiation fluxes (Fig. 7). The annual cycle of the energy budget is rather flat with an average annual energy
325 gain of $\sim 60 \text{ W m}^{-2}$. The minimum of SW_{Net} in February/March is combined with a smaller energy loss by LW_{Net} , while during the dry season LW_{Net} and QL inversely compensate the high SW_{Net} . The turbulent fluxes are more important during the dry season, the sensible (latent) flux being constantly

positive (negative) throughout the year. The resulting SMB cycle follows a bimodal pattern: the first peak (less negative MB_{4750}) in February is due to a combined effect of a smaller energy gain and a maximum of accumulation, while the second peak in July is related to the stronger energy sink by QL.

The composites presented on the right panel of Fig. 7 (note the different y axis ranges) provide useful information about the factors that possibly control the differences between Niño and Niña periods. The differences in SEB are overwhelmingly dominated by the short-wave balance, the other fluxes playing a smaller role (higher energy loss by LW_{Net} in January/February of Niño years, smaller energy loss from April to June by QL). The increase in SW_{Net} is directly related to a snowfall deficit, mostly between December and May. At least in the ablation zone of the glacier, the picture seems unequivocally following the pattern described for other tropical Andes glaciers (e.g. Favier et al., 2004).

3.2.2 Inter-annual variability

The individual Niña and especially Niño years are highly variable regarding their signal on MB_{4750} since the events differ in strength, but how well is the Pacific SST related to MB_{4750} ? Figure 8 displays the annual averages of MB_{4750} and of Niño 3.4 SSTA. The relationship is striking throughout most of the period with a coefficient of determination of $r^2 = 0.8$ ($p \ll 10^{-5}$) which reduces to $r^2 = 0.67 \pm 0.06$ ($p \ll 10^{-5}$) when taking the RMSE into account². The latter figure is more realistic because the downscaled MB_{4750} represents the *deterministic* part of the “real” MB_{4750} : local and random processes which are not caught by the downscaling procedure are more likely to weaken the relationship than enhance it. We distinguish two periods with a slightly weakened relationship: 1991–1995 and 2002–2005, which are the exact same periods described by Rabatel et al. (2013) (their Fig. 9) or by Kaser et al. (2003) (their Fig. 9, for 1991–1995).

4 Distributed SEB/SMB: exploring the potential and limitations of the procedure

In the previous section we limited our analyses to 4750 m a.s.l. where the accuracy of the reference SEB/SMB model could be assessed thoroughly using external data (ablation stakes), leading to a robust error assessment of the entire modelling chain. Using *DownGlacier* for the entire glacier is straightforward, at least in practice: the distributed SEB/SMB data is averaged over altitude slices of a fixed range (here 50 m, see Sect. 2.2.3) and each variable/slice is downscaled independently. The cross-validation scores are computed in the same way (Fig. 9). The scores of $PRCP_{Solid}$ and LW_{Net} are stable for all altitudes ($PRCP_{Solid}$ is getting closer to $PRCP_{Total}$ as temperature lowers). The score of SW_{Net} , however, is highly variable and determines the accuracy of MB at lower altitudes where it is the largest energy input. In the 4800–4900 altitude range the capacity to downscale

²Mean and standard deviation of r^2 computed from 10 000 random realisations of $MB_{4750} \pm RMSE$.

SW_{Net} worsens with a maximum $RMSE_{\sigma} = 0.83$ (the reasons for this low accuracy are discussed below). After 5000 m a.s.l., SW_{Net} becomes less relevant for the energy budget and has less impact on the model skill. The BSS scores are low at high altitudes due to uncertainties in the estimation of the energy available for melting (QM). To address this issue, we can introduce a correction factor c which guarantees that the average downscaled QM is equal to the average calibration QM. The usage of this factor can also be cross-validated (MB_{Cor} in Fig. 9): it has a positive impact from 4950 m a.s.l upwards, and is particularly efficient at high altitudes. However, it has a negative impact at low altitudes where it constrains the variability of the model. Altogether, this correction factor has only a very small impact on our conclusions and we decided to use the non-corrected time series for further analyses.

Figure 10 shows that the negative BSS at 5450 m a.s.l. is related to exceptional errors during the dry season where unrealistic negative MB is predicted for a few isolated months, an issue that is strongly reduced when using MB_{Cor} (not shown). At 5700 m a.s.l. the problem is weaker and the predictions are satisfying. At ~ 4850 m a.s.l. however we reach the limits of the downscaling procedure: abrupt MB variations from one month to another are not reproduced and the model's attempts to catch those result in bad predictions for the second half of the period. These jumps from positive to highly negative values are directly related to the surface conditions of the glacier: snow cover is a function of previous snowfall and melt, information which is not available in the reanalysis data. Our efforts to account for this monthly persistence by including lagged predictors were unsuccessful: increasing the number of predictors also increased the noise, and it is probable that the linear nature of the Lasso method is not able to cope for these complex effects.

The conditions for the successful downscaling of SW_{Net} are found for example at 4750 m a.s.l. where snowfall and melt occur within days, or at higher altitudes when there is a permanent snow cover. It is therefore probable that the current version of *DownGlacier* will perform poorly on e.g. mid-latitudes glaciers, where persistent effects can be determinant for the annual MB (e.g. Mölg et al., 2013, , who showed that spring snowfall conditions on a Tibetan glacier regulate the entire annual mass-balance due to the albedo feedback). In these cases the purely statistical approach used here should be complemented by physical albedo models.

The altitudes between 4850 and 4950 m a.s.l. with the highest RMSE represent approx. 20% of the glacier area and are responsible for most uncertainties of the MB variability³. Despite of these errors occurring around the location of the equilibrium line, the MB averaged over the entire glacier (specific MB) is well predicted by the model ($RMSE_{\sigma}$ of 0.5 and BSS of 0.64, time series in Fig. 10). The reasons for these good scores are the reliable downscaling in the lower parts of the glacier (which account for the majority of the mass loss) and of the accumulation processes in the upper parts.

³These errors however have no systematic impact on the average specific MB, thanks to the property of statistical models to preserve the mean.

