Once again we thank the reviewers for comments and suggested improvements. The final version of the submitted manuscript and track version do not exactly match because the tracked version does not include the final set of the improvements. Nevertheless we match the reviewer's comments according to the both versions. We also made a number of minor grammatical corrections. Our replies marked in blue.

Abstract

Thank you for adding some concrete results here. I would make a further suggestion, however: increasing the total amount of simulated carbon can be easily achieved in many ways (for example, change the decomposition rate), however the key thing is that it is simulated in the right places. Therefore I would suggest you also add something along the lines of – the spatial correlation of the simulated and observed distribution of carbon is increased from x to y?
Done. Line 18-20

Introduction
Line 22: "and emissions to amplify climate warming" -> "and emissions that amplify climate warming"
Done. Line 24.

Line 40: Typo: Hugeluis -> Hugelius
Corrected everywhere in the manuscript.

Line 44-45: Deleted either 'area' or 'extent'
Done. Line 46.

Line 71: "an SOL" -> "a SOL"
Done. Line 76.

Last paragraph is much better. One minor comment is that it just says the aim is "to reduce the bias of initial permafrost carbon stocks" - but as you have discussed in the preceding paragraphs, improving the thermal dynamics not only improves the initial carbon stocks but the response to warming. So perhaps change this to "to reduce the bias of initial permafrost carbon stocks and improve the dynamics"
We reworded the text.

Methods
Move lines 215 - 223 (until end of sentence) to the next section as they are about the roots. Lines 267-270. The following is basically a repeat of the previous paragraph: "We restricted simulated root growth to occur only in thawed soil layers. In SiBCASA, leaf growth is linked to fine root growth (Schaefer et al., 2008), so this also delays spring leafout until the soil begins to thaw. We first calculated the fraction of thawed roots within the root zone defined by:"
I suggest to change it to

"In order to restrict simulated root growth to thawed soil layers, we first calculated the fraction of thawed roots within the root zone defined by:"
Done. Lines 242-250.

Results

Lines 370-394: Paragraph on vertical profiles. Discusses what the modelled profiles are but does not compare to measured ones. Harden et al. 2012 (which is referenced, but not discussed) shows some observed profiles. I suggest to add one or two sentences along the lines of: The carbon in the active layer below the organic layer is lower than in the observed profiles in Harden et al. This is probably because cryoturbation is not included in the model. The top SOL and deeper carbon match well with the observed profiles (?).
Done. Lines 331-333.

Lines 405-433: Final paragraph of results. Discusses new initialisation. This paragraph is not totally clear. I am a bit confused by this sentence: "However, the NCSCD map (Fig 6B) shows that not all permafrost regions contain a uniform amount of frozen carbon." Would we expect them to? How discusses the differences between NCSCD and the simulation, but it would be good to indicate actually how much the distribution is improved by initialising with the NCSCD rather than the original method. For this I would suggest to make a spatial correlation of the NCSCD with your simulations. This value can then go into the conclusion and abstract as well.
Lines 352-355. Now it read as: The spatial correlation between simulated and observed permafrost carbon is 0.63 when initializing with the NCSCD (Fig 6b), compared with a spatial correlation of 0.12 for the uniform permafrost carbon density (Fig 6a). The amount and spatial distribution of permafrost carbon significantly improves when initializing with NCSCD.

Discussion

Lines 489-492: Seems to suggest that when the carbon is below the active layer it does not influence the soil thermal dynamics. Does it not still change the thermal properties of the permafrost, and because this part of the soil column is thermally connected to the active layer part above it, it should have at least a small influence on the active layer thermal dynamics?
Lines391-393: The carbon content does influence thermodynamic properties of the permafrost and we now see that this statement was misleading, so we removed the active layer carbon dynamics from the statement. Now it read as: Consequently, the ALT does not change between simulations and the volume of permafrost in the top three meters of soil does not change as well.

Line 556: 'SND' -> 'SD'?
Fixed in the current version

Lines 505-561. This is interesting but I'm not sure it is completely relevant. I realise this was added on my suggestion, but the reason I suggested it was because you were saying that permafrost was or wasn't simulated in particular regions due to meteorological variables / snow, and my concern was that those assertions shouldn't be made without showing something more concrete. However, now those original comments are not in the manuscript I think it might be better to remove this paragraph? But I leave it up to you to decide.
We decided to keep the material in the manuscript, but shortened the text to maintain a smooth flow. Lines 419-436

Conclusion

As I have mentioned in the comments for the abstract/results, it would be really good to say something about the spatial distribution improving as well as increasing the amount of carbon simulated.
Lines 450-453. Now reads: Our model developments improved both the total amount and the spatial distribution of simulated permafrost carbon. The total permafrost carbon increasing from 313 Gt C to 560 Gt C, compared to the observed value of 550 Gt C, and the spatial correlation with the observed distribution increased from 0.12 to 0.63. These improvements indicate the importance of including these developments in all land surface models.

I also suggest that you add a sentence along the lines of 'These improvements indicate the importance of including these developments in all land surface models.'
Line 619 : 'modified' -> 'modify'
Done

The importance of a surface organic layer in simulating permafrost thermal and carbon dynamics

Abstract

Permafrost-affected soils contain twice as much carbon as currently exists in the atmosphere. Studies show that warming of the perennially frozen ground could initiate significant release of the frozen soil carbon into the atmosphere. Initializing the frozen permafrost carbon with the observed soil carbon distribution from the Northern Circumpolar Soil Carbon Dataset reduces the uncertainty associated with the modeling of the permafrost carbon feedback. To improve permafrost thermal and carbon dynamics we implemented a dynamic surface organic layer with vertical carbon redistribution, and introduced dynamic root growth controlled by active layer thickness, which improved soil carbon exchange between frozen and thawed pools. These changes increased the initial amount of simulated frozen carbon from 313 to 560 GtC, consistent with observed frozen carbon stocks, and increased the spatial correlation of the simulated and observed distribution of frozen carbon from 0.12 to 0.63.

