# **Reviewer #1**

Thank you for preparing this manuscript. It is an interesting paper to read as it involves multiple assumptions and conclusions.

The key question authors try to answers is as follows. What is the rate of ice-bonded permafrost degradation, when the permafrost got submerged by the ocean? Therefore, the authors try to estimate a location of the upper boundary of the ice-bonded permafrost (IBP) at two moments of time. Conveniently, the first measurement of IBP surface was done by drilling in 1983. Consequently, the authors try to estimate the IBP surface location in 2011, using geoelectrical surveys (no drilling this time).

**Response**: We thank the reviewer for a useful review of our paper. We provide responses to each criticism and suggestion below.

One of the primary assumptions is concerned about "How to define the surface of IBP using the recovered resistivity values?" Note that the latter are not measured, but estimated from the electrical currents. Nevertheless, after citing some literature, the authors declare that "IBP depth was defined at values of 15 Om and higher" (Page 3749, Line 9). This conclusion was based on a similar study by Overduin et al., (2012) in Alaskan Beaufort Sea, as cited. The difference between this study and the Overduin et al., (2012) work is that in 2012 Overduin et al. drilled into the sediments recovered ground material samples, measured their resistivitytemperature dependence, etc. Unfortunately, nothing similar is performed for the Laptev Sea sediments. Moreover, in the 2012 paper, Overduin mentions that "previous work by Overduin et al. [2008] suggests that the transition from ice-free to ice-bonded sediment may not be sharp but occur over tens of meters, depending on the sediment temperature and pore water salinity". In the present manuscript (Page 3749, Line 3), the authors also state that "Kang and Lee (2015) show an increase in electrical resistivity on freezing for silt-sand mixtures with 40% saturation from around 5 100Om to over 300 kOm. For 100% saturated mixtures with saline pore water, the resistivities can be expected to be around 4 to 10 times lower (Kang and Lee, 2015)." Therefore, it seems to the reviewer that the threshold value of 15 Om used to define the IBP depth is picked up rather arbitrary. It would be great to learn more further justification of 150m! How would the final results change if the threshold value is different, e.g. range between 10 and 100 Om?

**Response**: We agree with the reviewer's assessment of our logic and the problems with using resistivities estimated via inversion from measured voltages at the water surface. As the reviewer points out, assigning a boundary of 15 Ohm to the frozen ground boundary is arbitrary and inconsistent with what we have previously written about the possible spatial extent of the transition from unfrozen to frozen.

To address these issues, we have changed from an arbitrarily defined IBP at 15 Ohm.m to a transition in the range of 10 to 100 Ohm.m, based on literature cited. We have also added explicit statement of the lack of validation data from this site and of our assumption to the methods section (please see track changes version of document). These changes are then

adopted for Figures 3, 6 and 7 (figure numbers in original manuscript), which now show the range of transition between 10 and 100 Ohm.m rather than an arbitrary value of 15 Ohm.m.

Another primary assumption is concerned about timing of the flooding for boreholes 304 and 305. On page 3755, Line 18, the authors state that "the time of submergence at any point along the geoelectric profiles can be calculated based on the assumption that past erosion rates are similar to the long term mean rates observed over the past sixty years." As a result, the authors suppose that the borehole 305 is flooded almost 250 years ago. This is a very strong hypothesis, which may lead to some erroneous results, since it involves extrapolation into the past for 250 years based on 60 years of measurements (4 times longer than the period of observations). On the other hand, it is possible to assume that it could have been a different erosion pattern the Muostakh Island. The spit, connecting the island to the Bykovsky Peninsula, could have eroded across its entire shoreline, not from the tip as the authors assume. Hence, the boreholes 304 and 305 could have been flooded much later, and hence the permafrost degradation rates could be estimated much differently.

**Response**: We agree that the assumption of more-or-less constant coastal erosion rates over time since the time of flooding of the boreholes is problematic. We cannot exclude the possibility that storm frequency, wave energy, or sea ice cover have changed over the period of interest, however. It would be reasonable to expect variability in these driving forces. We chose to make this assumption because it provides a first-order estimate, where otherwise none would exist, over a time period in which sea level rise was more or less a negligible source of variability. Our assumption is weakly supported by the fact that erosion rates in Siberia tend towards similar values the higher the temporal and spatial scales at which they are averaged. Nonetheless, this assumptions brings with it uncertainties that are difficult to quantify.

Unfortunately, no subsea permafrost drilling to validate the geoelectrically estimated location of the IBP surface was performed. Without the actual validation, there are always speculations about the location of the IBP surface. No right or wrong,.. nobody can give a definite answer without drilling and validating the geoelectrical survey.

**Response**: Validation is a requirement for good geophysical surveys. For this reason, we chose to make measurements where at least historical borehole data are available. Drilling did in fact take place in the spring following our surveys (April 2012), and could provide data for comparison. Unfortunately, the data are under embargo until published by the study's lead author. We decided not to wait for these data to be published and hope that they will appear soon. Knowing that thaw depths have been measured, however, we see value in providing the complementary geophysical data.

Anyways, in the present form of this manuscript, the reviewer do not see an in-depth analysis of all uncertainties and how the uncertainties influence the estimated rate of the IBP degradation.

**Response**: We agree that our paper did not address sources of uncertainty sufficiently, and hope that changes to the manuscript make these clearer.

It would be also great to put this study into the perspective of other submarine permafrost profiles displayed by M. N. Grigoriev in presentations, e.g. "The permafrost evolution of the shelf-coastal zone in the Eastern Russian Arctic", 2010, see the attached.

**Response**: This is a good point as well. We have added a reference to Grigoriev's figure to the discussion (figure 6.29 from his habilitation or doctoral thesis, 2008). However, for most

of the profiles pictured, coastal erosion rates do not exist, making a direct comparison to our results difficult. The permafrost table profile we observe, whether for, 1982/3 or 2011, falls within the range of profiles shown by Grigoriev.

# Specific comments:

1) P 3748, L 25: Regarding the "modelled water-layer resistivity value": What is the modeled value for the water? How does it correspond to the observation by the CTD datalogger? It looks like the observed resistivity value changes a lot. **Response**: We added the following text to the results section on water resistivity: "The water in Buor Khaya Bay is generally stratified, with a brack-water overlying colder saltier water. This position of this interface between the layers changes with time, in response to varying fluvial discharge rates and sea ice melting and freezing, and as a result of stormgenerated mixing (Günther et al., 2013) but is usually lower than 7 m bsl in summer. Geoelectric resistivity surveys took place in shallow water not subject to stratification. Seven surface water samples were collected during surveys on August 20 and 24, 2011. Their electrical conductivity was measured on the same day and ranged between 0.6 to 1.7 Ohm m. Based on these values, we used values of 0.65, 0.98 and 0.90 Ohm m for the western, drilling and eastern profiles, respectively."

2) What are the uncertainties in the estimated resistivity values? Please incorporate them into the analysis. On page 3754, Line 24: How were the error bars computed? **Response**: Based on changes in how we relate resistivity to sediment state, these values have now changed to correspond to the depth ranges between 10 and 100 Ohm m.

3) In figure 4, how do you derive the electrical resistivity for the boreholes? Is it based on formula (1)?

**Response**: Yes, it is based on application of Formula 1 to the analyses of TDS made on the pore solution of the sediment core material. We have added explicit statement of this to the figure caption. This is an empirical relationship that varies depending on solution composition. Given that differences in resistivity between saline and fresh water are large, however, it suffices as a basis for comparison. These results are expected to differ from resistivity of the bulk sediment, where the mineral component of sediment affects the bulk resistivity. We have added a reference to the equation to the figure caption.

4) Figure 5 might be omitted or better tied to the analysis.

**Response**: We have removed figure 5 as well as one reference to it (pg. 3752 line 20) and text referring to the figure in the discussions (pg. 3758 lines 15-20). Based on reviewer 2's comments, this figure has been replaced by photos.