395 These encouraging results call for an analysis of the model’s glacier-wide predictions for 1980–
 2013, presented in Fig. 11. We arbitrarily multiplied the cross-validation RMSE by a factor 2 to
 account for unknown errors in the upper parts. We see that the SSTA → MB relationship is less
 strong for the glacier average, with a deterministic correlation of $r^2 = 0.51$ ($p < 10^{-5}$) diminishing
 to $r^2 = 0.38 \pm 0.08$ ($p < 10^{-3}$) when taking the RMSE into account. These values are lower than
 400 at the 4750 m a.s.l. altitude, and are closer to the correlation values found by Vuille et al. (2008b).
 As for most tropical glaciers (Kaser and Osmaston, 2002), Shallap glacier has large accumulation
 areas where precipitation falls as snow most of the time. Total precipitation is less sensitive to ENSO
 events than temperature: at 4750 m a.s.l. the deterministic correlation of snowfall with Pacific SSTA
 is $r^2 = 0.75$ ($p < 10^{-5}$) while it is 0.39 ($p < 10^{-3}$) for total precipitation.

405 5 Sensitivity analyses

We test the robustness of our conclusions by presenting the results of a series of sensitivity experi-
 ments grouped in three categories: downscaling method, predictor set and reanalysis data (Table 3
 and Fig. 12). In a fourth experiment we analyse the sensitivity of our results to the choice of the
 ENSO index and lag value.

410 5.1 Sensitivity to the downscaling method

In this study we have used the Lasso, but other traditional regression methods include stepwise
 regression or principle component regression (e.g. Wilby et al., 2002; Hessami et al., 2008). We test
 several variants:

- $S_{P_{cor}}$: after an iterative selection, all predictors have a partial correlation significant at the
 415 $p = 0.01$ value.
- S_{RMSE} : predictors are added and removed until the inner cross-validation RMSE reaches
 a minimum.
- S_{PC} : same as $S_{P_{cor}}$ but run with the 11 most important principle components (explaining 98 %
 of the total variance).
- 420 – L_{8fold} : same as the standard run (Lasso) but with the λ parameter selection based on 8-fold
 cross-validation (instead of 4-fold).

All methods have a lower skill than the reference run (Table 3), with an increase of the RMSE
 by about 20 % for S_{RMSE} or $S_{P_{cor}}$ and up to 33 % for S_{PC} . As shown by the correlation values and
 the time series in Fig. 12, the sensitivity of the results to the chosen method is marginal with respect
 425 to the MB_{4750} variability (with the exception of the principle components regression which shows
 a different trend and smaller variability). The Lasso is only weakly sensitive to the method chosen

to select the penalization parameter. Stepwise regression methods show a stronger sensitivity to the choice of the stopping rule, such as the significance of the partial correlation (not shown).

5.2 Sensitivity to the predictor choice

430 We run five experiments with another predictor set. Predictors were either removed (temperature, relative humidity or surface variables), changed (pressure levels) or added (with a lag of one month). Here again, all experiments result in lower downscaling skill but lead to similar conclusions. Surprisingly, omitting temperature has the smallest effect on the model skill and has only a relative impact on the correlation with SST. This means that large parts of the temperature signal can be
435 found in the other predictors. This is not the case with relative humidity: omitting this predictor has the strongest negative impact on the prediction skill. Further predictor denial experiments lead to inefficient models and are not shown here.

The Lag₁ experiment is particularly instructive with respect to the skill of the downscaling procedure: doubling the number of predictors by adding the lagged ones results in a lower out of sample
440 cross-validation skill by increasing the noise and the chance for Lasso to select false-positive predictors. This is more likely to occur with short calibration periods and might also be one of the reasons for the increase of RMSE of 15 % when changing the predictor pressure levels (hPa experiment). Indeed, it is possible that the MB₄₇₅₀ variability is more related to the levels chosen for the reference run (350, 450, 550 and 650 hPa) than the new ones, but it is more likely that the hPa experiment
445 increased the noise and made the job for the Lasso more difficult.

5.3 Sensitivity to the reanalysis choice

Several studies (e.g. Brands et al., 2012; Hofer et al., 2012, 2015) have discussed the sensitivity of the downscaling results to the choice of the reanalysis products used for calibration. Here we test three additional datasets chosen for their historical significance (NCEP/NCAR R1) or for their
450 relative novelty and sophistication (ERA-Interim, MERRA and CFSR)⁴:

- NCEP: NCEP/NCAR R1 reanalysis (Kalnay et al., 1996) belongs to the most widely used reanalysis datasets. It is of coarser resolution (2.5°) and is one of the oldest systems still operating to date.
- MERRA: Modern Era Retrospective- Analysis for Research and Applications reanalysis from
455 the NASA (Rienecker et al., 2011) is of higher resolution (0.5°) and belongs to the so-called “third generation” of reanalysis products (including ERA-Interim and CFSR).
- CFSR: NCEP Climate Forecast System Reanalysis (Saha et al., 2010), also of higher resolution (0.5°).

⁴Refer to the acknowledgements for data access and acronym description.

The sensitivity of the downscaling to the various reanalysis datasets is larger than to the other
460 experiments (Table 3). The three most recent reanalyses have comparably higher skills than NCEP,
and CFSR shows the highest skill overall (higher than the reference run). Unlike for the other ex-
periments, the differences in skill are accompanied with differences in trends and correlations with
Pacific SST. As shown in Fig. 12, the time series still display a strong covariability but disagree for
certain years (e.g. 1985, 2010). The low correlation of NCEP with SST is attributed to a smaller
465 variability and a lower accuracy, while the lower correlation of CFSR is quite unexpected. Overall,
the most striking differences concern the trends of the time series, from negative for MERRA and
CFSR to statistically insignificant for ERA and NCEP. Looking for the reasons of these disagree-
ments is beyond the scope of this study, but we can learn from this analysis that if the ENSO \rightarrow
MB₄₇₅₀ relationship is quite stable regardless of the method and data used, it is less the case for
470 trends or for the predicted absolute MB₄₇₅₀. In Appendix A5, we use NCEP/NCAR R1 to analyse
the relationship for the longer period 1950–2013.

5.4 Sensitivity to the ENSO index

In this study we used the Niño 3.4 index which is widely acknowledged as a good indicator for
ENSO variations (e.g. Trenberth, 1997) and was also used by Vuille et al. (2008b) for their study in
475 the Cordillera Blanca. However, other studies found that the Niño 1+2 index had a higher predictive
skill for Chacaltaya Glacier’s MB in the outer tropics (Francou et al., 2003; Rabatel et al., 2013,
with a lag of 2 and 4 months, respectively). Recently, the Multivariate ENSO Index (MEI, Wolter
and Timlin, 2011) was presented as alternative to the purely SST based indices such as Niño 3.4.
In Table 4, we test if our results at 4750 m a.s.l. are sensitive to a change to the Niño 1+2 and MEI
480 indices. It appears that Niño 3.4 and MEI both have very high correlations with MB₄₇₅₀, with a
maximum at lag 2 and 3, respectively (which was to expect since both indexes are highly covariable
during the study period). The Niño 1+2 however has a lower predictive skill, which maximises
at lag 2. Most of these differences, however, are not significant in comparison to the uncertainty
estimates of our computed MB.

