

Our response for editor comments:

1) Comment: Change the title to include the fact that you are focusing on the 'shortwave' component, as suggested by the reviewers.

Response: We have put shortwave in the title.

2) Comment: I encourage you to add updated citations for the snow cover trends, as , for example, the Arctic report card published every year (one reference would be the essay led by C. Derksen)

Response: We have added couple of more references from Arctic report. Also added some extra detail in section 3.3.

3) Comment: On Page 2, change concentrating to concentrates

Response: We changed it.

4) Comment: Please justify in the text why the analysis is until 2013. Most of the datasets should be available through 2015 or at least 2014

Response: When we finished our analysis, data only until 2013 was completely available. We did not want to include partial 2014 data for consistency. Data was only available after we finished our manuscript.

During our analysis, we found that including or removing the data for a year does not have any significant impact on the results. Hence, recreating the whole work for adding one more year (without any significant changes in the results) was not feasible during the review process. We also wanted to avoid any confusion created by many small changes made in the statistics.

We need another 5-10 years of data to observe any significant impact. Also the comparison period (2001-2008) between current study and Flanner et al., 2011 was not going to change. We need 20 years of MODIS data to do a comparison between two time-periods of same length. We have mentioned this in conclusion section of the manuscript.

5) Comment: One of the references (e.g. Box) is missing, please check that the references are properly cited and their format is correct

Response: We made sure that none of the references are missing anymore.

1 The Global Land Shortwave Cryosphere Radiative Effect 2 during the MODIS era

7 8 **Abstract**

9 The shortwave Cryosphere Radiative Effect (CrRE) is the instantaneous influence of snow-
10 and ice-cover on Earth's top of atmosphere (TOA) solar energy budget. Here, we apply
11 measurements from the Moderate Resolution Imaging Spectroradiometer (MODIS),
12 combined with microwave retrievals of snow presence and radiative kernels produced from 4
13 different models, to derive CrRE over global land during 2001–2013. We estimate global
14 annual mean land CrRE during this period of -2.6 W/m^2 , with variations from -2.2 to -3.0
15 W/m^2 resulting from use of different kernels, and variations of -2.4 to -2.6 W/m^2 resulting
16 from different algorithmic determinations of snow presence and surface albedo. Slightly
17 more than half of the global land CrRE originates from perennial snow on Antarctica,
18 whereas the majority of the northern hemisphere effect originates from seasonal snow.
19 Consequently, the northern hemisphere land CrRE peaks at -6.0 W/m^2 in April, whereas the
20 southern hemisphere effect more closely follows the austral insolation cycle, peaking at -9.0
21 W/m^2 in December. Mountain glaciers resolved in 0.05 degree MODIS data contribute about
22 -0.037 W/m^2 (1.4%) of the global effect, with the majority (94%) of this contribution
23 originating from the Himalayas. Inter-annual trends in the global annual mean land CrRE are
24 not statistically significant during the MODIS era, but trends are positive (less negative) over
25 large areas of Northern Asia, especially during spring, and slightly negative over Antarctica,
26 possibly due to increased snowfall. During a common overlap period of 2001–2008, our
27 MODIS estimates of the northern hemisphere land CrRE are about 18% smaller (less
28 negative) than previous estimates derived from coarse-resolution AVHRR data, though inter-
29 annual variations are well correlated ($r=0.78$), indicating that these data are useful in
30 determining longer term trends in land CrRE.

1 **1 Introduction**

2 Snow- and ice-covered surfaces are the most reflective regions on Earth, and their extent can
3 change substantially with small changes in climate. The presence of Earth's cryosphere
4 greatly alters the planet's albedo and changes in cryospheric extent and reflectivity therefore
5 partially determine the sensitivity of climate to anthropogenic and external forcings. After
6 water-vapor and cloud feedback, the albedo feedback is the third most powerful positive
7 feedback mechanisms operating within the current climate system (e.g., *Bony et al.*, 2006;
8 *Winton*, 2006; *Randall et al.*, 2007; *Soden et al.*, 2008; *Shell et al.*, 2008; *Flato et al.*, 2013).