# **Reviewer #2**

Overall assessment:

This is a well organized, presented, and written paper. It is topical for The Cryosphere Discussions and will be of interest to broad readership. The combination of techniques/tools used, the topic, and the field site location lead to a strong study. I recommend publication after addressal of a few comments/concerns.

**Response**: Thank you. We feel that both reviews, taken together, make a significant improvement to the paper, particularly with regard to consideration of uncertainties.

I urge the authors to provide a more holistic view/approach in the presentation of their results. For example, they ignore the sediment composition, ice content, and geomorphology of their coastal zone in their approach. This is described a bit more in the next paragraph and in my more specific comments.

I disagree that "past erosion rates are similar to the long term mean rates observed over the past sixty years." (p. 3755, lines 11-13). Changes in ice extent, storm fetch, wave and storm trajectories and the composition of permafrost coasts all play a role in heterogeneous erosion rates. The authors themselves have presented similar results in other studies. Perhaps they should say that the easiest and most "assumptive" approach is to assume linear rates but that to ascribe rates over time for ...

**Response**: We agree with you – please note that we do not assert that this is true. We had attempted to be open about the fact that this is a poorly supported assumption. Below, we describe changing the language on page 3755. Please see our response to more or less the same criticism from Reviewer 1 as well.

# Comments keyed to the text:

p. 3742 20: "profiles trace permafrost flooded" makes no sense

**Response::** replaced this sentence with: "We use geoelectrical estimates of IBP depth to estimate permafrost degradation rates since inundation. Degradation rates decreased from ..."

# p. 3743 5:

... there seems to be a comment missing here in the review. We have added "it is" to the second clause for clarity.

p. 3744 26: "probably" is a wimpy word. Be stronger. How about "likely" or cite a study to be even more strong.

**Response**: we removed the word "probably". There is no study, to our knowledge, that links coastal erosion to submarine permafrost degradation.

p. 3751 12: "The three periods with the most rapid rates were observed in the past nine years (2006–2007, 2007–2009, 2010–2011)." (p. 3755, lines 11-13). What does this say about the "past erosion rates are similar to the long term mean rates observed over the past sixty years" comment?

**Response**: The comment on "similar to the long-term mean observed over the past sixty years" with which we begin our discussion (Pg 3755 line 20) is not precise enough. In fact, we are assuming that the longest available observation period comes closest to the long term mean erosion rate. This seems a reasonable first order approximation Although it is not likely to be correct, since it ignores possible past variability in forcing factors for coastal erosion, it provides a "best guess".

The comment on the "three periods with the most rapid rates" applies to the observations made relative to the geodetic point at the north end of Muostakh Island only, which happens to be the only place where annual measurements for longer than a decade exist. Since this observation point is located on a spit, it is not ideal for estimating long-term rates. It is difficult to draw inferences on long term rates based on short-term recent variability at this location.

We have changed the sentence in the discussion to be more precise:

"Following this approach, the time of submergence at any point along the geoelectric profiles can be calculated based on the assumption that the longest available record of mean erosion rates (here observed over the past sixty years) provides the best approximation for long term mean annual erosion rates."

p. 3753 16: "huge" is a simply awful word. Provide dimensions, scale, comparative perspective, or a photo.

**Response**: Removed the word "huge" and referred to Günther et al. (2015), which is open access and supplies the dimensions and an estimate of volumetric ice contents. We have also replaced Figure 5 with photos of the eastern and western coastal bluffs.

p. 3754 12: the "no" as in "number" is not needed. It is not provided for any of the other core mentions.

# Response: removed.

p. 3756 13: "based on four years of"? As currently written, and with the number "4" it is unclear what this means. **Response**: changed to "Based on coastal erosion rates for a four-year period..."

17: "chosen as our field site" **Response**: adopted

p. 3757 line 5 and onward talks about the differences between western and eastern shores' p. 3758, line 25 onward also talks about differences between eastern and western shores. The differences in shore morphology, composition, and response to erosive forces is a potential strength of this paper. I recommend making the comparison a separate paragraph(s), perhaps even with a separate heading, to provide a more holistic view of the differences in morphology, ice content, sediment composition, bathymetry, wave fetch, freshwater inputs, and overall characteristics of the two areas. For example, p. 3757, lines 29 and 30 address a local characteristic likely endemic to that site/location. Can these unique characteristic be used to better predict/address how and where erosion will occur along the coasts? **Response**: We have added the following headings to the discussions: "Permafrost degradation following erosion", "Comparing profiles" and "Submarine permafrost degradation". We have added text to the second subsection adding detail on the composition and similarity of material exposed at the eastern and western coastal bluffs of Muostakh Island, and to the conclusions. p. 3757 8: "on flooded" makes no sense Removed
24: "The IBP table position" Adopted
p. 3759 3: "affect the degradation rate." Adopted
4: "are at least"? Adopted
p. 3760 23: no comma needed after "coast" Adopted
27: "year-round and degradation rates" Adopted

# Conclusions:

Again I feel the paper misses an opportunity to state how and where and why small scale processes or characteristics along the coastal zone can react to or armor against erosive forces. Ice content, slope, position, bathymetry, sediment characteristics, etc. This paper could move the ball forward.

The paper ends with: "other factors being equal, greater rates of coastal erosion generally lead to a shallower inclination of the IBP table close to shore. These results show that IBP degrades most rapidly immediately after it is inundated year-round, and that degradation rates slow over time. On this basis, it is likely that degradation rates for most of the Siberian shelf permafrost are less than 0.1ma-1. Combined geophysical surveys and drilling are required to better study the salt water diffusion into the permafrost after inundation."

I recommend identifying what in here is new or novel (not that much as it is is currently written) and then stressing that. How and where might the combined approach here be used elsewhere? What is missing or needed? End with more of a bang to make this a more impactful paper. Think about what is presented as text in the caption for Figure 8c. Expand on that.

**Response**: The following text has been added to the conclusions:

"We have shown that the coastal zone can produce estimates of degradation rates and that coastal dynamics and submarine permafrost degradation rates interact to determine the shape of the IBP table. This study suggests that much can be learned about how small-scale processes accelerate or slow the degradation of submarine permafrost through detailed study of local controls on thawing. After characterizing shoreface bathymetry, geomorphology and sediment composition (particularly ice content), measurements of annual and seasonal variations in benthic and sediment temperature and salinity, and sediment flux on the shoreface are needed. Such observations are difficult to collect in an automated fashion in this highly dynamic environment."

Figure 1b. This is a great Figure but comes across as TINY in my version. I hope it can be larger in size in final print?

**Response**: the figure has been re-formatted and the font sizes have been enlarged.

Figure 5. In the legend it says "freshet" and in the caption is says "freshwater." Be consistent.

**Response**: the figure has been removed in response to reviewer 1

Figure 6. Figure 3 has a mark at 15 mega-ohms. I suggest providing the same mark here.

**Response**: in response to the first reviewer, we have changed these figures to reflect a range of resistivities over which the transition from unfrozen to frozen may occur. This is now represented by different types of hatching/cross-hatching and is indicated in the legend for both figures.