485 6 Summary and discussion

Based on four years of distributed SEB/SMB at Shallap glacier, we calibrated a statistical model
linking each individual SEB/SMB flux to local atmospheric variables extracted from reanalysis data.
We presented a new open-source tool developed for this purpose and applied it first to the abla-
tion area and then to the entire glacier surface. The downscaled time series (1980–2013) revealed
490 a strong ENSO footprint on glacier MB, a result consolidated by subsequent sensitivity analyses. If
individual Niño and Niña years can vary in intensity, the control of Pacific SSTA on MB appears to
be constant throughout the period as shown by the significant anti-correlation between annual MB

and Niño 3.4 SSTA. The mechanisms of this control could be quantified thanks to the decomposition of the SEB/SMB into individual fluxes (a summary of the SSTA ↔ SEB/SMB correlations is provided in Fig. 13). Niño (Niña) events imply an increase (decrease) of air temperature leading to a higher (lower) snowfall altitude and thus to an increase (decrease) of the net short wave radiation supply. This effect is enhanced by a further precipitation deficit (excess) during Niño (Niña) years. The influence of ENSO is therefore stronger at lower altitudes but it remains detectable at higher elevations through changes in total precipitation. We find a small influence of ENSO on the sensible heat flux but no significant influence on net long-wave radiation or sublimation.

Our results are in accordance with our current understanding of the ENSO/glacier relationship in the Central and Tropical Andes (e.g. Arnaud et al., 2001; Favier et al., 2004; Francou et al., 2004; Vuille et al., 2008b; Veettil et al., 2014). However, we find a stronger SSTA → MB relationship than described in Vuille et al. (2008b) and cannot confirm their exceptional years (1983 and 1994). This discrepancy could be explained by the different methods used to retrieve the MB, but it is likely that the relationship is also modified by regional and altitudinal differences: Vuille et al. (2008b) analysed the MB for the sum of several glacierized catchments of the western part of the Cordillera Blanca, while our results are valid for Shallap glacier only. If ENSO's influence on temperature is regionally stable in the Andes, its influence on precipitation is less known and highly variable. A recent study by Perry et al. (2014) found a Niño/wet signal in the Cordillera Vilcanota south of the Cordillera Blanca which, if confirmed, could counterbalance the albedo effect described here. A bit further south, Ronchail and Gallaire (2006) reported opposite ENSO effects within short distances, with a Niña/dry signal in the Zongo valley lowlands and a Niña/wet signal on the higher Altiplano. While our study aimed at identifying the ENSO footprint on glacier MB, future studies should focus on the atmospheric mechanisms of this relationship and assess its latitudinal and altitudinal stability.

A major source of uncertainty in our method is the short period available for calibration, preventing us to develop more sophisticated models (for example including distant predictors or seasonally dependant downscaling functions). Fortunately, the four years used here are dynamically variable and contain neutral and Niña periods, as well as a few months with SSTA above the Niño threshold. Our uncertainty estimates computed with cross-validation are robust, but they remain high and prevent more detailed analyses of individual events. In particular, the sensitivity analyses showed that if the MB variability is persistent between the experiments, the absolute values and trends can vary considerably. This is especially the case when changing the reanalysis products, an issue that should be kept in mind when carrying out long-term glacier modelling studies.

Nevertheless, *DownGlacier* proved to be a versatile and efficient tool to extend existing SEB/SMB series in time, provided that there are no persistence effects or heavy auto-correlation in the calibration time series. These conditions are met for monthly values in the tropics, where we expect *DownGlacier* to bring helpful insights on decadal to centennial glacier variability. For mid-latitude glaciers covered with seasonal snowpack it will be necessary to include non-linear and persistent

530 effects (for example by adding surface albedo parameterizations). The major obstacle to such enhancements is the lack of long and reliable SEB/SMB time series for calibration: here, combined statistical and dynamical approaches might help to complement the otherwise irreplaceable glacio-meteorological observations.

Appendix A

535 A1 Solving the SEB/SMB equations on monthly averages

On monthly averages, the ice surface is practically never at the melting point and the equality $F = QM$ does not hold true. *DownGlacier* implements a simple test to assess this error: in a “perfect downscaling” experiment, the downscaled variables (bold in Eqs. 1 and 2) are set to their calibration values and the skill of the diagnostic variables is assessed using the usual statistical scores that show
 540 the error related to the averaging only. Figure A1 displays the $RMSE_{\sigma}$ of the perfect downscaling experiment for all altitude slices of the glacier along with monthly air temperature. For most parts of the glacier the error is close to 1 % but reaches 14 % at the 5000 m a.s.l. altitude slice where the air temperature is closest to 0 °C. For conditions close to the melting point a substantial part of the energy residual F will not be converted to melt but will heat the ice. At colder temperatures, F will
 545 be close to 0 and less relevant. This error is small in comparison to the other uncertainties of the method (see Sect. 4) and is negligible at the altitude of 4750 m a.s.l.

A2 The Lasso

Extensive treatment of the Lasso method can be found in Tibshirani (1996) and in statistical textbooks (e.g. Hastie et al., 2009). Here we provide some elements about basic principles of the method.
 550 First, we recall that for a multiple linear regression problem with p predictors the objective is to find the parameters $\beta_0 \dots \beta_p$ such as:

$$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_p X_p \quad (A1)$$

Where Y is the variable to predict (vector of n observations $y_1 \dots y_n$) and $X_1 \dots X_p$ are the predictor vectors (also of length n). The free parameters $\beta_0 \dots \beta_p$ are usually fitted by minimizing the
 555 residual sum of squares RSS:

$$RSS = \sum_{i=1}^n \left(y_i - \beta_0 - \sum_{j=1}^p \beta_j x_{ij} \right)^2 \quad (A2)$$

This method becomes unstable when the predictors are collinear (anti-correlated predictors will lead to very high parameter estimates) and is subject to over-fitting when p becomes large. The role of stepwise regression algorithms is to select meaningful predictors in order to keep p small
 560 and prevent these problems. The Lasso, in turn, can fit a model containing all original p predictors

(thus generalizing the predictor selection problem) using a technique that constrains the coefficient estimates by minimizing the quantity:

$$\sum_{i=1}^n \left(y_i - \beta_0 - \sum_{j=1}^p \beta_j x_{ij} \right)^2 + \lambda \sum_{j=1}^p |\beta_j| = \text{RSS} + \lambda \sum_{j=1}^p |\beta_j| \quad (\text{A3})$$

where $\lambda \geq 0$ is a penalization coefficient which has to be determined separately. This penalization
 565 has the advantage to prevent over-fitting by shrinking the coefficients and to force some of the coefficients to be equal to zero (predictor *selection*) when λ is large. λ is usually chosen among an ensemble of predefined values which are tested one by one: the value leading to the smallest cross-validation RMSE is selected⁵.