1. Introduction

Warming of the global climate will lead to widespread permafrost thaw and degradation with impacts on ecosystems, infrastructure, and emissions that amplify climate warming (Oberman,

2008; Callaghan et al., 2011, Shuur et al., 2015). Permafrost-affected soils in the high northern latitudes contain 1300±200 Gt of carbon, where ~800 Gt C is preserved frozen in permafrost with ~550 GtC in the top three meters of soil (Hugelius et al., 2014). As permafrost thaws, organic matter frozen within permafrost will thaw and decay, which will initiate the permafrost carbon feedback (PCF), releasing an estimated 120±85 Gt of carbon emissions by 2100 (Schaefer et al., 2014). The wide range of estimates of carbon emissions from thawing permafrost depends in large part on the ability of models to simulate present permafrost extent (Brown et al., 1997). For example, the simulated permafrost in some models is significantly more sensitive to thaw, with corresponding larger estimates of carbon emissions (Koven et al., 2013). Narrowing the uncertainty in estimated carbon emissions requires improvements in how Land Surface Models (LSMs) represent permafrost thermal and carbon dynamics.

The active layer in permafrost regions is the surficial soil layer overlying the permafrost, which undergoes seasonal freeze-thaw cycles. Active layer thickness (ALT) is the maximum depth of thaw at the end of summer. LSMs used to estimate emissions from thawing permafrost typically assume that the frozen carbon is located in the upper permafrost above 3 meters depth and below the maximum ALT (Koven et al., 2011; Schaefer et al., 2011; MacDougall et al., 2012). Thus, the simulated ALT determines the volume of permafrost in the top 3 meters of soil, and thus the initial amount of frozen carbon. Consequently, any biases in the simulated ALT will influence the initial amount of frozen carbon, even if different models initialize the frozen carbon in the same way. Also, the same thermal biases that lead to deeper simulated active layers also lead to warmer soil temperatures, making the simulated permafrost more vulnerable to thaw and resulting in higher emissions estimates (Koven et al., 2013).

The surface organic layer (SOL) is the surface soil layer of nearly pure organic matter

that exerts a huge influence on the thermodynamics of the active layer. The organic layer thickness (OLT) usually varies between 5-30 cm, depending on a balance between the litter accumulation rate relative to the organic matter decomposition rate (Yi et al., 2009; Johnstone et al., 2010). A recent model intercomparision study shows that LSMs need more realistic surface processes such as a SOL and better representations of subsoil thermal dynamics (Ekici et al., 2014a). The low thermal conductivity of the SOL makes it an effective insulator, decreasing the heat exchange between permafrost and the atmosphere (Rinke et al., 2008). The effect of the SOL has been well presented in several modeling studies. For example, Lawrence and Slater (2008) showed that soil organic matter affects the permafrost thermal state in the Community Land Model (CLM), and Jafarov et al., (2012) discussed the effect of the SOL in the regional modeling study for Alaska, United States. Recently, Chadburn et al., (2015a,b) incorporated a SOL in the Joint UK Land Environment Simulator (JULES) model to illustrate its influence on ALT and ground temperatures both at a site specific study in Siberia, Russia, and globally. In essence, the soil temperatures and ALT decrease as the OLT increases. Consequently, how (or if) LSMs represent the SOL in the simulated soil thermodynamics will simultaneously determine the initial amount of frozen permafrost carbon and the vulnerability of the simulated permafrost to thaw.

In this study we improved present day frozen carbon stocks in the Simple Biosphere/Carnegie-Ames-Stanford Approach (SiBCASA) model to reduce biases in initial permafrost carbon stocks and improve the dynamics of future permafrost carbon release. To achieve this we introduced three improvements into the SiBCASA model: 1) improve the soil thermal dynamics and ALT, 2) improve soil carbon dynamics and build-up of carbon stocks in soil, and 3) initialize the older, frozen carbon using observed circumpolar soil carbon (Hugelius

et al., 2014).

2. Methods

We used the SiBCASA model (Schaefer et al., 2008) to evaluate current soil carbon stocks in permafrost affected soils. SiBCASA has fully integrated water, energy, and carbon cycles and computes surface energy and carbon fluxes at 10 minute time steps. SiBCASA predicts the moisture content, temperature, and carbon content of the canopy, canopy air space, and soil (Sellers et al., 1996a; Vidale and Stockli, 2005). To calculate plant photosynthesis, the model uses a modified Ball-Berry stomatal conductance model (Ball, 1998; Collatz et al., 1991) coupled to a C3 enzyme kinetic model (Farquhar et al., 1980) and a C4 photosynthesis model (Collatz et al., 1992). It predicts soil organic matter, surface litter, and live biomass (leaves, roots, and wood) in a system of 13 prognostic carbon pools as a function of soil depth (Schaefer et al., 2008). The model biogeochemistry does not account for disturbances, such as fire, and does not include a nitrogen cycle. SiBCASA separately calculates respiration losses due to microbial decay (heterotrophic respiration) and plant growth (autotrophic respiration).

SiBCASA uses a fully coupled soil temperature and hydrology model with explicit treatment of frozen soil water originally from the Community Climate System Model, Version 2.0 (Bonan, 1996; Oleson et al., 2004). To improve simulated soil temperatures and permafrost dynamics, Schaefer et al. (2009) increased the total soil depth to 15 m and added the effects of soil organic matter on soil physical properties. Simulated snow density and depth, and thus thermal conductivity, significantly influence simulated permafrost dynamics, so Schaefer et al. (2009) added the effects of depth hoar and wind compaction on simulated snow density and depth. Recent model developments include accounting for substrate availability in frozen soil

117 biogeochemistry (Schaefer and Jafarov, 2015).