Figure 7. I assume "a" means "annum"? Why not just say "years"? **Response**: changed

**Abstract.** Coastal erosion and flooding transform terrestrial landscapes into marine environments. In the Arctic, these processes inundate terrestrial permafrost with seawater and create submarine permafrost. Permafrost begins to warm under marine conditions, which can destabilize the sea floor and may release greenhouse gases. We report on the transition of terrestrial to submarine permafrost

- 5 at a site where the timing of inundation can be inferred from the rate of coastline retreat. On Muostakh Island in the central Laptev Sea, East Siberia, changes in annual coastline position have been measured for decades and vary highly spatially. We hypothesize that these rates are inversely related to the inclination of the upper surface of submarine ice-bonded permafrost (IBP) based on the consequent duration of inundation with increasing distance from the shoreline. We compared
- 10 rapidly eroding and stable coastal sections of Muostakh Island and find permafrost-table inclinations, determined using direct current resistivity, of 1% and 5%, respectively. Determinations of submarine IBP depth from a drilling transect in the early 1980s were compared to resistivity profiles from 2011. Based on borehole observations, the thickness of unfrozen sediment overlying the IBP increased from 0 up to 14 m below sea level with increasing distance from the shoreline. The
- 15 geoelectrical profiles showed thickening of the unfrozen sediment overlying ice-bonded permafrost over the 28 years since drilling took place. We use geoelectrical estimates of IBP depth to estimate permafrost degradation rates since inundation. Degradation rates decreased from over 0.4 m a<sup>-1</sup> following inundation to around 0.1 m a<sup>-1</sup> at the latest after 60 to 110 years and remained constant at this level as the duration of inundation increased to 250 years. We suggest that long-term rates a suggest that long-term rates a subscription of the latest after 60 to 250 years.
- 20 are lower than these values, as the depth to the IBP increases and thermal and pore water solute concentration gradients over depth decrease. For the study region, recent increases in coastal erosion rate and changes in benthic temperature and salinity regimes are expected to affect the depth to submarine permafrost, leading to coastal regions with shallower IBP.

## 1 Introduction

- Submarine permafrost refers to solid earth material below modern sea level that has perennial temperatures below 0 °C. It contains and traps significant amounts of methane and organic carbon, which may be released to the atmosphere during permafrost warming and thawing (McGuire et al., 2009), if it is not oxidized before it reaches the seabed (Overduin et al., 2015). Cold sediment temperatures stabilized by shelf permafrost extend the gas-hydrate stability zone (Dallimore and Collett, 1995)
- 30 and the frozen sediment may limit gas diffusion into the water column and atmosphere (Shakhova and Semiletov, 2007). Despite its importance, little of what we know about submarine permafrost distribution and temperature is based on direct observation, especially on the East Siberian shelves, which make up over 80 % of the potentially permafrost-affected arctic shelf area (Brown et al., 2001). Most submarine permafrost originally formed as terrestrial permafrost on arctic shelves, exposed
- 35 during late Pleistocene cold periods, which was subsequently inundated by rising sea levels following the last glacial period. Even today, rapid coastal retreat along the ice-rich coastline of the Laptev and East Siberian shelf seas causes about 10 km<sup>2</sup> of land loss annually (Grigoriev, 2008). Deglaciation after the Last Glacial Maximum led to sea-level rise in the Laptev Sea region more than ten times as rapid as modern rates (Bauch et al., 2001), inundating most of the more than 1.5 million
- 40 km<sup>2</sup> East Siberian shelf region within several thousand years. Both processes (coastal erosion and sea-level rise) covered cold (less than  $-2^{\circ}$ C at the seasonal damping depth) and thick (hundreds of meters) permafrost with sea water and seasonal sea ice, separating it from the cold air with mean annual temperatures of less than  $-10^{\circ}$ C. In the coastal zone (shallower than 10 m) of the Laptev Sea, bottom temperatures currently range from 1.6 °C in summer to  $-1.4^{\circ}$ C in winter (Dmitrenko
- 45 et al., 2011). After inundation, submarine permafrost began to equilibrate thermally with benthic temperatures. This temperature increase resulted in warming and thawing of permafrost below the sea-bed (Lachenbruch, 1957). Thawing also occurred due to penetration of salt-water into the sea-bed, which lowered the freezing point of the sediment's pore water. Thus, modern submarine permafrost can have temperatures below 0 °C but contain little or no ice. What is generally observed, by
- 50 geophysical methods or direct observation in sediment cores, is the depth of ice-bonded permafrost (IBP) below the sea floor (which is equivalent to the thickness of the overlying unfrozen sediment). Direct current resistivity and controlled source electromagnetic techniques for the investigation of submarine permafrost have been established in a number of studies (Barnes, 1963; Constable, 2010; Corwin, 1983; Sellmann et al., 1989). Laboratory measurements of the bulk electrical properties of
- 55 frozen porous media show the effect of ice content and thus saline pore water on electrical resistivity (Overduin et al., 2012). Sediment bulk electrical resistivity increases by orders of magnitude between ice-bonded, freshwater sediment and ice-free, saline sediment (Scott et al., 1990), making it suitable for the detection of the ice-bonded permafrost table.

Benthic temperature and salinity control warming of the sea floor and the rate of salt penetra-60 tion into the sediment column, but there are number of processes active in shallow water near the coastline that additionally affect permafrost following inundation. Sedimentation of eroded material, sediment re-suspension and transport by wave action and by currents and the entrainment of suspended material and sediment in sea ice are important in determining initial rates of degradation in water depths where wave cycles and ice gouging can turbate and erode the sea bed. Where the

- 65 water depth is less than the maximum sea ice thickness, bottom-fast ice (BFI) forms (Solomon et al., 2008). Sea ice has a higher thermal conductivity than sea water, and BFI thermally couples the sea floor to the cold winter air temperatures, which can lead to seasonal freezing of the sediment and the injection of brines into the sediment (Harrison, 1982). Since the rate of coastal erosion affects sed-iment flux, and therefore bathymetry, submarine permafrost degradation rates following inundation
- 70 are related to coastal erosion.

Our objective is to use inundation periods inferred from remote sensing, geophysical surveys and borehole observations of IBP to investigate the relationship between coastal erosion and submarine permafrost degradation beneath the shoreface

# 2 Study area

- 75 Muostakh Island (71.58° N, 130.01° E), a sliver of land about 40 km offshore of Tiksi in the Central Laptev Sea (Fig. 1), is an ideal site for the study of submarine permafrost processes (Are, 2003). About 10 km long and less than 500 m wide, the island is located 25 km north-east of the mainland and 15 km south-east of Bykovsky Peninsula. Ships leaving Tiksi, one of the major ports on the Northeast Passage, travel within sight of Muostakh Island, and it has therefore long been an object
- 80 of research, from as early as the late 19th century. This research includes studies of coastal dynamics, and coastline erosion rates observed at Muostakh Island in the Central Laptev Sea include some of the highest observed in the Arctic (Grigoriev et al., 2009). The island was originally the south-eastern continuation of the Bykovsky Peninsula coast and consists mainly of late Pleistocene Ice Complex (IC) deposits. IC deposits are ice-rich (Muostakh Island is composed of 87 % ground ice
- by volume; Günther et al. (2015)), polygenetic in origin, and characterized at the ground surface by the polygonal network of ice wedges formed over thousands of years by melt-water infiltration into cold winter thermal contraction cracks (Schirrmeister et al., 2011b). Coastal thermo-erosion on Muostakh Island varies widely in intensity (from close to 0 to over  $25 \text{ m a}^{-1}$ ) over a relatively small region (Grigoriev et al., 2009; Günther et al., 2015). The spatial variability of coastal retreat rates
- 90 along the island's coastline offers an opportunity to investigate its influence on submarine permafrost development while other aspects of environmental forcing are similar.

IC coastlines are prevalent throughout much of the Laptev and East Siberian seas. On Muostakh Island, IC deposits are exposed along the east coast from below sea level up to the island's surface. Much of the Chukchi and Beaufort seas coastlines are similarly ice-rich and can be expected to be

95 subject to the same mechanisms of geomorphologic change in response to shifts in environmental

drivers of coastal dynamics (Ping et al., 2011). Regionally, relevant shifts in the energy and water balances at the land-atmosphere interface (Boike et al., 2013), increases in Lena River discharge (Fedorova et al., 2015), and increases in the duration of open water and coastal erosion (Günther et al., 2015) have been recently observed, matching similar circumpolar observations (Barnhart et al., 2014).