The advantage of Lasso over stepwise regression is shown by our sensitivity analyses (Sect. 5)
 570 and is also illustrated in Fig. A2 (see next Appendix for details). The improvements over the other methods is not overwhelming in this case but Lasso proved to be much more stable (and fast) in the early exploration stages of this study, when we considered many different predictor combinations. With very large p , stepwise regression showed high variance and high sensitivity to the predictor set (low out-of-sample cross-validation scores) while Lasso remained robust.

575 A3 Cross-validation

The principle of cross-validation is to hide information to the statistical model by calibrating it with a smaller subset of the data and testing its predictions against the remaining (unseen) subset. *DownGlacier* realizes two automatic steps to choose the downscaling function f : *selection* (s) and *calibration* (c). In the case of Lasso, (s) consists of choosing the penalization parameter λ using in-sample cross-validation and (c) consists of fitting the penalized coefficients. In the case of
 580 stepwise regression, (s) consists of choosing a subset of the predictors and (c) consists of fitting the least-square coefficients. As discussed early by e.g. Elsner and Schmertmann (1994), it is crucial to evaluate both steps (s) and (c) in the cross-validation procedure.

The need for out-of-sample cross-validation is not always obvious (when model selection is based
 585 on partial-correlation for example) even if all automated predictor selection methods should be cross-validated. The following way to select the predictors is more obvious: the predictors might be added and removed iteratively for their capacity to reduce the cross-validation RMSE. We provide an example of using this stepwise algorithm in Fig. A2, which displays the scores of three different validation steps: full model (selection s and fit f based on all available data), cross-validation (selected only
 590 once based on all available data but fitted 48 times using cross-validation) and out-of-sample cross-validation (selected and fitted 48 times using cross-validation). We see that the algorithm is able to reach “better” cross-validation scores than the Lasso. However, several of the predictors chosen

⁵*DownGlacier* uses the coordinate-descent algorithm implemented by Scikit-learn, with a 4-fold cross-validation.

by the algorithm are very likely to be added by chance rather than for their real predictive skill, as shown by the out-of-sample cross-validation scores.

595 **A4 Interpretation of the downscaling functions**

The number of predictors selected by the Lasso varies between 7 and 17 (Table 2), which is larger than the number of predictors we would obtain with stepwise regression algorithms. Indeed, the Lasso might choose a linear combination of correlated predictors instead of a single predictor with less predictive skill, by shrinking less significant coefficients to values close to zero. Table A1
600 presents the six most important predictors and their coefficients (normalized in %) for each down-
scaled variable. Some of the functions allow a direct and meaningful interpretation: LW_{in} for exam-
ple is strongly related to relative humidity. It is also coherent that higher temperatures imply a more
negative LW_{out} . Similarly, the first two predictors of QS are wind components, and QL is controlled
by relative humidity to a large extent. $PRCP_{Total}$ is a function of relative humidity and total cloud
605 cover and is also inversely proportional to the zonal wind flow at 650 hPa, which is consistent
with the assumption that most of the moisture in the Cordillera Blanca originates from the Amazon
Basin. We should however not over-interpret these functions, as shown by some unexpected results
(e.g. $prcp_{sfc}$ positively correlated to SW_{in}). Covariability (positive and negative) between predictors
confuses the interpretation, and choosing another predictor set can produce very similar predictions
610 despite of distinct downscaling functions (see Sect. 5.2).

A5 Relationship between SSTA and MB for 1951–2013

The NCEP/NCAR R1 products are available from 1948 onwards and the SSTA data from 1950 on-
wards, allowing us to analyse the $SSTA \rightarrow MB_{4750}$ relationship for the period 1951–2013 (Fig. A5).
In general, the downscaled MB_{4750} does not correlate as well with NCEP/NCAR R1 as it does
615 with other reanalysis products (Table3). The relation is clear throughout the 60 years but with lower
correlations values for the 1951–1980 period (“deterministic” r^2 , i.e. without RMSE and without
detrrending):

- 1951–2013: $r^2 = 0.45$ ($p < 10^{-5}$)
- 1981–2013: $r^2 = 0.56$ ($p < 10^{-5}$)
- 620 – 1951–1980: $r^2 = 0.42$ ($p < 10^{-3}$)

The lower pre-1980 correlations are mostly due to several exceptionally low MB_{4750} values during
La Niña and Neutral events during that period. The reasons for these differences are speculative but
some discrepancies are likely to be explained by deficiencies in the reanalysis products before the
introduction of satellite data in 1979. This effect is particularly strong in the southern hemisphere,
625 where observational data are sparse (e.g. Tennant, 2004).

Author contributions. F. Maussion developed *DownGlacier*, analysed the results and wrote the paper, based on an original idea by M. Großhauser. W. Gurgiser did the SEB/SMB model runs and prepared the calibration data. W. Gurgiser, M. Großhauser, G. Kaser, and B. Marzeion participated in field work. All authors continuously discussed the results and developed the analysis further.

Table 1. Selected predictors from the monthly ERA-Interim fields.

Name	Description	Levels (Surface or hPa)
prcp	Precipitation	sfc
ssrd	Short-wave downward radiation	sfc
tcc	Total cloud cover	sfc
<i>t</i>	Temperature	650, 550, 450, 350
rh	Relative humidity	650, 550, 450, 350
gh	Geopotential height	650, 550, 450, 350
<i>u</i>	Zonal wind component	650, 550, 450, 350
<i>v</i>	Meridional wind component	650, 550, 450, 350
ws	Wind speed	650, 550, 450, 350

Table 2. Variables statistics (monthly mean and standard deviation), number of selected predictors and out-of-sample cross-validation scores r^2 , RMSE, RMSE_σ (expressed in % of the standard deviation σ) and Brier Skill Score BSS for the downscaled variables and the diagnostic variable MB at the 4750 m a.s.l. altitude slice. The variables Temp (air temperature), VP (vapor pressure), WS (wind speed) and $\text{PRCP}_{\text{Total}}$ (total precipitation) are downscaled and listed here for information, but they are not used to calculate MB.