9 Earth's Cryosphere has shown compelling indications of climate change during recent
10 decades, including mass loss from ice sheets and glaciers (e.g., *Rignot et al.*, 2011, *Gardner*
11 *et al.*, 2013), rapid ablation of autumn Arctic sea-ice (e.g., *Serreze et al.*, 2007; *Stroeve et al.*,
12 2012), and reduced seasonal snow coverage (e.g., *Dery and Brown*, 2007; *Brown and*
13 *Robinson*, 2011). The Arctic is one of the most sensitive regions on Earth to global climate
14 change (*Manabe et al.*, 1992; *Manabe and Stouffer* 1994; *Miller and Russell* 2000; *Meehl and*
15 *Washington* 1990). Several recent studies (e.g., *Chapman and Walsh*, 2007, *Monaghan et al.*,
16 2008, *Steig et al.*, 2009) have shown that climate is also warming over west Antarctica, and is
17 related to Pacific Ocean warming (*Ding et al.*, 2011) and circumpolar winds.

18 The shortwave Cryosphere Radiative Effect (CrRE) is the instantaneous influence of snow-
19 and ice-cover on Earth's top of atmosphere (TOA) solar energy budget (*Flanner et al.*, 2011;
20 *Hudson*, 2011; *Perket et al.*, 2014). CrRE depends not only on snow and sea-ice coverage,
21 but also on local insolation, cloud cover, and properties of the snow, ice and their underlying
22 surface that determine reflectance. These features determine the impacts of cryospheric
23 presence on net TOA solar flux (e.g., *Winton*, 2006; *Qu and Hall*, 2005). Changes in the
24 extent of seasonal snow cover and sea-ice can drive large changes in CrRE on sub-decadal
25 timescales, whereas the areal coverage of ice sheets and glaciers tend to evolve on much
26 longer timescales. The presence of the cryosphere also perturbs Earth's longwave energy
27 budget, e.g., through changes in emissivity and surface temperature resulting from the
28 insulating effect of snow and the change in surface elevation induced by ice sheets. This
29 study, however, concentrates exclusively on the shortwave component of CrRE (hereafter
30 referred to simply as CrRE).

31 Our work focuses on developing a global, gridded, time-resolved dataset of the land-based
32 CrRE, using modern remote sensing observation of surface albedo and snow presence;

1 combined with radiative kernels that provide TOA radiative impacts. *Flanner et al* (2011)
2 derived a 30-year record of the northern hemisphere CrRE from coarse-resolution
3 determinations of snow cover extent. Here we apply higher-resolution, higher quality remote
4 sensing data from the MODerate-resolution Imaging Spectroradiometer (MODIS) to derive
5 global land-based CrRE over 2001-2013, helping inform on the utility of the longer-term
6 record derived by *Flanner et al* (2011), and broadening the scope of these estimates to
7 include the southern hemisphere. We generate CrRE for both all-sky and clear-sky conditions
8 to help assess the masking effect of clouds and atmospheric aerosols. We provide statistics
9 including global, hemispheric, glaciated and non-glaciated land CrRE averages. We also
10 perform multiple analyses to determine the sensitivity of our estimates to the use of different
11 thresholds for snow cover determinations, different climatologies for missing data, and
12 radiative kernels generated with different distributions of clouds. These sensitivity analyses
13 help us identify the sources of uncertainty that have relatively high impact on CrRE. In this
14 paper, we focus only on land based CrRE, and refer readers to other recent estimates of CrRE
15 from Arctic sea-ice (*Pistone et al.*, 2014; *Cao et al.*, 2015).