#### **3** Materials and methods

100

## 3.1 Geodetic measurements of coastline position

Coastal change rates on Muostakh Island have been estimated since the early 1950s by combining on-site and remote sensing methods (Fig. 2; Grigoriev et al. (2009)). A geodetic benchmark was established near the northern end of the island in 1950. Measurements were made at irregular intervals thereafter, by measuring the distance from the geodetic benchmark to the top of the coastal bluff along various bearings, either with measuring tape or a theodolite. The coastline positions reported here were measured as the position of the upper edge of the coastal bluff along a bearing from the geodetic benchmark and the signal tower on Cape Muostakh, at the southern end of the Bykovsky

- 110 Peninsula. Since there were unrecorded differences from year to year in how measurements were carried out, it is difficult to assess uncertainty in the measurements. Sources of uncertainty include determination of the direction in which coastal position was measured, small differences in time of year for measurements, and difficulty in safely reaching the cliff edge. We conservatively estimate the measurements to be better than  $\pm 0.5$  m. Between measurements in 2010 and 2011, the geode-
- 115 tic reference point was toppled by coastal erosion. For purposes of continuity, a network of survey points was established by theodolite in 2011 immediately thereafter to make a continuation of the measurement series possible. Ground control points were established to align field observations with remote sensing data (Günther et al., 2013).

#### **3.2** Temperature and electrical resistivity

- 120 Benthic temperature and electrical conductivity were recorded using a bottom-moored conductivity  $(\pm 0.1 \,\mathrm{mS} \,\mathrm{cm}^{-1})$ , temperature  $(\pm 0.2 \,^{\circ}\mathrm{C})$  and water depth  $(\pm 0.2 \,^{\circ})$  (CTD) datalogger. The CTD datalogger (Minilogger, UIT Umwelttechnik GmbH) was mounted on a metal plate and deployed with two 50 m cables attached to anchors. By dredging with a cat's claw anchor after deployment, the cables could be snagged and the datalogger recovered. The datalogger was deployed at 71.672°
- 125 N, 129.996° E in 7.2 m water depth on August 10, 2008, just outside of the north-eastern corner of the frame for figure 2. Data were collected hourly between September 1, 2008 and August 31, 2009. Although electrical conductivity values were measured and recorded, the inverse value (electrical resistivity) is reported here for comparison to the results of the geoelectrical surveys.

## 3.3 Core and borehole data

- 130 Sediments of on-shore and off-shore permafrost north of Muostakh Island were drilled during the Northern Expedition of the Siberian Branch of the Soviet Academy of Sciences (SBSAS) Mel'nikov Permafrost Institute Yakutsk in 1982 and 1983. Six boreholes were sunk up to 54 m depth and 2.5 km off the shore (in 1983) along a straight line across the shallow water zone between Cape Muostakh at the southern end of the Bykovsky Peninsula and the northern cape of Muostakh Island (Kunitsky,
- 135 1989; Slagoda, 2004). The boreholes were drilled using a portable rotary drill rig and a dry drilling technique. Metal casing was drilled through the sea ice, water column and into the sediment to prevent water from entering the borehole. Temperature and geochemical data are summarized by Kunitsky (1989) while granulometric, cryolithologic and mineralogic data are presented by Slagoda (1993, 2004). Results from these publications, originally in Russian, are made available here to
- 140 a non-Russian readership. Observations made during drilling from the land-fast ice in spring and during laboratory investigation of the cores included sediment temperature and lithology, and porewater salinity. Borehole temperatures were measured in 1982 and 1983 using a thermistor string and a voltmeter. Sediment porewater from cores was analyzed for total dissolved solids, which was converted to electrical resistivity based on the resistivity of a sodium chloride solution:

145 
$$R = 0.55 \cdot TDS - 0.97$$

where R is the electrical resistivity in  $\Omega m$  and TDS are the total dissolved solids in g per 100 g solution. Locations of boreholes, their depths, water depth and the depth of the unfrozen/frozen interface beneath sea level are summarized in Table 1.

## 3.4 Electrical resistivity and time of inundation

- 150 Geoelectric surveys of submarine apparent resistivity collected on August 21-24, 2011 were combined with bathymetry measurements to invert for sub-bottom sediment resistivity, which gives an indication of the depths of saline sediment and of the underlying ice-bonded submarine permafrost. The results from three surveys are presented here, two profiles of 1.5 km length from the eastern and western coasts of the northern cape of Muostakh Island, as well as a profile of 4 km length along
- 155 the historical borehole profile (Fig. 1). The sub-bottom apparent electrical resistivity profiles were collected using an IRIS Syscal Pro<sup>TM</sup> Deep Marine system. Voltages were measured around an electrical current injection dipole of 10 m size, using a floating electrode streamer towed behind a small boat. The injection and potential electrodes were stainless steel plates (10 × 30 cm). Electrical potential was measured across 10 channels spanning between 20 and 110 m. Electrode position (relative
- to a GPS aboard the boat), the injection current, measured electrode pair potentials and water depth (using an echo-sounder with better than  $\pm 0.1$  m resolution attached to the boat) were recorded at intervals of at least 2 m as the array was towed. We used RES2DINV<sup>TM</sup> software to invert the apparent
- resistivity data via least-squares inversion for floating electrodes with a modelled water-layer resis-

tivity, allowing for a sharp change in modelled resistivity across sediment surface. Model resistivity

- 165 was smoothed to produce reasonable variations in the resistivity values. Prior to inversions, data values were inspected graphically and less than 0.1 % of collected apparent resistivities were identified as outliers and removed. Inversions required less than five iterations in order to reach better than 5 % RMS error between modelled and observed resistivity. Relating estimated sediment resistivity to ice content requires either measurements on sampled sediment or some rather arbitrary assumptions.
- 170 No resistivities were measured on samples from this site, since no recent drilling took place. Some literature values for sediment resistivity as a function of temperature, salinity and ice content exist. Kang and Lee (2015), for example, show an increase in electric resistivity on freezing for silt-sand mixtures with 40 % saturation from around  $100 \,\Omega m$  to over  $300 \,k\Omega m$ . For  $100 \,\%$  saturated mixtures with saline pore water, the resistivities can be expected to be around 4 to 10 times lower (Kang and
- 175 Lee, 2015). Laboratory measurements of saline silty and sandy sediment, similar in grain size distribution to those at Muostakh Island, show that ice is present in the sediment for bulk resistivities over  $10 \Omega m$  (Overduin et al., 2012), although the boundary between ice-free and ice-bonded sediment may not be sharply defined, so that resistivity changes gradually with depth. We consider that any sand-silt mixture that is ice-bonded with fresh porewater, as is the case here based on the pore water
- 180 concentrations from the drilling samples, and consistent with previous observations of submarine permafrost in the Laptev Sea, will have a resistivity not lower than  $10 \Omega m$ , and probably higher than  $100 \Omega m$ . This assumption is also based on laboratory measurements of bulk resistivity as a function of temperature and salinity for marine sediments which show that the change in bulk sediment resistivity from an unfrozen seawater-saturated sediment to a frozen ice-saturated sediment corresponds
- to a jump in resistivity from less than 10 to over  $100 \Omega m$  (Frolov, 1998; King et al., 1988; Overduin et al., 2012). Uncertainties in IBP depth estimated from resistivity profiles thus correspond to the depth range of the bulk sediment resistivity increase from 10 to  $100 \Omega m$ .