	Units	Mean	SD	N_{preds}	r^2	RMSE	RMSE_σ	BSS
Temp	K	1.58	0.39	14	0.78	0.18	0.47	0.82
VP	hPa	4.99	0.71	11	0.93	0.19	0.27	0.78
WS	m s^{-1}	2.48	0.63	11	0.83	0.26	0.42	0.59
SW_{in}	W m^{-2}	208.21	20.31	12	0.54	13.93	0.69	0.50
SW_{out}	W m^{-2}	-112.22	30.65	12	0.58	19.99	0.65	0.47

Table 3. Results of the sensitivity experiments for MB₄₇₅₀: skill scores RMSE (mm w.e month⁻¹) and BSS, linear trend (m w.e yr⁻¹) and correlation with Pacific SST Anomalies (detrended, without taking RMSE into account). Trends and correlation values adjoined with a * indicate significance at $p < 0.01$.

		Notes	RMSE	BSS	Trend	SST r^2

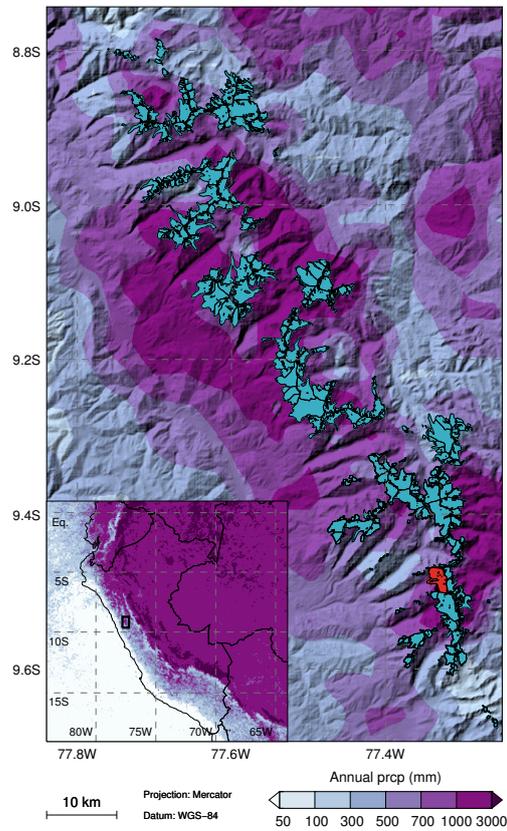

Figure 1. Map of the Cordillera Blanca with glacier outlines from the Randolph Glacier Inventory (Arendt et al., 2014). The Shallap Glacier is coloured in red. Colour contours: 1998–2009 annual rainfall climatologies (mm) at ~ 5 km resolution provided by Bookhagen and Strecker (2008) (<http://www.geog.ucsb.edu/~bodo/TRMM/>).

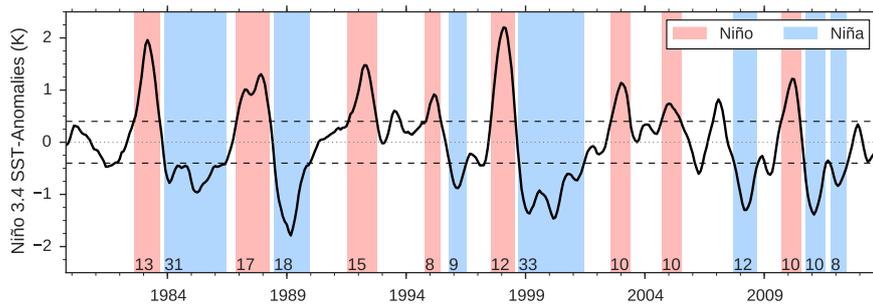

Figure 2. Five-month running average of Niño 3.4 sea surface temperature anomalies (SSTA, base period: 1981–2010) and Niño/Niña classification after Trenberth (1997). The threshold values (-0.4 and 0.4 K) are indicated by black broken lines. The length of each period (in months) is indicated at the bottom. Note that here and throughout the paper the SSTA time series have been shifted forward by 3 months to account for the lagged response of the atmospheric conditions at Shallap Glacier.

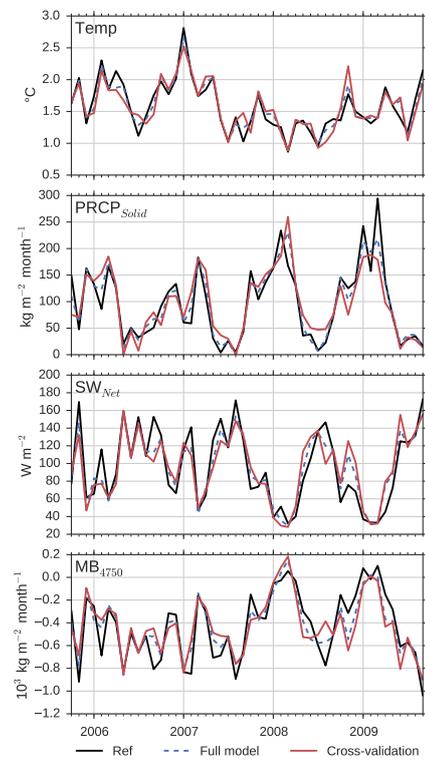

Figure 3. Time series of the reference dataset (black), full downscaling model (dotted blue) and out-of-sample cross-validation (red) during the calibration period. Shown are the variables air temperature, solid precipitation, net shortwave radiation, and MB at 4750 m a.s.l.