16 **2 Methods**

17 **2.1 Satellite Dataset Used**

18 MODIS MCD43C3 collection 5 surface albedo data (e.g., *Schaaf et al.*, 2002) and
19 accompanying snow coverage statistic (both provided at spatial resolution $0.05^\circ \times 0.05^\circ$) are
20 the primary input datasets we use to generate land based CrRE (LCrRE) at 16-day resolution.
21 The snow presence parameter (0-100%) is a measure of the fraction of native measurements
22 within each 16-day period and each 0.05° pixel in which the presence of snow was detected.
23 We assume any pixel with snow coverage greater than zero has a surface albedo that was
24 affected by the presence of snow. We apply data with quality flag 4 and better to maximize
25 the spatial and temporal coverage of albedo measurements. Missing data in this collection
26 arise from cloud cover and absence of sunlight at high latitudes during winter. To derive a
27 spatially and temporally continuous LCrRE record, we also apply snow-cover information
28 from the Near-real-time Ice and Snow Extent (NISE) dataset (*Nolin et al.*, 1998), as described
29 in the next subsection. NISE provides daily binary snow-cover at 25 km Equal-Area Scalable
30 Earth Grid (EASE-grid) spatial resolution, projected on a polar stereographic grid. Because it
31 is determined from microwave remote sensing observations, it offers estimates of snow
32 presence under all conditions, including environments with clouds and low illumination.

1 Since these datasets have different spatial resolutions, the NISE dataset has been remapped to
2 the higher resolution MODIS grid prior to analysis.

3 We use global gridded estimates of snow-free albedo derived from MODIS (*Moody et al.*,
4 2008), also provided at 16-day and 0.05 degree resolution, as a baseline for determining the
5 surface albedo contrast induced by snow. These data are climatological 16-day averages
6 derived from 2000-2004 MODIS measurements.

7 **2.2 Global Albedo Climatology for filling missing data**

8 A 16-day global surface-albedo climatology with spatial resolution of $0.05^\circ \times 0.05^\circ$ is
9 generated to fill any missing MODIS data-points, using the following steps:

10 *Step 1:* For each pixel and each 16-day period of the year, we take the average albedo over all
11 the years (2001-2013) of MODIS data during periods with valid measurements and non-zero
12 snow cover. Since this is a seasonally-varying gridded climatology, it is primarily used to
13 replace albedo of missing MODIS data in situations deemed to be snow-covered in the NISE
14 dataset.

15 *Step 2:* We take the annual mean of the albedo values generated from the previous step for
16 each snow-covered unfilled pixel in step 1. We only apply this average at locations and times
17 when the climatology from step 1 does not provide valid data (e.g., at pixels and 16-day
18 intervals that had substantial cloud cover during each of the 13 years of MODIS
19 observations).

20 *Step 3:* Albedo values generated from the previous two steps are averaged spatially over all
21 pixels within each land classification type defined in the MODIS MCD12C1 product using
22 IGBP (Type 1) land cover classification. This procedure produces an annual-mean snow-
23 covered albedo climatology by land classification (listed in Table A.1), and is used to fill any
24 remaining missing pixels unfilled by steps 1 and 2.

25 MCD12C1 provides the global dominant land cover types at $0.05^\circ \times 0.05^\circ$ spatial resolution. It
26 is continuous and therefore completely eliminates the chance of having any missing pixels
27 after applying step 3.

28 Although the snow-free surface albedo dataset is continuous, it is undefined in regions with
29 large solar zenith angle or near-permanent snow cover. To define snow-free albedo in these

1 regions, we apply annual averages of the snow-free albedo values for each pixel (similar to
2 method applied in step 2).

3 The ice-free surface albedo for permanent glaciated areas (e.g. Greenland, Antarctica) is
4 assumed to be 0.26, an average value of snow-free albedo over barren land (*Flanner et al.*,
5 2011). This assumption enables a rough estimate of the TOA impact associated with presence
6 of the full ice sheets. While our estimates of absolute LCrRE in these regions are therefore
7 subject to ambiguities (such as the type of vegetation that would thrive without the ice sheet),
8 seasonal and inter-annual changes in glacier surface albedo, e.g., as caused by altered
9 insolation, melt extent, and snow metamorphic state, drive changes in LCrRE that are
10 unaffected by this assumption, since the ice-free albedo is assumed to be static.