Mean submarine permafrost degradation rate was caluclated as the quotient of the depth to IBP  $(z_{pf})$  and the time of erosion (t<sub>0</sub>; time of inundation).  $z_{pf}$  was either observed in sediment recovered

- 190 from the boreholes, or was inferred from geoelectric inversions using the depth of the 10 and 100 Ωm isopleths. The time since inundation was determined using coastlines digitized from remotely sensed imagery. In addition to the remote sensing dataset used by Günther et al. (2015), we increased temporal resolution by adding coastal erosion observations based on a CORONA KH-4B satellite image dating from July 24 in 1969, a HEXAGON image from July 17, 1975, and a SPOT-4 image
- 195 taken on July 1, 2001. After stitching image tiles of the CORONA and HEXAGON images and pansharpening of the SPOT scene, each image was orthorectified to mean sea level using specific sensor models. In contrast to on-site measurements of the upper coastal bluff edge, we digitized the cliff bottom line as the location where inundation occurs in the form of thermo-abrasion (Are, 1988). For consistency with the 1983 drilling campaign, as an important baseline, the coastline of 1983
- 200 was reconstructed based on an interpolation between digitized coastlines from high resolution aerial

and satellite images (1951, 1964, 1969, 1975, 2001, 2010 and 2011). Taking digitized coastlines as isolines of equal time, we estimated the time of inundation ( $t_0$ ) at the location of each sounding in 2011. Given a mean coastal erosion rate of  $1.8 \text{ m a}^{-1}$  on Muostakh (Günther et al., 2015), interpolation was done to a raster size of 2 m, corresponding to a resolution of at least 1 year. However, our

205 geoelectric transects are concentrated around the northern cape, where more rapid erosion is taking place, resulting in an almost monthly resolution. For two of the transects, some of the geoelectric measurement sites lay within the region flooded by sea water since 1951 (83 soundings from the borehole profile and 337 from the eastern transects). We calculated the period of inundation ( $t_{sub}$ ) at the location of each sounding as:

210  $t_{sub} = t_{obs} - t_0$  (2)

where  $t_{obs}$  is the time of observation (2011) and  $t_0$  the time of inundation raster cell value. This yields a mean rate of submarine permafrost degradation for this period of:

$$r_{deg} = \frac{z_{pf}}{t_{sub}} \tag{3}$$

- Uncertainties in degradation rates derive from uncertainties in  $t_{sub}$  and  $z_{pf}$ . The former are better
- 215 than 1 year, based on the resolution of the shoreline rasterization. For the set of permafrost observations within the region for which remote sensing data exist, the positions of  $z_{pf}$  estimates for degradation rates are not based on extrapolation of coastal erosion rates from the current coastline, but on interpolation of coastline position between observations. Variations of coastal erosion rate on shorter time scales (the longest averaging period was 26 years between 1975 and 2001) may have
- 220 occurred as observed by ? on the Bykovsky Peninsula but cannot be quantified for Muostakh. Uncertainty in  $z_{pf}$  for borehole determinations was set at 0.5 m to allow for tidal variations (<0.3 m), sea level rise and uncertainty in determining core sediment depth in the borehole (estimated at better than 0.1m). For resistivity soundings, determining  $z_{pf}$  is somewhat arbitrary. We choose to select a range of resistivities within which variations in sediment characteristics may be accommodated
- 225 (and set the uncertainty to an arbitrary 1 m. Nautical charts of the early 1980s showing points of bathymetry measurements every 500 m and isobaths with an equidistance of 2 m were digitized and interpolated for the coastal waters around Muostakh Island, in order to account for shoreface profile changes.

#### 4 Results

## 230 4.1 Shoreface morphology

Figure 1 shows coastlines of Muostakh Island from two different points in time. Based on data from Grigoriev et al. (2009), the mean erosion rates for the northern cape of Muostakh Island for the period of record (1951-2014) was  $10.7 \text{ m a}^{-1}$  with variations between 2 and  $25 \text{ m a}^{-1}$  (Fig. 2). This

value includes multiple-year periods for which erosion rate was determined using remote sensing

- data. Observations between 1995 and 2014 were conducted in the field, and give a mean erosion rate of  $10.2 \text{ m a}^{-1}$ . Longer-term coastal erosion rates of over  $10 \text{ m a}^{-1}$  decreased to less than  $5 \text{ m a}^{-1}$ in 1984 and then fluctuated between 2 and  $10 \text{ m a}^{-1}$  until 2006. In 2006/2007, rates at the northern cape increased to  $25 \text{ m a}^{-1}$ . The three periods with the most rapid rates were observed in the past nine years (2006–2007, 2007–2009, 2010–2011). Rates of coastal retreat along the eastern shore of
- the island reported by Günther et al. (2015) confirm recent higher rates of erosion relative to the long-term means. In that context, the rates shown here are more indicative of the increased rates of land loss at the exposed cape than of changes in erosion rates for the island as a whole. For example, the western coast of Muostakh Island has had mean coastal erosion rates of less than  $1 \text{ m a}^{-1}$  (Fig. 1) for the past 60 years. The mean annual rates of erosion where the digitized coastlines intersected with
- the geoelectric profiles on the western and northeastern sides of the island over the period 1982-2011 were  $0.5 \text{ m a}^{-1}$  and  $6.5 \text{ m a}^{-1}$ , respectively, resulting in the inundation of 14 m (western shore) and over 180 m (eastern shore) of land over this period.

Based on positions reported in the field notes of the drilling campaigns (Kunitsky, 1989) core positions were charted and used to define the position of the northwestern geoelectrical resistivity

- 250 profile (Drilling profile in figure 1). Due to coastline retreat, the southern 1.4 km of this resistivity profile corresponded to what had been land at the time of coring in 1983, 645 m of which were within the drilling profile (Fig. 1). The altitude of the coastal bluff in 1983 exceeded 20 m asl (Fig. 3). Bathymetric profiling was used to survey modern water depths and comparisons showed that shoreward of 2 km in the historical data (Fig. 3), coastal retreat resulted in the erosion of the coastal bluff
- and eroded the shoreface profile, increasing water depths by up to 3 m. Changes in the bathymetric profile over 30 years from about 1.8 km out to 4 km were less than 0.4 m and probably within the uncertainty generated by interpolation of the historical bathymetry and by changes in water level. According to Kunitsky (1989), in 1983, water shallower than the thickness of the annual sea-ice cover extended out to around 150-200 m from the shore, corresponding to the extent of the BFI zone
- 260 which is separated from land-fast ice by cracks in sea ice. The intertidal zone exposed at low water levels and submerged at high-water levels resulted in a foreshore zone width of up to 180 m, where sea ice freezes to the bottom and isolated pockets of saline water up to 41 ‰ may collect (Kunitsky, 1989). Along the drilling profile, the unfrozen sediment layer increased in thickness from this border towards the sea, while landwards and in sand bars a seasonally frozen layer developed (Fig. 3, upper
- profile). In 2011, the mean depth along the entire profile was 2.76 m (Fig. 3, lower profile).

## 4.2 Water temperature and resistivity

Benthic water electrical conductivity and temperature measured between September 2008 and September 2009 in 7.2 m water depth directly before the east coast of the northern end of the island (Günther et al., 2013) varied strongly seasonally (Figs. 4a). Bottom water temperature dropped from over 8°C

- 270 on September 1 to negative temperatures by October 16, 2008. During most of this period, bottom water resistivity also fell, from peak values of 35  $\Omega$ m to less than 2  $\Omega$ m. At the end of the period of observation, from July 28 until the end of August in 2009, variations in temperature and resistivity fell within a similar range of values. After the late summer cooling period, from mid-October until the beginning of July, temperatures are below  $-0.8 \,^{\circ}\text{C}$  and resistivity is below  $3 \,\Omega\text{m}$ . In June, bot-
- tom water began to freshen at temperatures below -1 °C, eventually reaching summer values. In the 275 early summer, following breakup of the sea ice, high resistivity (>15  $\Omega$ m) bottom water varied in temperature, reaching peak values of 12 °C.