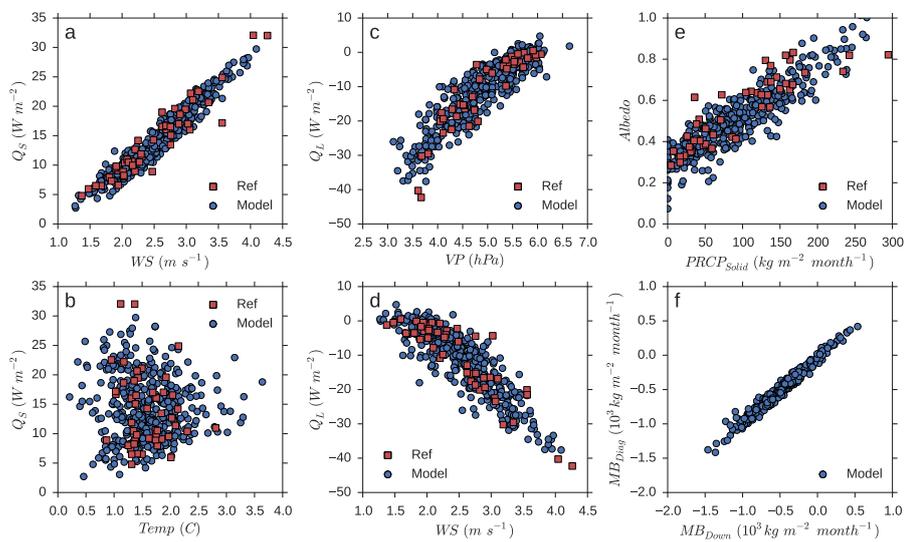

Figure 4. Checking the physical consistency of the downscaled variables. Scatter plots of reference (2005–2009, red) and downscaled (1980–2014, blue) time series at 4750 m a.s.l. **(a)** and **(b)**: sensible heat flux vs. wind-speed and air temperature. **(c)** and **(d)**: latent heat flux vs. vapor pressure and wind-speed. **(e)**: albedo vs. solid precipitation. **(f)** represents the scatter plot of the diagnostic mass balance (computed from the several downscaled variables) vs. the downscaled mass balance (1980–2014).

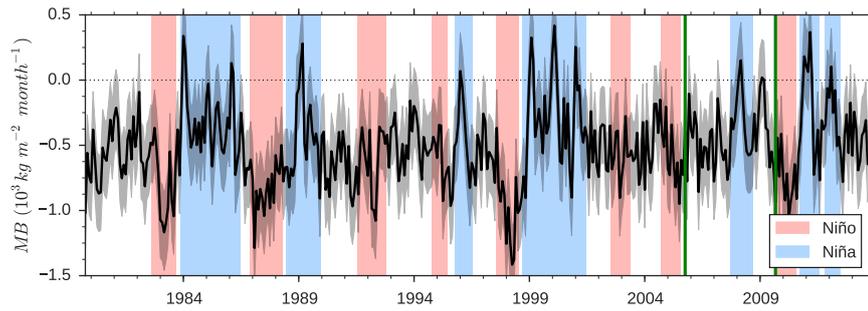

Figure 5. Time series of the computed monthly mass balance at 4750 m a.s.l. The grey shading represents \pm RMSE (including the RMSE of both the downscaled and the reference data). The calibration period is outlined by the green vertical bars.

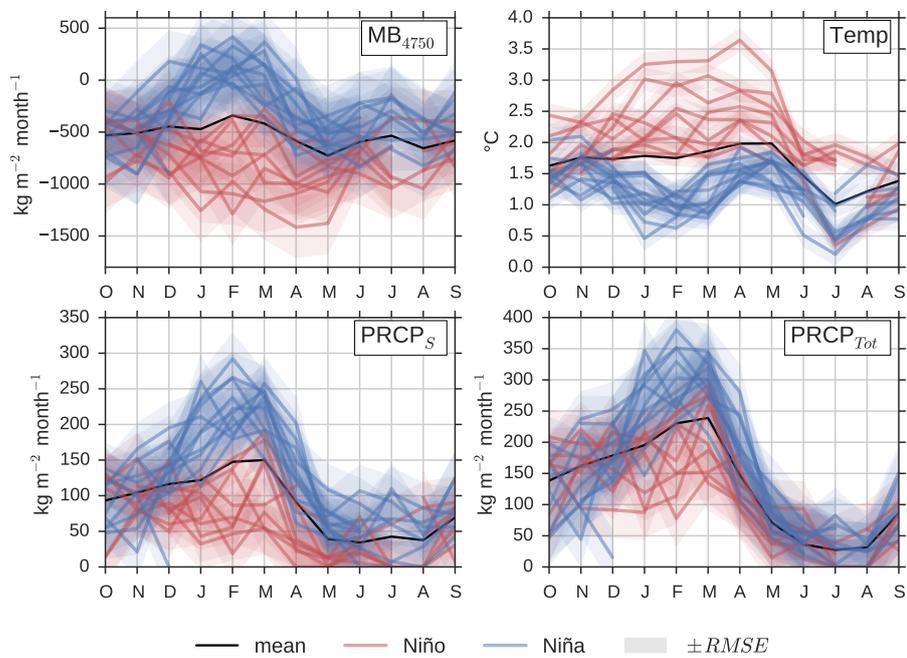

Figure 6. Annual cycles of mass balance, air temperature, solid and total precipitation at 4750 m a.s.l. for each Niño (red) and Niña (blue) periods (note that some annual cycles are incomplete). The average of all neutral months is drawn in black (error range omitted for clarity).

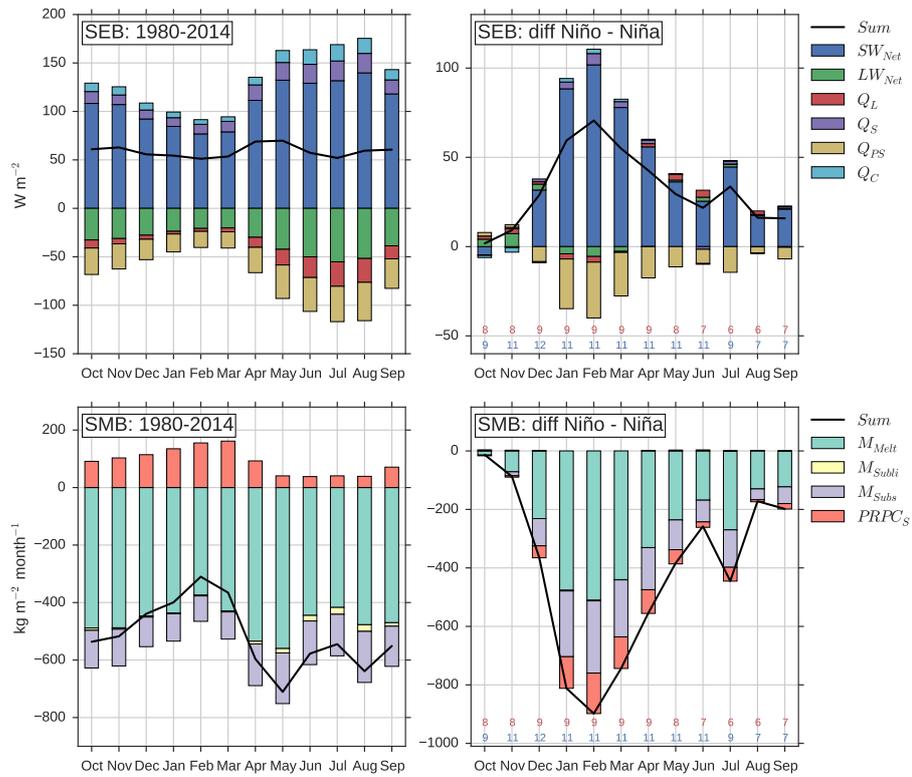

Figure 7. Annual cycles of the surface energy (top) and mass (bottom) fluxes at 4750 m a.s.l. Left: 1980–2014 average. Right: average difference between the Niño and Niña composites. The numbers of values for the Niño (red) and Niña (blue) composites are indicated at the bottom of the plots. Note the different y axis ranges and that none of these differences is significant in the statistical sense because of the large standard deviation between years combined with the small number of composites and the variables' RMSE.