118 We spun SiBCASA up to steady-state initial conditions using an input weather dataset
119 from the modified Climatic Research Unit National Center for Environmental Predictions
120 (CRUNCEP)[1] (Wei et al, 2014) for the entire permafrost domain in the northern hemisphere
121 (Brown et al., 1997). CRUNCEP is modeled weather data at 0.5x0.5 degree latitude and
122 longitude resolution optimally consistent with a broad array of observations. The CRUNCEP
123 dataset used in this study spans 110 years, from 1901 to 2010. We selected the first 30 years
124 from the CRUNCEP dataset (1901 to 1931) and randomly distributed them over 900 years. To
125 run our simulations we used JANUS High Performance Computing (HPC) Center at University
126 of Colorado at Boulder. The 900-yr time span was chosen in order to make optimal use of the
127 computational time, which allowed us to finish one spinup simulation on JANUS HPC without
128 interruptions.

129

130 **2.1. Frozen carbon initialization**

131 We initialized the frozen carbon stocks using the Northern Circumpolar Soil Carbon
132 Dataset version 2 (NCSCDv2) (Hugelius et al., 2014). The NCSCDv2 includes soil carbon
133 density maps in permafrost-affected soils available at several spatial resolutions ranging from
134 0.012^{o} to 1^{o}. The dataset consists of spatially extrapolated soil carbon data from more than 1700
135 soil core samples. This dataset has three layers, each 1 meter in depth, distributed between
136 ground surface and 3 meter depth.

137 We placed the frozen carbon within the top three meters of simulated permafrost,
138 ignoring deltaic and loess deposits that are known to extend well beyond 3 meters of depth

Elchin Jafarov 1/30/2016 11:04 AM

Kevin Schaefer 2/2/2016 11:38 AM
Deleted: main

[1] ftp://nacp.ornl.gov/synthesis/2009/frescati/temp/land_use_change/original/readme.htm

(Hugelius et al., 2014). The bottom of the permafrost carbon layer is fixed at 3 meters, while the top varies spatially depending on the simulated ALT during the spinup run. We initialized the permafrost carbon by assigning carbon from the NCSCDv2 to the frozen soil carbon pools below the maximum thaw depth. These frozen pools remained inactive until the layer thaws.

We initialized frozen carbon between the permafrost table and 3 meters depth using two scenarios: 1) spatially uniform distribution of the frozen carbon throughout the permafrost domain (Schaefer et al., 2011), and 2) observed distribution of the frozen carbon according to the NCSCDv2. It is important to know the "stable" depth of the active layer before initializing frozen carbon. We run the model for several years in order to calculate ALT, and then initialized frozen carbon below the maximum calculated ALT. The frozen carbon was initialized only once after the first spinup simulation. For the next simulation we used the previously calculated permafrost carbon. We defined an equilibrium point when changes in overall permafrost carbon were negligible or almost zero.

The total initial frozen carbon in each soil layer between the permafrost table and 3 meters is

$$C_{fr}^{i} = \rho_c \Delta z_i, \quad (1)$$

where C_{fr}^{i} is the total permafrost carbon within the i^{th} soil layer, ρ_c is the permafrost carbon density, and Δz_i is the thickness of the i^{th} soil layer in the model. For the uniform permafrost carbon distribution, spatially and vertically uniform ρ_c of 21 kg C m^{-3} (Schaefer et al., 2011). For the observed distribution from the NCSCDv2, ρ_c varies both with location and depth (Hugelius et al., 2013).

The permafrost carbon in each layer is divided into three soil carbon pools as follows:

$$C_{slow}^{i} = 0.8 C_{fr}^{i}$$
$$C_{met}^{i} = 0.2 f_{root2met} C_{fr}^{i} \quad (2)$$
$$C_{str}^{i} = 0.2 f_{root2strt} C_{fr}^{i},$$

where $f_{root2met}$ and $f_{root2strt}$ are the simulated fractions of root pool losses to the soil metabolic and structural pools respectively (Schaefer et al., 2008). The nominal turnover time is 5 years for the slow pool, 76 days for the structural pool, and 20 days for the metabolic pool. Schaefer et al., (2011) has a 5% loss to the metabolic pool and a 15% loss to the structural pool based on observed values in Dutta et al., (2006). The simulated fractions are actually 5.6% to the metabolic pool and 14.4% to the structural pool. We found it encouraging that the numbers calculated with the SiBCASA metabolic fractions resulted in numbers that are close to the observed values in Dutta et al., (2006).

2.2. Dynamic SOL

We modified SiBCASA to include a dynamic SOL by incorporating the vertical redistribution of organic material associated with soil accumulation. SiBCASA calculates the soil physical properties as a weighted average of those for organic matter, mineral soil, ice and water (Schaefer et al., 2009). The physical properties include soil porosity, hydraulic conductivity, heat capacity, thermal conductivity, and matric potential. The model calculates the organic fraction used in the weighted mean as the ratio of simulated carbon density to the density of pure organic matter. The model does not account for the compression of organic matter. Since the prognostic soil carbon pools vary with depth and time, the organic fraction and the physical properties all vary with time and depth. We only summarized these calculations here since the calculations are covered in detail in Schaefer et al. (2009).

As live, above-ground biomass in the model dies, carbon is transferred into the first layer as litter. Without the vertical redistribution we describe here to create a surface organic layer, the top layer of the model tended to accumulate carbon in excess of that expected for pure organic matter. To allow vertical movement and build up a SOL, we placed a maximum limit on the amount of organic material that each soil layer can hold. When the simulated carbon content exceeds this threshold, the excess carbon is transferred to the layer below. This is a simplified version of the Koven et al., (2009) carbon diffusion model, which accounts for all sedimentation and cryoturbation processes. This simplified model is better suited for our application because we wanted to focus only to the buildup of a SOL.