Beneath the sea ice, from the end of October until after mid-May, bottom water electrical resistivity was below  $1.7 \,\Omega {\rm m}$  (i. e. above a conductivity of  $6 \,{\rm mS \, cm^{-1}}$ ), whereas the influence of the Lena

- River discharge increased this value up to over  $10\,\Omega m$  (corresponding to electrical conductivity be-280 low  $1 \,\mathrm{mS \, cm^{-1}}$ ) for the early summer (June). In July, the freshwater at the sea bed warmed to over  $10^{\circ}$ C. Winter resistivity varied less than 0.5  $\Omega$ m, whereas open-water season resistivity (July to mid-October) varied between 0.1 and 30  $\Omega$ m. The mean annual bottom water temperature was 2.1 °C, and the mean annual bottom water resistivity was  $10\,\Omega m$  (corresponding to electrical conductivity of  $0.09 \,\mathrm{mS} \,\mathrm{cm}^{-1}$ ). 285

The water in Buor Khaya Bay is generally stratified, with a brack-water overlying colder saltier water. This position of this interface between the layers changes with time, in response to varying fluvial discharge rates and sea ice melting and freezing, and as a result of storm-generated mixing (Günther et al. (2013)) but is usually lower than 7 m bsl in summer. Geoelectric resistivity surveys

290 took place in shallow water not subject to stratification. Seven surface water samples were collected during surveys on August 20 and 24, 2011. Their electrical conductivity was measured on the same day and ranged between 0.6 to 1.7 Ohm m. Based on these values, we used values of 0.65, 0.98 and  $0.90\,\Omega{
m m}$  for the western, drilling and eastern profiles, respectively.

#### **4.3** Permafrost properties

- 295 The permafrost of Muostakh Island belongs to late Pleistocene Yedoma IC deposits that accumulated in the region between at least 46.8 and 19.5 ka BP based on radiocarbon ages (Schirrmeister et al., 2011a). It is overlain by a Holocene peat cover (Fig. 3). The IC is characterized by the occurrence of syngenetic ice wedges embedded in ice-rich silts and sands, peat horizons, and a considerable overall amount of organic carbon (total organic carbon content of up to 5% by weight; Schirrmeister et al.
- 300 (2011a)). The oldest IC deposits lie up to 10 m below modern sea level at Muostakh Island and are underlain by silts, sands and gravels interpreted as fluvial deposits of Pliocene to Early Pleistocene age (Fig. 3; Slagoda (2004)). Syngenetic ice wedges of former polygon tundra are up to 5 m wide and up to decameters deep. Intrasedimentary ice occurs in horizontal to subhorizontal ice bands, ice lenses, and ice cement. Ice wedges defined as macro ground ice by Günther et al. (2015) constitute
- 305 up to  $44 \pm 4.6$  vol %. Intrasedimentary ice adds another 43 vol % to the total ice content and sums up

to 87 vol % (Günther et al., 2015). Along both sides of the island, this high ground ice content renders the coastline susceptible to thermo-erosion. Thermokarst mounds (baidzherakhs) are left over when ice wedges melt, leaving these former polygon centers of the Yedoma IC preserved on the coastal bluff. They exist on both coasts of Musotakh island, which is underlain everywhere by Yedoma and

310 (shaped by Holocene thermokarst features, including an alas (former lake basin) that intersects the (western coast midway up the island (Fig. 5).

Assuming the same geological subsurface of the island, i.e. mainly Yedoma IC, the different shape of the island's eastern and western shore is controlled by intensity of coastal erosion. As intensively studied by Günther et al. (2015) the interplay of thermo-denudation and thermo-abrasion efficiently

- erodes the north-eastern coast while the western coast appears almost stable. Strong winds occur mainly during the winter season from S to SW direction when the sea is ice-covered (Günther et al., 2015) and have therefore no impact on coastal retreat. Due to its location close to the mainland coast, the maximum fetch from S to SW during the sea-ice free period is less than 50 km while the fetch from N to NE is nearly unlimited (Günther et al., 2015). The latter is of importance during the sea
- 320 (ice break-up when wind events prevail from N to NE directions, and cause rising water level and constant heavy swells that promote marine abrasion (thermo-abrasion).

# 4.4 Borehole observations

In the following analysis, we report borehole observations and geoelectric surveys with reference to depths or elevations relative to sea level. Since sea-level changes over time, these results are not

- 325 directly comparable. However, tidal variations around Tiksi are generally less than 10 cm, although storm surges can lead to larger changes in sea level, up to ±0.6 m. The net change in mean annual sea level recorded three times per month at the Tiksi tide gauge between May 1983 and August 2011 was 0.12 m (data from Arctic and Antarctic Research Institute, St. Petersburg, accessed at www.whoi.edu/science/po/arcticsealevel/laptev.html on March 16, 2015).
- Borehole temperatures are available for the cores 101, 304 and 305 obtained after drilling in May 1982 and June 1983 (Fig. 4b; Kunitsky, 1989). The on-shore core 101 shows the cold-temperature regime of terrestrial permafrost with almost stable ground temperatures of about -9 °C at the time of measurement that decrease slightly due to the seasonal winter signal in the upper 10 meters of the sediment (Fig. 4b). Both off-shore cores 304 and 305 have temperatures that increase upwards from
- about -2 °C at the borehole bottoms to 0 °C at the sediment surface. Saline sea water lowers the pore water freezing temperature and decreases the resistivity in the upper part of the profile (Fig. 4b). The boundary between IBP and ice-free (unfrozen) permafrost lay at a depth of 8.3 m bsl in core 304 and 16 m bsl in core 305. No boundary was encountered in core 101, which was frozen throughout. The IBP in the offshore boreholes was up to 7 °C warmer than temperatures measured in borehole
  101 at the shoreline.
  - 10

## **4.5** Profiles of electrical resistivity and bathymetry

The results from three surveys conducted between August 21 and 24, 2011 are presented here. Two profiles of 1.5 km length perpendicular to the eastern and western coasts of the northern cape of Muotakh Island, as well as one longer profile (4 km) along the borehole profile drilled 28 years earlier

- 345 (Figs. 1, 3 & 6; borehole 101 was drilled 29 years before surveying). Inverted bulk-sediment resistivities reached maximum values of 182 Ωm for the western profile, 180 Ωm for the drilling profile and 1300 Ωm for eastern profile. The depth to any of the isopleths of constant resistivity (e.g. 0, 40, 70, etc. Ωm) in 2011 was greater at each point along the drilling profile than observed in 1983. The range of values defined as containing the transition from thawed to frozen sediment (10 to 100 Ωm)
- 350 descended with distance from the coastline and extended beyond the maximum depth of the inversions from 220-500 m along the western profile, beyond 1050 m for the drilling profiles and beyond 1065 m for the eastern profile. The of depths corresponding to this transition zone at the locations of cores 101, 304 and 305 were 5.9 to 17.4 m bsl, 9.8 to >19 m bsl and 18 to >19 m bsl determined using geoelectric soundings in 2011 (Fig. 3). The depth of the 10 Ωm contour shows more variabil-
- ity with distance from the coastline than in either of the other profiles. There are two pronounced dips of more than 4 m, between borehole locations 302 and 303 and beyond borehole location 304. Deeper contour lines no longer show this variability in depth. The 25 Ωm dips from 8.4 to 16.8, 17.0, 16.0, 17.9 and to more than 19 m depth at the borehole locations. Differences between the position of the IBP observed in sediment recovered from the boreholes and the 25 Ωm (normalized to period)
- 360 of inundation) increase from  $0.3 \text{ m a}^{-1}$  at borehole 101 to  $0.5 \text{ m a}^{-1}$  at boreholes 301 and 302, and then decrease further offshore to  $0.3 \text{ m a}^{-1}$  at boreholes 303 and 304 and to  $0.1 \text{ m a}^{-1}$  at borehole 305. If we arbitrarily choose the 25  $\Omega$ m as a proxy for IBP, then these rates correspond to submarine permafrost degradation rates. Choosing other values would give somewhat different rates, but the trend observed would be the same.
- 365 For geoelectric soundings within the 1951 coastline, we linearly interpolated coastline positions from remote sensing imagery to geoelectric sounding position to estimate the period of inundation at each sounding. Figure 7 shows inferred mean submarine permafrost degradation rates since inundation as a function of these periods for soundings along the drilling profile and eastern profile. Since no interim determinations of IBP table depth were made since inundation, these degradation
- rates are mean rates for the period of inundation ending in 2011. Instantaneous rates of degradation at or nearer to the shore line are probably higher. Results indicate that initial submarine permafrost degradation rates following inundation range between 0.4 to over  $1.0 \text{ m a}^{-1}$  (using 10 and 100  $\Omega$ m isopleths), and that rates decrease over time, reaching a mean values between 0.1 and 0.3 m a<sup>-1</sup> sixty years after inundation. Assuming that the long-term erosion rate at the northern cape represents the
- mean rate since inundation, we can infer the duration of degradation for the borehole locations. In this case, the periods of inundation for boreholes 101, 304 and 305 were about 28, 112 and 253 years, respectively. Rates thus inferred were 0.18, 0.09 and 0.10 m a<sup>-1</sup> (Fig. 7).