11 Considering the current bed topography removal of the West Antarctic Ice Sheet would
12 expose open-ocean (albedo 0.07). Although, we still use barren land albedo because of
13 several other uncertain effects that would occur in the event of total ice sheet ablation, e.g.,
14 isostatic rebound of land, sea-level rise, encroachment of vegetation over open land. Our
15 objective is to quantify the instantaneous LCrRE and quantifying all the aforementioned
16 uncertainties in this study are beyond the scope of this paper. We also note that the MODIS
17 land mask applied in our study excludes ice shelves.

18 **2.3 Methodology**

19 Our interest lies in the change in solar energy reflected because of snow, and we therefore
20 assume that measured albedo increase in the presence of snow, relative to the snow free state,
21 is caused entirely by snow. *Flanner et al* (2011) employed a definition of CrRE that utilizes
22 snow cover fraction, in order to facilitate the use of snow extent data without coincident
23 albedo measurements from several decades ago. Here we utilize a simpler definition that
24 omits snow cover fraction, since we have direct measurements of surface albedo from
25 MODIS. Using this approach, the mathematical framework to describe CrRE at time t within
26 a region R that is composed of N partially snow- or ice-covered grid-cells i is:

$$27 \quad CrRE(t, R) = \frac{1}{A(R)} \sum_{i=1}^N \text{Max}[(\alpha(t, i) - \alpha_{\text{snow-free}}(t, i)), 0] \frac{\partial F}{\partial \alpha}(t, i) A(i) \quad (1)$$

28 where A is area, $\alpha - \alpha_{\text{snow-free}}$ is the albedo contrast ($\Delta\alpha$), and $\partial F/\partial \alpha$ is the change in TOA
29 net solar energy flux with changing surface albedo. The ‘Max’ function is used to avoid any
30 negative albedo contrast values. We determine $\partial F/\partial \alpha$ using radiative kernels that provide
31 the instantaneous effect on TOA energy budget associated with small perturbations in surface

1 albedo (e.g., *Shell et al.*, 2008). This equation is only applied to gridcells where snow
2 presence has been detected, and LCrRE is otherwise assumed to be zero.

3 We created kernel datasets using the general framework of *Perket et al.*, (2014), using the
4 Community Atmosphere Model versions 4 and 5 (CAM4 and CAM5). TOA energy fluxes
5 were calculated with and without surface albedo perturbations every model time-step for one
6 year of simulation, and flux differences were then averaged into monthly resolved kernels.
7 We also apply radiative kernels generated previously with the CAM3 model (*Shell et al.*,
8 2008) and Geophysical Fluid Dynamics Laboratory Atmosphere Model (AM2) (*Soden et al.*,
9 2008).

10 A graphical representation of the basic algorithm used in our analysis is shown in Fig.1, and
11 can be summarized as follows:

- 12 a) We first check for the presence of snow in a particular pixel using MODIS data. If snow
13 was present at any time during the 16-day retrieval (snow flag >0) then the difference
14 between actual (16-day) surface albedo and snow-free albedo is taken as the albedo
15 contrast.
- 16 b) If MODIS data were missing then presence of snow is checked using NISE data. If snow
17 is present during some or all of the 16-day period, then albedo contrast is determined by
18 taking the difference between climatological snow-covered albedo for that gridcell (and
19 time of year, as described in the previous subsection) and snow-free albedo. Since the
20 NISE dataset is continuous and daily-resolved, we are able to determine those situations
21 when a particular pixel was covered with snow for only a portion of the 16-day period of
22 MODIS measurements. In those cases, if a pixel is covered with snow for D days out of
23 16, then the albedo contrast is multiplied with a scaling factor of $D/16$.
- 24 c) If MODIS determines a pixel is not snow-covered (snow flag = 0) or in the absence of
25 MODIS data if NISE does not indicate any snow ($D = 0$), then albedo contrast and
26 LCrRE are set to zero for that pixel.
- 27 d) After determining the albedo contrast, this term is multiplied with the various radiative
28 kernels to derive different estimates of all-sky and clear-sky LCrRE. Except as noted in
29 sensitivity studies described later, subsequent LCrRE results are derived from the CAM4
30 radiative kernel, which simulates an intermediate level of cloud masking compared with
31 the other kernels.