Elchin Jafarov 1/30/2016 11:20 AM
Deleted: The previous version of the model distributed fine and coarse root growth vertically within the soil column based on observed root distributions. As the roots die, carbon is transferred to the soil carbon pools for that layer. Thus, the maximum rooting depth determined the maximum depth of 'current' or 'active' carbon in the model. Of course, if the maximum rooting depth fell below the permafrost table, the model would accumulate permafrost carbon, which remains inactive until the layer thaws.

Kevin Schaefer 2/2/2016 11:46 AM
Deleted: limit our model

We calculate the maximum allowed carbon content per soil layer, C_{max}, as

$$C_{max} = \rho_{max} \Delta z \frac{1000}{MW_C}, \quad (3)$$

where ρ_{max} is the density of pure organic matter or peat, Δz is the soil layer thickness (m), MW_C is the molecular weight of carbon (12 g mol^{-1}), and the factor of 10^3 converts from grams to kilograms. Based on observations of bulk densities of peat, we assume ρ_{max}, is 140 kg m^{-3} (Price et al., 2005). The MW_C term converts the expression into mol C m^{-2}, the SiBCASA internal units for carbon. The simulated organic soil fraction per soil layer, f_{org}, is defined as

$$f_{org} = \frac{C}{C_{max}}, \quad (4)$$

where C is the carbon content per soil layer (mol m^{-2}). To convert to carbon we assume that the fraction of organic matter is 0.5, which means that half of the organic matter by mass is carbon. The original formulation allowed f_{org} to exceed 1.0 such that the excess organic material was essentially 'compressed' into the top soil layer, resulting in a 2-cm simulated SOL. We place an

upper limit of 0.95 on f_{org} and transfer the excess carbon to the layer below. The OLT is defined as the bottom of the lowest soil layer where f_{org} is 0.95.

2.3. Coupling growth to thaw depth

We coupled simulated gross primary productivity (GPP), plant phenology, and root growth to simulated thaw depth as a function of time. The model assumes root growth decreases exponentially with depth based on observed vertical root distributions (Jackson et al., 1996; Schaefer et al., 2008). The maximum rooting depth for completely thawed soil is defined as the soil depth corresponding to 99% of the observed vertical root distribution or 1.1 m for the tundra and boreal forest biomes. In real life, growing roots cannot penetrate frozen soil, so we restricted simulated root growth to occur only within the thawed portion of the active layer (Tryon and Chapin 1983, Van Cleve et al., 1983). The date of snowmelt determines the start date of the growing season and the start of active layer thawing (Grøndahl et al. 2007; Wipf and Rixen 2010). Since fine root and leaf growth are coupled (Schaefer et al., 2008), constraining root growth to thawed soil also constrains spring leafout to occur after the active layer starts thawing. In real life plants cannot photosynthesize without liquid water in the soil, so we scaled simulated GPP based on the fraction of thawed roots in the root zone.

The previous version of the model distributed fine and coarse root growth vertically within the soil column based on observed root distributions. As the roots died, carbon was transferred to the soil carbon pools for that layer. Thus, the maximum rooting depth determined the maximum depth of 'current' or 'active' carbon in the model. Of course, if the maximum

Kevin Schaefer 2/2/2016 11:51 AM
Deleted: is

rooting depth fell below the permafrost table, the model would incorrectly grow roots directly into frozen soil and consequently accumulate permafrost carbon.

In order to restrict simulated root growth to thawed soil layers, we first calculated the fraction of thawed roots within the root zone defined by:

$$R_{th} = \sum_{i=1}^{n_{root}} R_{f_i}\left(1 - F_{ice_i}\right), \quad (6)$$

where R_{th} is the fraction of total roots that are thawed, n_{root} is the soil layer corresponding to the maximum root depth, R_{f_i} is the reference root fraction for the i^{th} soil layer based on observed root distributions, and F_{ice_i} is the ice fraction calculated from the simulated ice content for the i^{th} soil layer. When R_{th} equals one, the entire root zone is thawed and when R_{th} is zero, the entire root zone is frozen. We assume evenly distributed liquid water in each layer such that F_{ice} equals the frozen soil fraction. We then calculated R_{eff_i}, the effective root fraction for the i^{th} soil layer,

$$R_{eff_i} = R_{f_i}\left(1 - F_{ice_i}\right)/R_{th}. \quad (7)$$

We then use R_{eff_i} to distribute new fine and coarse root growth within the soil column. When R_{eff_i} equals zero, the soil layer is frozen with no root growth. Dividing by R_{th} ensures R_{eff_i} sums to one within the soil column to conserve mass. This formulation makes the effective maximum rooting depth equal to the thaw depth.

To couple GPP to thaw depth, we treated the reference root zone distribution for completely thawed soil as the maximum root growth capacity defining the maximum potential GPP. When $R_{th} < 1$, the root zone is partially frozen and GPP is less than its full potential. We defined a GPP scaling factor, $S_{soilfrz}$, as

Kevin Schaefer 2/2/2016 11:53 AM
Deleted: , which remains inactive until the layer thaws

Elchin Jafarov 1/30/2016 11:23 AM
Deleted: We restricted simulated root growth to occur only in thawed soil layers. In SiBCASA, leaf growth is linked to fine root growth (Schaefer et al., 2008), so this also delays spring leafout until the soil begins to thaw. We first calculated the fraction of thawed roots within the root zone defined by

$$S_{soilfrz} = \begin{cases} R_{th} & \text{for } R_{th} \geq 0.01 \\ 0 & \text{for } R_{th} < 0.01 \end{cases} \quad (8)$$

This assumes that at least 1% of the roots must be thawed for GPP to occur, corresponding to about ~1 cm of thawed soil. $S_{soilfrz}$ is applied along with the drought stress and temperature scaling factors to constrain photosynthesis (Schaefer et al., 2008). SiBCASA assumes that the factors that control GPP also control wood and leaf growth, so we also included $S_{soilfrz}$ as a new scaling factor in addition to the drought stress and temperature scaling factors that control wood and leaf growth.