## 5 Discussion

#### 5.1 Permafrost degradation following erosion

- As coastal retreat progresses, the rate of IBP degradation slows (Hutter and Straughan, 1999). Are (2003) suggests using the distance from shoreline to approximate a time scale of inundation. Following this approach, the time of submergence at any point along the geoelectric profiles can be calculated based on the assumption that the longest available record of mean erosion rates (here observed over the past sixty years) provides the best approximation for long term mean annual ero-
- **385 sion rates.** The decrease in degradation rate with prolonged period since inundation is visible in our geoelectric profiles as a steeper inclination of the IBP table closer to shore (Fig. 6). The length of inundation of points distal to the island are approximately 260 years on the eastern profile, and closer to 3500 years of erosion on the western profile (based on profile length of 1700 m and coastal retreat rates of 0.5 and  $6.5 \text{ m a}^{-1}$ , respectively). Using the positions of the geoelectrical soundings
- 390 for which date of inundation can be inferred, there is a decrease in the rate of degradation over time (Fig. 7). Nixon (1986) models a mean degradation rate of 0.1 m a<sup>-1</sup> after 50 years of degradation for sediments with a freezing point of −1.8 °C., matching the observations from the geoelectrical soundings shown in figure 3. Grigoriev 2008 shows a mean degradation rate of 0.05 m a−1 for 12 profiles of IBP for the Laptev and East Siberian Seas, with a range between 0.01 and 0.15 m a−1.
- 395 Over the long term, Nixon's 1986 model and these results show a decrease in degradation rate to levels less than  $0.1 \text{ m a}^{-1}$ , as the thermal and solute concentration gradients between the sea floor and the IBP table become less and less steep, decreasing fluxes of heat and salt, respectively.

Studies in Siberia and Alaska have shown that submarine permafrost degradation is most rapid following inundation, when the thickness of the unfrozen sediment layer overlying the IBP is small,

- and thermal and diffusion gradients are steepest (Are, 2003; Harrison, 1982). Figure 7 shows an asymptotic reduction in degradation rate as the length of inundation increases. The permafrost temperatures reported by Slagoda (2004) show warming of permafrost by almost 9 °C within the first 100 years of inundation (Fig. 4b), up to the freezing temperature of the pore space solution. Based on coastal erosion rates for a four-year period, Molochushkin (1978) estimates that warming of the
- permafrost off the eastern shore of Muostakh Island occurs at  $0.4 \,^{\circ}\text{C}\,a^{-1}$  over the first 10 years, but at an average rate of  $0.25 \,^{\circ}\text{C}\,a^{-1}$  for the first 30 years at a depth of 10 m below the sea floor.

## 5.2 Comparing profiles

Muostakh Island was chosen as our field site for studying submarine permafrost degradation because its coastal retreat rate varies widely within a small area, over which larger scale drivers, such as air
temperature, sea ice cover and storm events, can be assumed to be similar. Obvious differences between the eastern and western coasts include the orientation of the coastline, the potential maximum fetch before each coast, and the relative influence of riverine water and alongshore currents. Mean

coastal retreat rates on the western and eastern shores of the island have differed by a factor of 13 for the past decades. Along both shores, thermo-abrasion of the submarine shoreface results in offshore

- 415 transport of sediment, creating a concave submarine profile shape from the waterline out to about 1 km from shore. In contrast, mean water depth along the drilling profile was more than 2.5 m based on bathymetry measured during geoelectric surveying, throughout the profile. Although we could find no local sea ice thickness data for Muostakh Island, this exceeds probable maximum sea ice thickness. Ice thickness of 2.1 m was observed within 1 km of the coastline on the eastern shore of
- 420 Buor Khaya Bay at the end of winter in 2012 (Günther et al., 2013). Sediment is thermo-abraded and deposited here in roughly equal measure. Differences in IBP depth along this profile are the result of differences in the duration and/or rate of IBP degradation. Differences between the western and eastern shores may be the result not only of differing IBP degradation rates and inundation periods but also of sediment budgets. Molochushkin (1978) attributes the thicker unfrozen sediment
- 425 on the western side of Muostakh Island to the accumulation of marine sediment whereas erosion of sediment determines the depth to the IBP off the eastern shoreline. The similarity of the shoreface profiles suggests that this explanation is not sufficient to explain differences in IBP table inclination, however. Molochushkin and Gavrivev (1982) also present interstitial salinity profiles for two cores from positions northeast of Muostakh Island (mean TDS 6.4 g/100 g: 2.6 Ωm) and west of Muostakh
- 430 (mean TDS of 1.8 g per 100 g;  $<0.1 \Omega$ m) suggesting diffusion of seawater into the sediment rather than deposition under marine conditions.

The shape of the IBP table along the drilling profile is more complicated and may have depended on the shape of the northern cape over time. A distance 2.5 km from the 1983 coastline (core 305, Fig. 3) has probably been submerged for at least 250 years based on the mean erosion

- rate of  $10 \text{ m a}^{-1}$  for the period of record. Along the drilling profile, 645 m of the geoelectric profile have been inundated since drilling took place in 1982 and 1983 (Fig. 3). In figure 3, the position of the IBP table is interpolated linearly between borehole sites. In the geoelectric profile (Fig. 3), its position relative to sea level is determined at soundings spaced between 2 and 5 m apart along the entire profile. The IBP table position based on geoelectric soundings therefore shows more detail
- than the borehole profile. It shows a pronounced dip of over 7 m (from 8.5 to 15.6 m bsl) between the locations of boreholes 301 and 303, suggesting that the IBP there thawed more rapidly over the previous 28 years than locations closer to or further from shore. The slight rise in IBP beyond this dip corresponds to locally shallow parts of the 1983 bathymetry, where a sand bar resulted in water depth less than 1.5 m and where BFI probably formed each winter, allowing seasonal freezing of the
- 445 sea floor (Kunitsky (1989), borehole 303; also shown for Muostakh Island in Are (2003)). Although bathymetry can vary throughout the season and between years, the presence of BFI at least at the time of drilling may have led to cooling of the sediment and relative slowing of degradation locally (Osterkamp et al., 1989; Sellmann et al., 1992).

BFI acts as a thermal couple between the seabed and the atmosphere in winter, due to the higher

- 450 thermal conductivity of ice compared to seawater. This effect tends to delay permafrost degradation immediately after inundation, until bathymetry exceeds the maximum depth of winter ice thickness around 2 m, and the sea bed is covered by bottom water throughout the year (Osterkamp, 2001). Therefore, our observation of shallower IBP in places of former sand bars suggest that submarine permafrost preservation through thermal coupling of BFI outpaces the degradation effect associated
- with elevated brine concentration and injection under BFI. The duration of degradation on the abscissa in figure 7 includes any periods of BFI formation, and can therefore include a period of initial retardation of degradation. Molochushkin (1978) reports mean annual seawater temperatures at Muostakh of 0.2-0.3 °C and resistivities of 10 Ωm. Although the frequency and depth of measurements are not reported, these values are cooler than the 2.1 °C observed in this study but have the same mean salinity.