32 **3 Results and Discussion**

33 **3.1 Spatial and Seasonal Variability of the Mean Climate State**

1 All-sky global annual-mean LCrRE during 2001-2013 calculated using the CAM4 kernel is -
2 2.58 Wm^{-2} , and ranges from -2.16 to -2.96 Wm^{-2} with application of different radiative
3 kernels. Table 1a shows LCrRE averages over different domains and calculated with different
4 radiative kernels. Permanent glaciated regions (e.g., Greenland and Antarctica) contribute
5 about two-thirds of the net global LCrRE, due to their persistently high albedo around the
6 year. For this discussion, land classified as snow or ice in the MODIS MCD12C1 land type
7 dataset (Appendix A) is considered as permanently glaciated.

8 Due to the size of the Antarctic Ice Sheet, the Southern Hemisphere contributes about 60% of
9 the global LCrRE. On the other hand, non-glaciated regions in Northern Hemisphere
10 contribute about 32% of the global LCrRE. Because the areal extent of seasonal snow has
11 little "memory" beyond a year, non-glaciated component of the LCrRE can respond rapidly to
12 climate change and drive albedo feedback on sub-decadal timescales. Impact of non-glaciated
13 region in Southern Hemisphere is negligible because of less land presence at mid and high
14 latitudes (Fig. 2), contributing only about 0.08% of the global LCrRE. In the Northern
15 Hemisphere, non-glaciated regions contribute about 3.7 times more to LCrRE than glaciated
16 areas. LCrRE associated with permanent glacier cover in mountain regions (e.g., the
17 Himalaya) is also clearly visible, even though they are situated at much lower latitudes (Fig.
18 2). Table 1b and 1c shows percentage contribution of different domains and separate land
19 masses to the global LCrRE respectively.

20 Clear-sky LCrRE values are expectedly higher than all-sky LCrRE values because of the
21 absence of cloud scattering. Similarly, all-sky LCrRE derived from the CAM5 kernel is
22 higher than that derived from the CAM4 kernel because cloud masking is substantially less in
23 CAM5, due to the prevalence of thinner clouds (*Kay et al., 2012, Perket et al., 2014*). AM2
24 and CAM4 values are similar, indicating a similar degree of cloud masking in these two
25 kernels, whereas the CAM3 kernel provides substantially greater attenuation of surface
26 albedo anomalies at the TOA (*Flanner et al., 2011*). *Cao et al., (2015)* determined that the
27 CAM3 and AM2 radiative kernels likely mask too much of the Arctic sea-ice radiative effect,
28 but it is unclear if these kernel biases exist over land and have persisted in the more modern
29 CAM4 and CAM5 models.

30 Fig. 3 shows global and hemispheric monthly variations of LCrRE for both all-sky and clear-
31 sky conditions. Seasonal variations are apparent in both hemispheres. LCrRE values peak
32 (become most negative) during April in the Northern Hemisphere, about 2 months before the

1 peak boreal solstice insolation. On the other hand, Southern Hemisphere LCrRE peaks in
2 December, during maximum austral insolation. These differences occur because the Northern
3 Hemisphere LCrRE is dominated by seasonal snow, while Southern Hemisphere LCrRE is
4 dominated by permanent glaciated Antarctica, and thus the seasonal cycle of LCrRE is
5 determined more directly by insolation in the Southern Hemisphere. Spatial distributions of
6 tri-monthly seasonal averages of LCrRE are shown in Fig. 4, indicating the same insolation-
7 modulated tendencies over glaciated terrain described earlier. The timing of peak LCrRE in
8 regions with seasonal snow, however, depends on the timing of melt onset, which almost
9 always precedes the peak insolation period.