3. Results

The dynamic SOL decreased the simulated ALT on average 50% across the domain and allowed the model to simulate permafrost in discontinuous zones where it could not before (Figure 1). The area of near surface permafrost simulated with the current version of the model equals to 13.5 mil km^2 which is almost 38% greater than without the dynamic SOL (Schaefer et al., 2011). This area is closer to the observed area from the International Permafrost Association: 16.2 mil km^2 (Brown et al., 1997). Simulated ALT less than 2 m covers about 92% of the area in the new simulations (Figure 1B) in comparison to 66% of the area in the Schaefer et al. (2011) simulations (Figure 1A). The previous version of SiBCASA could not simulate permafrost in many parts of the discontinuous zone with relatively warm climate. Adding the dynamic SOL essentially decreased the thermal conductivity of the surface soil allowing SiBCASA to simulate permafrost where the mean annual air temperatures (MAAT) are close to 0 °C.

To illustrate the improvement of the simulated ALT with respect to the observed data, we compared simulated ALT with measured values from Circumpolar Active Layer Monitoring

297 (CALM) stations. The CALM network is a part of the Global Terrestrial Network for Permafrost
298 (GTN-P) (Burgess et al., 2000). The monitoring network measures ALT either using a
299 mechanical probe or a vertical array of temperature sensors (Brown et al., 2000; Shiklomanov et
300 al., 2010). After matching up the CALM coordinates with the coordinates of previously
301 simulated ALT (Schaefer et al., 2011), we excluded sites with no measurements or ALT greater
302 than 3m depth, ending up with 76 CALM stations. Figure 2 shows simulated vs. observed ALT
303 for the 76 CALM sites. The current simulations have a higher resolution than Schaefer et al.
304 (2011) simulations, which allowed us to reach a higher order of heterogeneity between measured
305 and simulated ALTs. The Pearson's correlation coefficient, R, is negative and not significant for
306 the Schaefer et al. (2011) simulations (Figure 2A), but is positive and statistically significant for
307 the current simulations assuming $p < 0.05$ (Figure 2B). The dynamic SOL greatly improves the
308 simulated ALT, but SiBCASA still tends to overestimate ALT.

309 Figure 3 illustrates the effect of the frozen soil restrictions on phenology and GPP at a
310 single point in central Siberia. Before applying a frozen soil restriction, SiBCASA maintained
311 fine roots even in winter, resulting in root growth all year with a peak in spring corresponding to
312 simulated leafout (Figure 3A). Simulated GPP was restricted by liquid water availability and
313 was closely tied to thawing of the active layer, resulting in a lag as high as 60 days between
314 leafout and start of GPP in spring. Restricting growth and GPP to when the soil is thawed
315 essentially synchronizes all phenological events to occur at the same time (Figure 3B).

316 Restricting growth and GPP to when the soil is thawed delayed the onset of plant
317 photosynthesis in spring in permafrost-affected regions. Introduction of the thawed root fraction
318 in the model reduced GPP primarily in early spring. To illustrate the difference between
319 unconstrained and restricted root growth (Figure 3), we ran the model for ten years for both

cases. The difference between unconstrained and restricted root growth resulted in an overall ~9% reduction in annual GPP for the entire permafrost domain, nearly all of which occurred in spring.

To illustrate soil carbon distribution with depth we selected three representative areas: a continuous permafrost area corresponding to tundra type biome above the Arctic Circle, an area in the boundary of continuous and discontinuous permafrost corresponding to the boreal forest biome, and an area near the south border of the discontinuous permafrost corresponding to poorly vegetated-rocky areas. We calculated the mean and standard deviation of the carbon density distribution with depth for 200 grid points around each of the three selected locations. Simulated typical carbon densities from the selected locations are shown on Figure 4. All profiles shown on Figure 4 show a similar pattern: a 20-30 cm SOL with reduced carbon content at the bottom of the active layer. The SOL and permafrost carbon content matches observed values (Harden et al., 2012), but carbon content near the bottom of the active layer does not, most likely because our model does not include cryoturbation processes.

The decrease in ALT resulting from a dynamic SOL increases the volume of permafrost in the top 3 meters of soil, greatly increasing the initial amount of frozen permafrost carbon in the simulations. Schaefer et al. (2011) without the dynamic SOL assumed a uniform permafrost carbon density of 21 $kg \cdot C \cdot m^{-3}$, resulting in a total of 313 Gt of permafrost carbon at the start of their transient run (Figure 5A). To compare with the Schaefer et al. [2011] results, we initialized the permafrost carbon using the same assumed uniform carbon density and ran SiBCASA to steady state initial conditions (Figure 5B). Assuming the same uniform carbon density, the current version with the dynamic SOL results in a total of ~680 Gt C compared to 313 Gt C in Schaefer et al. (2011). The dynamic SOL effectively doubled the volume of

permafrost in the top three meters of soil and the amount of simulated frozen carbon.