Differences in IBP depth between the eastern and western profiles may be the result of factors not observed in this study. For example, there may be systematic differences in benthic temperature and resistivity regimes on either side of Muostakh Island. We expect the sheltered western side to be

and re-suspension due to wave action on the eastern side, especially when winds are from the N to NNE, and/or fetch exceeds 100 km. Such differences change boundary conditions for submarine permafrost and affect the degradation rate. Nonetheless, the differences in IBP depth and inclination observed on either side of the island are at least consistent with differences in relative erosion rates even if permafrost degradation rates are assumed to be similar.

less affected by the outflow of the Lena River on the eastern side, whereas we expect greater mixing

### 470 5.3 Submarine permafrost degradation

Our results indicate that permafrost degradation rates at Muostakh Island are consistent with those inferred for near-shore sites elsewhere on the Siberian shelf (Overduin et al., 2007, 2015). Since we calculate a decrease in submarine permafrost degradation rate with increased duration of inundation, most of the Siberian shelf region, which has been inundated for longer periods, probably has lower rates than those observed here, near the coastline. The degradation rates that we infer for Muostakh Island are probably typical for permafrost near the coast and the sea floor, where vertical thermal and solute concentration gradients within the sediment are steeper than for most of the shelf region. Following inundation, ice content decreases throughout submarine permafrost due to warming and the consequent thaw of pore ice. Nicolsky et al. (2012) shows this as an increase in water content

based on assumed freezing characteristic curves. In this model, the rate of ice thaw depends on a suite of conditions during and antecedent to inundation. However, at 74.5° N, 118° E, for example, the depth of permafrost saturated to at least 50% by ice degrades from about 25 to 200 m bsf, a mean rate of just below 0.01 m a<sup>-1</sup> (Nicolsky et al., 2012). Romanovskii and Hubberten (2001) show even lower rates of degradation of ice-bonded permafrost (defined as liquid water contents of <5% by **485** (weight). Such slow rates of degradation make it difficult to detect changes in IBP depth. Further difficulties result from high uncertainties associated with geophysical techniques. As we observed, short-term changes in sea level and sediment dynamics can also create problems for comparing measurements made on multi-year time scales.

The rate of coastal retreat influences the inclination of the IBP within the sediment. The IBP table inclinations along the three georesistivity profiles are consistent with a relationship between coastal retreat rate and the inclination of the IBP table. If erosion is rapid, the IBP table will tend to lie closer to the sediment surface (Fig 8a; eastern profile). In cases where the coastal retreat rate is slow and permafrost degradation occurs, the inclination of the ice-bearing permafrost table will tend to be steeper (Fig. 8b; western profile). Thus, the duration of inundation and distance from the coastline are linked by the rate of coastline retreat, which is variable in time.

Observations of the inclination of the IBP table perpendicular to the coast in the Laptev and East Siberian seas show a high degree of spatial variability (Overduin et al., 2007), probably reflecting the temporally varying intensity of the processes described (Fig. 8c). Observing submarine permafrost depends on direct observation by drilling, sampling and temperature measurements (Fartyshev, 1993; Rachold et al., 2007) coupled with indirect observation using geophysical methods

500 tyshev, 1993; Rachold et al., 2007) coupled with indirect observation using geophysical methods sensitive to property changes between frozen and unfrozen sediment. Since the coastal zone is highly dynamic, especially during spring melt and fall freeze-up, the logistics of measurements and continuous monitoring are difficult, requiring innovative new instrumentation and platforms for use in shallow water.

#### 505 6 Conclusions

Offshore Soviet borehole data from 1982-1983 near the coast of Muostakh Island shows warming, salinization and increasing depth to ice-bonded submarine permafrost (IBP) with increasing distance from shore. Geoelectric surveys along the borehole profile 28 years later show that land has been inundated as a result of coastal erosion and suggest that the submarine permafrost created has degraded at mean rates of between 0.6 and 0.1 m a<sup>-1</sup> over decades to centuries. Based on comparison of two geoelectric profiles at an eroding and a stable stretch of coast we suggest that, other factors being equal, greater rates of coastal erosion generally lead to a shallower inclination of the IBP table close to shore. These results show that IBP degrades most rapidly immediately after it is inundated

year-round and degradation rates slow over time. On this basis, it is likely that degradation rates for

most of the Siberian shelf permafrost are less than  $0.1 \text{ m a}^{-1}$ . We have shown that the coastal zone can produce estimates of degradation rates and that coastal dynamics and submarine permafrost degradation rates interact to determine the shape of the IBP table. This study suggests that much can be learned about how small-scale processes accelerate or slow the degradation of submarine permafrost through detailed study of local controls on thawing. Shallow bathymetry, for example,

- 520 such as sand bars shallower than the maximum annual sea ice thickness, may lead to temporary stabilization of permafrost following erosion. After characterizing shoreface bathymetry, geomorphology and sediment composition (particularly ice content), measurements of annual and seasonal variations in benthic and sediment temperature and salinity, and sediment flux on the shoreface are needed.

Table 1. Borehole characteristics.

<sup>a</sup> data from Kunitsky (1989); Slagoda (1993, 2004); <sup>b</sup> IBP: ice-bonded permafrost

**Figure 3.** A comparison of the results of the drilling expedition in 1982 and 1983 with the inverted resistivity in 2011. The stratigraphy in the upper figure is based on the coastal exposures and the interpolation of borehole sediment stratigraphy, redrawn from Slagoda (2004). A range of resistivities (from 10 to  $100 \Omega$ m), inverted from measured apparent resistivities, is indicated with cross hacthing on the resistivity cross-section in the lower figure. The position of the IBP interpolated from the boreholes is repeated on the lower figure (dashed gray line) for reference. The vertical exaggeration is 37 times.

**Figure 4.** Water electrical resistivity and temperature are shown for: (a) bottom water measured for the period September 1, 2008 – August 31, 2009 in 7.2 m water depth and (b) for sediment pore water (based on eq. 1) from cores recovered from boreholes 101, 304 and 305 on the dates indicated (Figs. 1 & 3; Tab. 1).

**Figure 5.** Photographs of the western (top) and eastern (bottom) coastal bluffs show similarities in the height (ca. 22 m) and morphology. The presence of thermokarst mounds (baidzherakhs) characterizes both coasts, but the comparatively stable western baidzherakhs are completely vegetated, whereas pioneer species are sparsely established on the eastern baidzherakhs. The top of the eastern coastal bluff has over-hanging vegetative mats, below which melting polygon ice wedges are exposed. On the western coast, ice wedges have already to at least the depth of annual ground thaw.

Figure 6. Inversions of the georesistivity of the eastern and western geoelectric profiles (positions shown in Fig. 1).

Figure 7. Permafrost degradation rate inferred from geoelectric soundings and their positions, for the eastern and borehole geoelectric profiles and for three boreholes indicated by number (diamonds). Only soundings/boreholes located within the region eroded since 1951 are used. Degradation rates are shown for 10 and 100  $\Omega$ m are indicated with crosses and circles, respectively. The hatched area corresponds to the union of the hatched areas in Fig. 3b and Fig. 6.

**Figure 8.** The relative rates of coastline retreat and permafrost degradation affect the shape of the ice-bonded permafrost (IBP) table beneath the shoreface profile sediment. In A., rapid coastline retreat lead to an IBP table close to the sediment surface; in B., a stable coastline leads to an IBP table that is more steeply inclined; in C., most IBP table inclinations can be expected to reflect a complicated suite of factors, including temporally variable coastline retreat, permafrost degradation rates, and near-shore sediment dynamics.