10 Peak LCrRE over glaciated regions of the Northern Hemisphere occurs in May, lagging the
11 peak over non-glaciated regions by about one month (Fig. 5). Glaciated LCrRE in the
12 Northern Hemisphere peaks before the summer solstice because Greenland surface albedo
13 decreases between May and the end of June as summer melt commences. This tendency is
14 not apparent over Antarctica because a smaller portion of the Antarctic Ice Sheet experiences
15 surface melt during summer. Also the LCrRE change is more gradual for glaciated than non-
16 glaciated regions during both melting and freezing seasons. As the temperature rises,
17 temporary snow over non-glaciated land ablates relatively quickly. This causes a rapid
18 decrease in surface albedo and hence lowering of the albedo contrast. Similar observations
19 cannot be made for Southern Hemisphere due to negligible LCrRE contribution from non-
20 glaciated region. Global LCrRE values show less seasonal variation than the hemispheric
21 averages because they are basically averages of two hemispheric seasonal cycles that are
22 somewhat out of phase with each other. Nonetheless, global LCrRE does exhibit a minimum
23 during July and August, when there is little seasonal snow cover in the Northern Hemisphere
24 and Antarctica receives little insolation.

25 We observe a contribution of about -0.037 Wm^{-2} (1.43% of the global total) from high
26 mountainous regions (Himalayas, Andes, etc.) towards global LCrRE. The Himalayan region
27 alone contributes about 93.8% of the total mountainous region LCrRE. (Here, we define the
28 high mountainous contribution to LCrRE as that coming from permanent glaciated areas
29 between latitudes of 60°S and 60°N .) The contribution from these high-altitude areas is
30 relatively smaller but consistent throughout the year. Our use of 0.05 degree resolution data
31 allows us to determine LCrRE over many regions with patchy snow extent, though mountain
32 snow cover varies substantially on even smaller spatial scales. Fig. 6 shows LCrRE
33 contribution of the Andes and the Himalayas averaged over the MODIS era.

1 **3.2 Sensitivity Analysis**

2 A sensitivity analysis of LCrRE has been done to estimate its dependence on various
3 parameters included in the algorithm (Table 2). In this part of the study, CAM4 kernels are
4 used and other parameters are varied. The first column represents the LCrRE values from the
5 default case using the algorithm discussed in section 2.3 (Fig. 1). The second column lists
6 LCrRE values generated using only the NISE snow flag (i.e., snow presence is determined
7 exclusively with NISE measurements, rather than MODIS). Differences between these
8 estimates are due to the different remote sensing techniques applied to determine snow
9 presence and different spatial and temporal resolutions of the NISE and MODIS datasets.

10 The third and fourth columns are similar to first and second columns, respectively, but apply
11 the land class climatology of albedo contrast instead of spatially- and temporally-varying
12 albedo contrast (section 2.2). The derivation of these land class climatology values is
13 described in step 3 of section 2.2. A list of mean albedo values and standard deviations for
14 the different land classes is provided in Appendix A. In these cases land class climatology
15 albedo values have been used irrespective of data availability in MODIS, in combination with
16 snow presence determined from MODIS+NISE (column 3) and exclusively from NISE
17 (column 4). This sensitivity study is designed to assess the utility of using much simpler
18 estimates of snow-covered albedo than our more involved space- and time-dependent
19 estimates.

20 LCrRE values in the second, third and fourth columns (Table 2) are very similar to each
21 other. In all three cases the estimated LCrRE is lower than the original analysis (column 1).
22 This indicates the dependence of LCrRE on MODIS snow flag and global albedo
23 climatology, and changing either of those drops the LCrRE estimates by about 8% globally.
24 Also when land class climatological albedos are used, LCrRE is very similar for different
25 choice of snow flags. This may be due to the fact that the land class climatology only depends
26 on land class type and does not vary with time.

27 MODIS MCD43C3 albedo data are accompanied by quality flags, indicating the fraction of
28 input measurements to each 16-day data point that were made under cloud-free conditions
29 with sufficiently small solar zenith angle (e.g., *Schaaf et al*, 2002). Table 3 shows a
30 comparative study of LCrRE determined without quality flag filtering (i.e., quality flag 4 and
31 better), and determined using only quality flag 2 or better albedo data. Quality flag 2 is
32 mixed, with 75% or less of the underlying data derived from inverting reflectance for the

1 BRDF retrievals, and 25% or less of the underlying data filled. Using better albedo data
2 (lower quality flag) does not make a significant difference in our determination of global
3 LCrRE. This indicates that the fill values applied in the MCD43C3 retrieval algorithm are
4 similar to our developed climatology (section 2.2).