Initializing SiBCASA with the observed spatial distribution of permafrost carbon from the NCSCDv2 resulted in ~560 GtC of carbon stored in permafrost after spinup, close to the observed value ~550 GtC in the top three meters of soil (Hugelius et al., 2014). This does not mean that after the spinup simulated permafrost carbon stocks exactly matched the NCSDC data. In discontinuous zones, for example, if the model simulated permafrost, it tended to produce a deeper ALT and thus less permafrost carbon than the NCSCDv2. Assuming a uniform permafrost carbon density does not account for the spatial heterogeneity in permafrost carbon and overestimates the total amount of permafrost carbon compared to the NCSCDv2 (680 Gt C vs. 550 Gt C). The spatial correlation between simulated and observed permafrost carbon is 0.63 when initializing with the NCSCDv2 (Fig 6b), compared with a spatial correlation of 0.12 for the uniform permafrost carbon density (Fig 6a). The amount and spatial distribution of permafrost carbon significantly improves when initializing with NCSCDv2.

Kevin Schaefer 2/2/2016 12:35 PM
Deleted: During spinup, ALT varies with time, introducing carbon movement from frozen to thawed pools.

Kevin Schaefer 2/2/2016 12:49 PM
Deleted: The major difference between uniform frozen carbon initialization (Fig 6A) and initialization using the NCSCD (Fig 6B) is that SiBCASA simulated permafrost in more places. However, the NCSCD map (Fig 6B) shows that not all permafrost regions contain a uniform amount of frozen carbon. Therefore simulating 'correct' ALT is important and should improve the overall permafrost carbon storage.

4. Discussion

Failure to simulate soil carbon in southeast Canada and southwest Siberia (Figure 6C) is attributed to deep ALT. These areas correspond to the peat lands. Our model uses Harmonized World Soil Carbon Database (HWSD) (FAO et al., 2009) to initialize soil texture and related thermal properties. Deep layers of peat have low thermal conductivities providing an ideal condition for permafrost existence. However, The HWSD does address peat lands in southeast Canada and southwest Siberia.

Kevin Schaefer 2/2/2016 12:04 PM
Deleted: active layer thickness

The overestimation of SOC in Central Siberia results from coupling between GPP and ALT. The dynamic SOL and rooting depth strengthens the feedback between GPP and ALT (Koven et al., 2009). Higher GPP produces greater litter fall, which increases the input soil carbon at the surface and results in a thicker SOL. The dynamic SOL changes the properties of the near surface soil, resulting in a shallower ALT and cooler soil temperatures. The dynamic rooting depth accounts for a shallower ALT and modulates GPP accordingly. The cooler soil temperatures slow microbial decay and increase the carbon accumulation rate, which in turn increases the SOL and reduces ALT further. Eventually, this feedback results in the development of a peat bog. The changes we describe here indicate that SiBCASA can simulate the dynamics of peat bog development, but the model does not yet include a dynamic vegetation model to account for conversions between biome types, such as boreal forest to peat bog.

The overall amount of permafrost carbon is less than that calculated assuming a uniform frozen carbon distribution. It is important to note that the SOL, ALT, and the permafrost thickness are the same for both cases (Figure 6A and B). This is due to the fact that in both cases soil carbon is added in the permafrost layer below the active layer. Consequently, the ALT does not change between simulations and the volume of permafrost in the top three meters of soil does not change as well. The smaller permafrost carbon stock simulated for the non-uniform case is mainly due to the fact that we did not initialize frozen carbon in regions where according to the NCSCDv2 it is not present, such as the Brooks Range in Alaska.

The dynamic SOL insulates ALT from air temperature, allowing SiBCASA to simulate permafrost in many discontinuous permafrost regions where it could not before, consistent with previous results where changes in thermal properties associated with the presence of soil organic matter cooled the ground (Lawrence and Slater, 2008; Yi et al., 2009; Ekici et al., 2014b;

Chadburn et al., 2015a,b). In addition, our work confirms findings by Koven et al., (2009) showing that including SOL dynamics into the model improves agreement with the observed permafrost carbon stocks. However, to better simulate known permafrost distribution in the discontinuous permafrost zone it is important to know the exact OLT. Unfortunately, in situ measurements of OLT are scarce and essentially lacking in most areas of continuous and discontinuous permafrost.

To investigate further the influence of the environmental factors on ALT we looked at the relationship between ALT and near surface air temperatures (NSAT), soil wetness fraction (SWF), down-welling long-wave radiation (DLWR), and snow depth (SD). The simulated ALT is most influenced by NSAT and soil SWF, with a slightly smaller influence by DLWR, and nonlinearly influenced by SD (Figure 7). To show the influence of the NSAT we averaged two early fall months over 10 years. The areas with deep simulated ALT correspond to annual NSAT > 1° C in southwest Siberia and NSAT > 5° C in the southeast Canada with a statistically significant correlation of 0.62 (Figure 7A). DLWR showed a similar, but slightly weaker relationship with ALT, with deeper ALT in southeast Canada and southwest Siberia and statistically significant correlation of 0.45 (Figure 7B). Figure 7C shows maximum simulated snow depth calculated over the last 10 years of the steady state run. Our results show no correlation between SD and ALT, but the effects of snow on ALT are less obvious and depend on different physical processes, such as wind, snow metamorphism, and depth hoar formation (Sturm et al., 1997; Ekici et al., 2014; Jafarov et al., 2014). Zhang (2005) indicates that SD less than 50cm have the greatest impact on soil temperatures. We also observe high SWF in southwest Siberia and southeast Canada (see Figure 7D) where SiBCASA simulates deep ALT

with a statistically significant correlation of 0.68, suggesting wet soils modulate the insulating effects of the SOL (Lawrence and Slater, 2008).

This work does not address the fire impacts on soil thermodynamics and recovery from fire, both of which are strongly influenced by the changes in the SOL (Jafarov et al., 2013). Studies show that wildfires and climate change could substantially alter soil carbon storage (Yuan et al., 2012; Yi et al., 2010). In the current version of the model the topsoil carbon stays in the system and provides resilience to permafrost. However, in reality, the upper SOL could be removed by fire, which would alter soil thermal properties and perturb permafrost carbon stability.