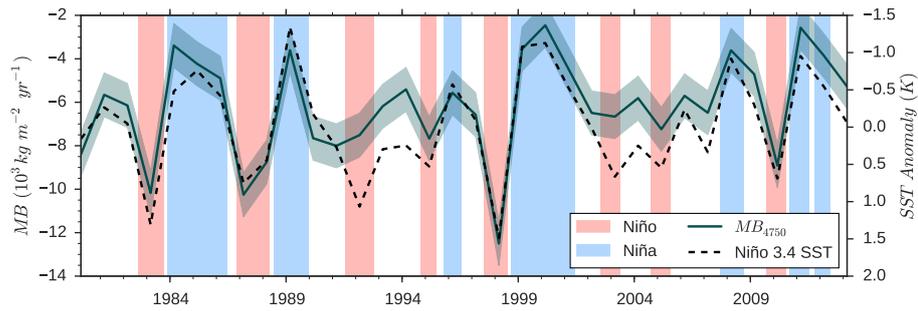

Figure 8. Annual average of the computed MB_{4750} and of Niño 3.4 SSTA shifted forward by 3 months (note the inverted right y axis). The shading represents $\pm RMSE$ (including the error of both the downscaling and the reference datasets).

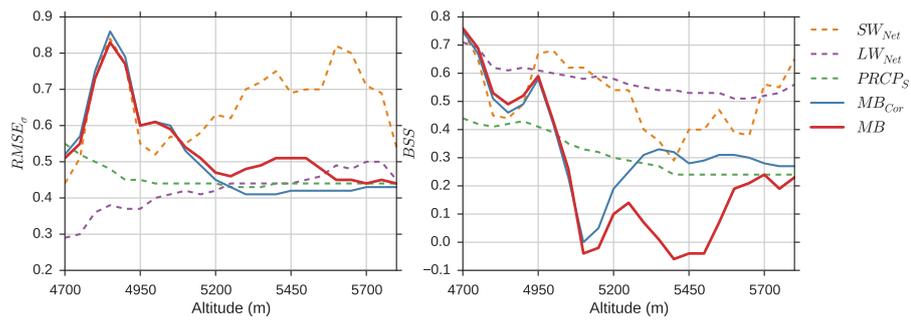

Figure 9. Out-of-sample cross-validation scores for selected variables and for each 50 m altitude slice at Shallap Glacier. Left: RMSE expressed in % of the standard deviation σ . Right: Brier Skill Score BSS.

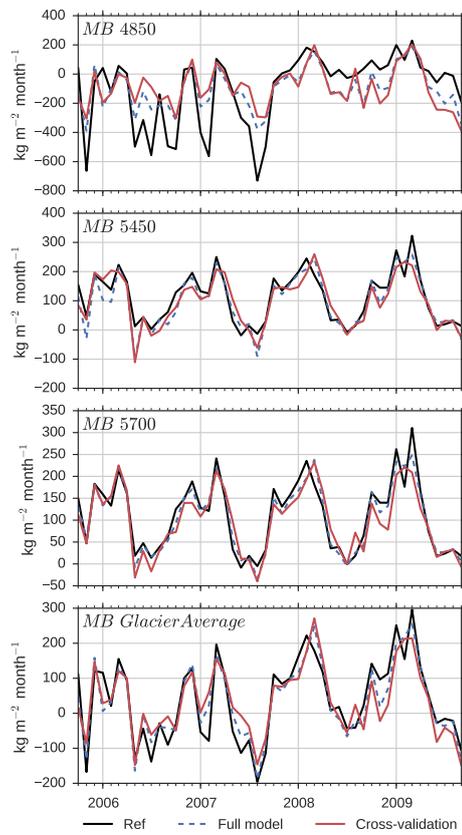

Figure 10. Time series of the reference dataset (black), full downscaling model (dotted, blue) and out-of-sample cross-validation (red) during the calibration period. Shown are the Mass-Balance time series at the 4850, 5450 and 5700 m a.s.l. altitude slices and averaged over the whole glacier.

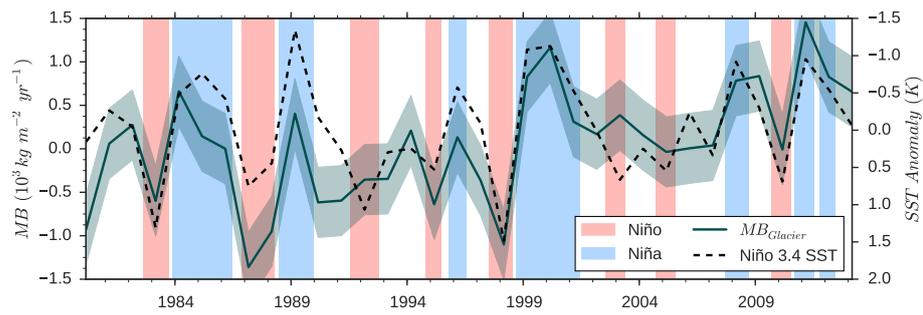

Figure 11. Same as Fig. 8 but for the glacier averaged MB. The shading represents ± 2 RMSE. Note that this mass balance does not account for changing glacier geometry.