5. Conclusion

This work shows the dynamic organic layer directly improves the distribution of carbon in soil, as well as indirectly through the improved ALT. Initialization of the carbon according to the NCSCDv2 map allowed us to better match with the observed carbon distribution. Restriction of the root growth within the thawed layer prevented artificial accumulation of permafrost carbon. Our model developments improved both the total amount and the spatial distribution of simulated permafrost carbon. The total permafrost carbon increasing from 313 Gt C to 560 Gt C, compared to the observed value of 550 Gt C, and the spatial correlation with the observed distribution increased from 0.12 to 0.63. These improvements indicate the importance of including these developments in all land surface models.

In addition, most of the LSMs calculate soil properties based on prognostic soil carbon and soil texture from HWSD. We found that HWSD does not include thermal properties of peat lands,

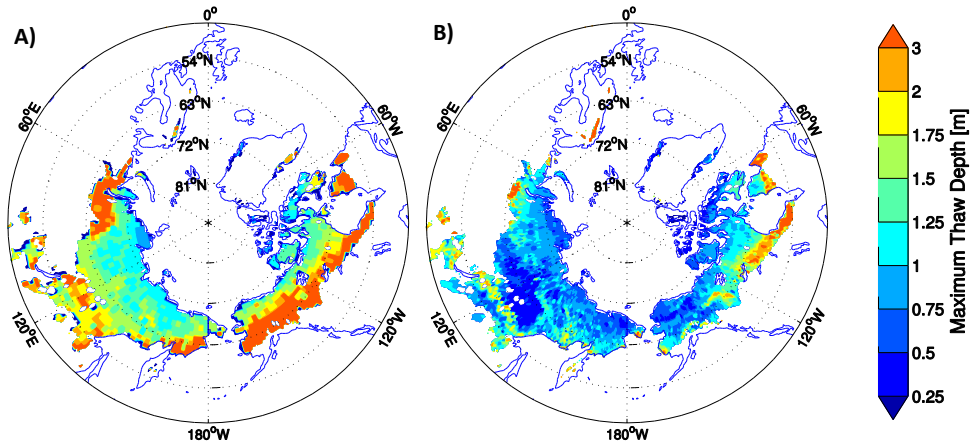

Figure 1. Maximum thaw depth (ALT) averaged over last five years after spinup from A) Schaefer et al., (2011) and B) this study, in meters.

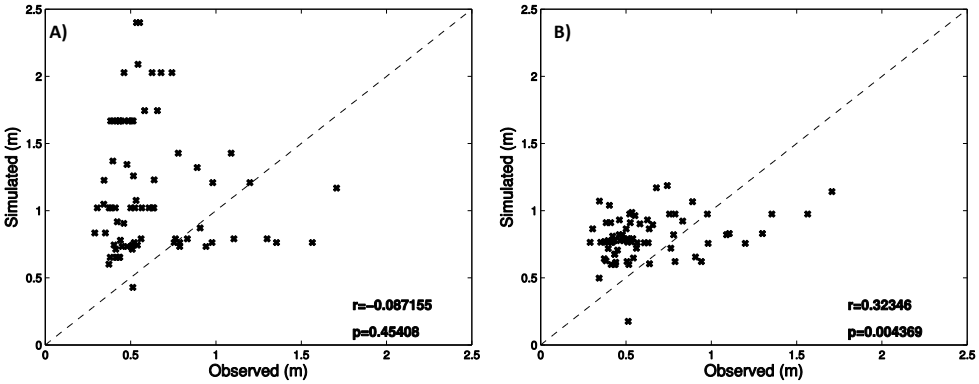

Figure 2. Comparison of ALT from 76 Circumpolar Active Layer Monitoring stations with the averaged ALT from last five years after spinup from A) Schaefer et al., (2011) and B) this study. r is a Pearson's correlation coefficient and p is a significance value, p<0.05 stands for the 95% of confidence.

Kevin Schaefer 2/2/2016 12:56 PM
Deleted: the mean active layer thickness (ALT)

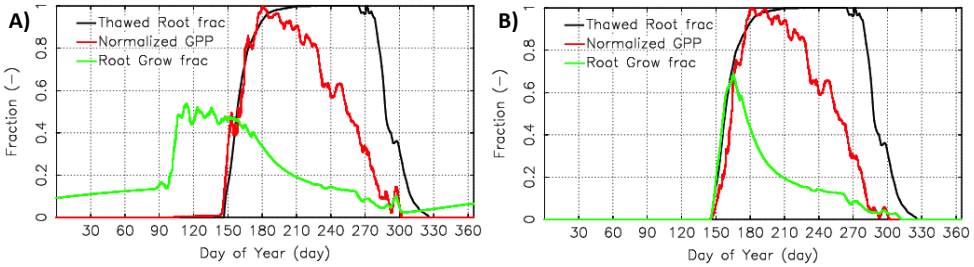

Figure 3: Root growth and GPP without (A) and with (B) the frozen soil constraint on growth. GPP is normalized to a maximum value of 1.0. The root growth fraction is relative to total plant growth.

Kevin Schaefer 2/2/2016 12:58 PM
Deleted: A) and B) r

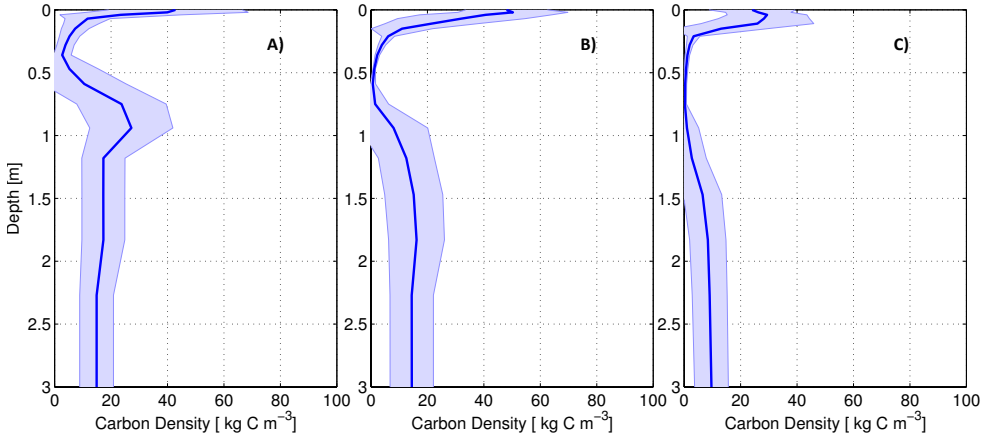

Figure 4. The average soil carbon distribution from 200 grid cells for A) a tundra region in continuous permafrost zone, B) boreal forest on the boundary between continuous and discontinuous zones, and C) low carbon soil at the south border of the discontinuous permafrost zone. The solid blue curve indicates the mean the white blue shading indicate the spread in the simulated soil carbon density.

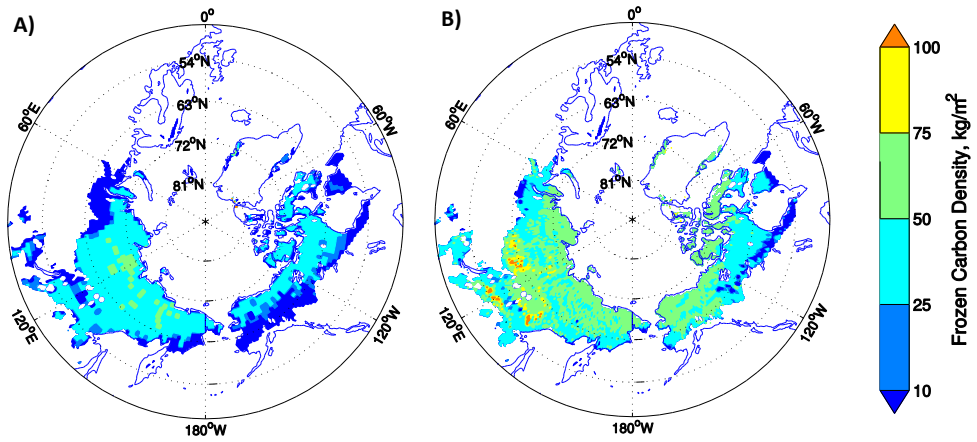

Figure 5. The frozen carbon maps obtained assuming a uniform frozen carbon distribution at the initial time step, and averaged over five years at the end of the steady state run: A) from Schaefer et al., (2011), and B) from the current run, correspondingly.

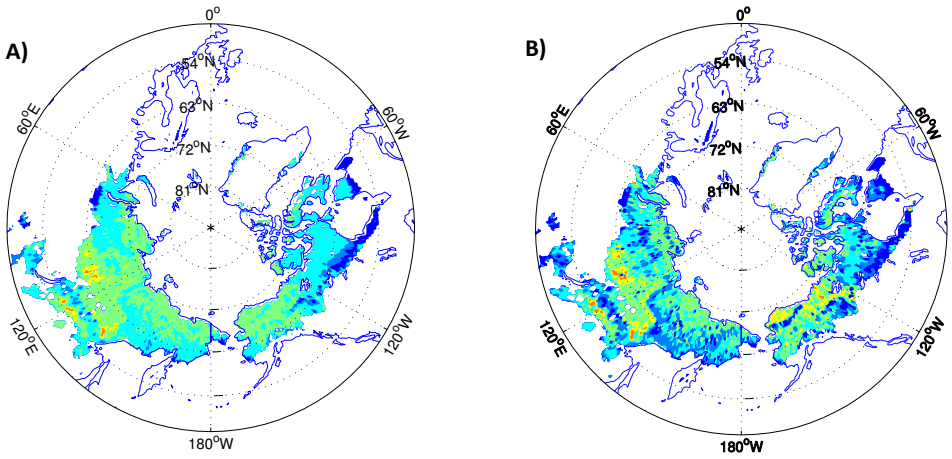

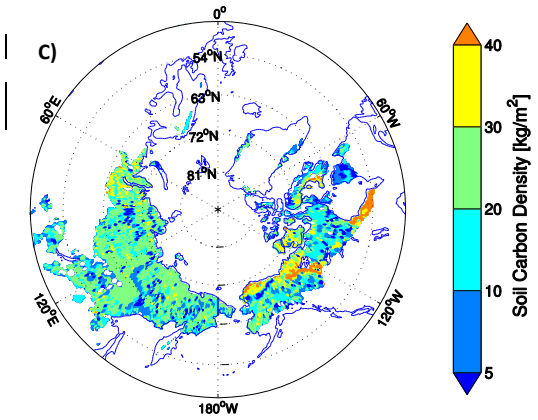

Figure 6. The soil carbon maps averaged over top 3 meters: A) from SiBCASA at the end of the steady state run with constant permafrost carbon density, B) from SiBCASA at the end of the steady state run with spatially varying permafrost carbon density, and C) from the NCSCDv2.

672

673 **Figure 7.** A) The near-surface air temperature averaged over first two month of the fall season. B) The
674 down-welling long-wave radiation, averaged yearly over 10 years. C) The maximum snow depth obtained
675 over 10 years for the steady state run, and D) the soil wetness fraction (dimensionless fraction of 1),
676 representing overall near-surface soil wetness, averaged yearly over 10 years.