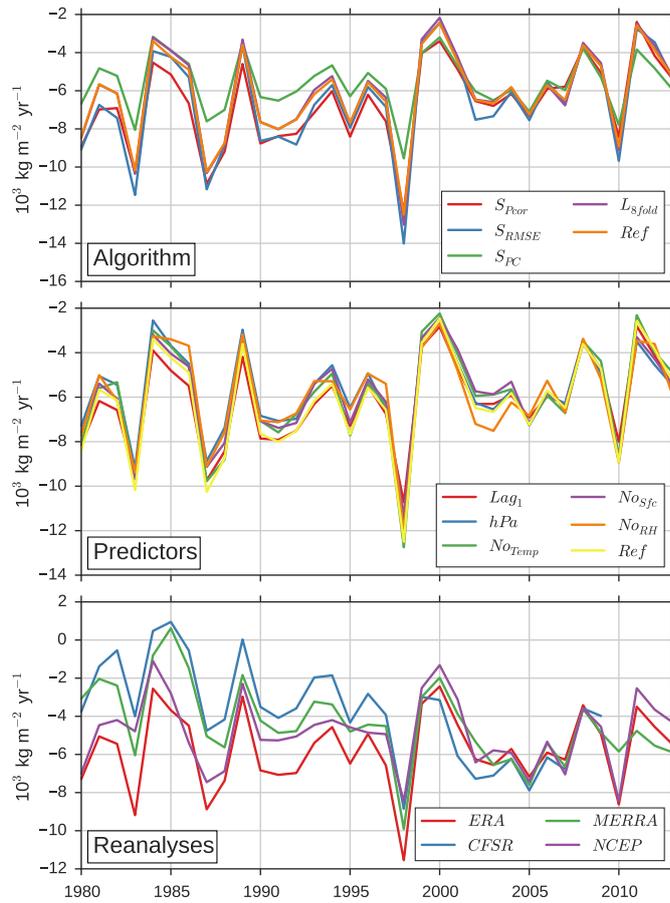

Figure 12. Computed annual MB_{4750} for each category of the sensitivity experiments (see Table 3 for the description of the experiments). The period 2005–2009 is the calibration period and thus with the smallest spread.

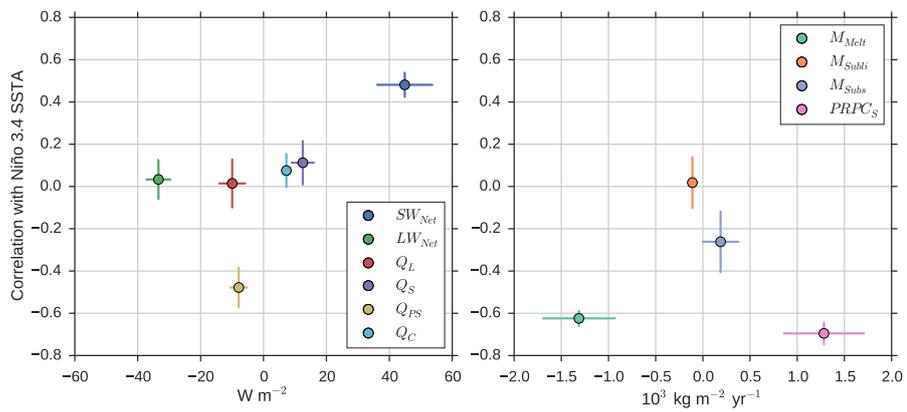

Figure 13. Glacier averaged contribution (x axis) and correlation (y axis) between annual Niño 3.4 SSTA and each SEB (left panel) and SMB (right panel) flux for 1980–2013. Note that the error bars are related to the uncertainty of the downscaling only (not of the calibration data) and that these results do not account for changing glacier geometry.

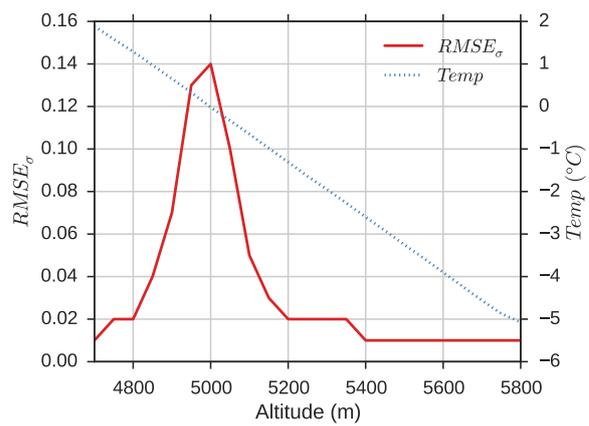

Figure A1. Results of the “perfect downscaling” experiment (see Appendix A1): $RMSE_{\sigma}$ and Temp for each 50 m altitude slice at Shallap Glacier.

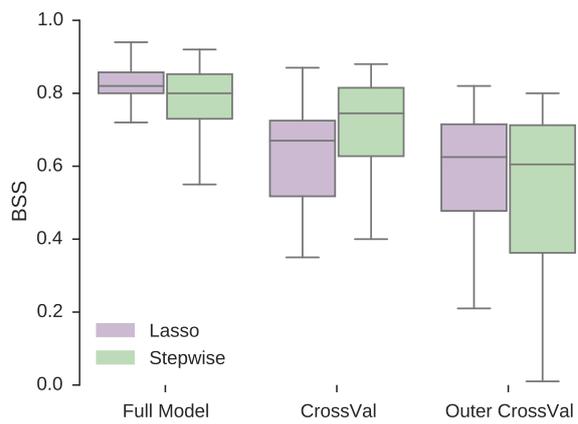

Figure A2. Box plots of the Brier Skill Score BSS of each validation step for the Lasso and the Stepwise downscaling algorithms. Each box represents a population of 14 scores (one for each downscaled variable listed in Table 2).

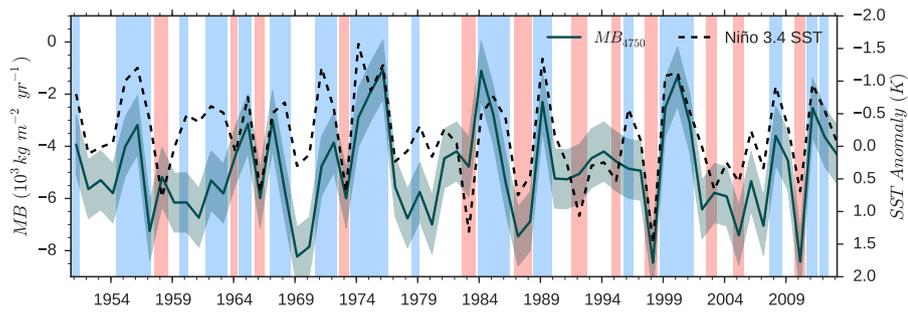

Figure A3. Same as Fig. 8 but using NCEP/NCAR R1 reanalysis and for the period 1951–2013.