5 **3.3 Inter-annual trends**

6 Annual global LCrRE averages do not show significant inter-annual trends during the
7 MODIS era (Fig. 7), perhaps partially due to the relatively short duration of this period.
8 Slopes for global, northern hemisphere and southern hemisphere LCrRE are $-2 \times 10^{-3} \text{ Wm}^{-2}\text{yr}^{-1}$,
9 $-1.3 \times 10^{-3} \text{ Wm}^{-2}\text{yr}^{-1}$ and $7.3 \times 10^{-4} \text{ Wm}^{-2}\text{yr}^{-1}$, respectively. These trends are not significant at
10 the 95% confidence level.

11 To better understand the LCrRE trend, pixel-by-pixel trend maps have been generated using
12 the Mann-Kendall regression technique with 95% significance level (Fig. 8). A strong
13 positive trend (indicating less negative LCrRE) is observed over some regions of the
14 Northern Hemisphere, especially over Northern Asia during the spring season (Fig. 8b).
15 Positive trends over seasonally snow covered areas are most likely due to a decrease in snow
16 coverage (e.g., *Qu and Hall, 2007; Vaughan et al., 2013*), and the trend in LCrRE that we
17 find over Northern Asia is consistent with studies showing recent declines in snow cover over
18 this region (e.g., *Dery and Brown, 2007; Brown and Robinson, 2011; Derksen et al., 2014*).
19 Possible reasons for the positive trends seen over Greenland include: 1) increased snow
20 metamorphism and black carbon deposition (e.g., *Box et al, 2012; Keegan et al., 2014*), 2)
21 transport and deposition of dust and other light-absorbing impurities over the ice-sheets due
22 to increased dust source areas associated with increased snow-free area (*Dumont et al., 2014*),
23 3) higher melt extent across the Greenland ice sheet expose more fresh water at the surface
24 (*Tedesco et al., 2014*) and 4) MODIS sensor degradation on the Terra satellite during recent
25 years (*Sun et al., 2014; Lyapustin et al., 2014*), which would indicate a spurious decline in
26 albedo.

27 We also observe slightly negative LCrRE trends over Antarctica, which may be due to
28 increases in snowfall that have decreased the duration that surface snow has to “age”, thereby
29 increasing surface albedo (*Picard et al., 2012*). Interestingly, LCrRE has also become more
30 negative over some regions of Central Asia, presumably due to increased temporal coverage
31 of snow.

1 **3.4 Comparison with previous study**

2 The current study and that of *Flanner et al.*, (2011) have a common overlap period of 2001-
3 2008. To compare the derivations of LCrRE between these two studies, we re-derived
4 Northern Hemisphere LCrRE during 2001-2008 using the CAM3 radiative kernel and an
5 assumption of ice-free albedo over Greenland of 0.316, as in *Flanner et al.* (2011). For this
6 overlap period, and using these assumptions, the current study gives a LCrRE value of about
7 -1.41 Wm^{-2} over the northern hemisphere as compared to -1.72 Wm^{-2} from *Flanner et al.*,
8 (2011), who determined snow presence during 1979-2008 from coarse-resolution AVHRR
9 data (e.g., *Robinson et al*, 2000). (The 1979-2008 mean northern hemisphere LCrRE found
10 by *Flanner et al*, (2011) was -2.0 W/m^2 , indicating less boreal cryospheric influence during
11 2001-2008 compared with 1979-2001). To understand this difference, an LCrRE difference
12 map between the current study and *Flanner et al.*, (2011) has been generated (Fig. 9). This
13 difference was taken between annual mean LCrRE values over the common overlap period.
14 We find that the use of coarse-resolution snow cover data (*Flanner et al*, 2011) likely leads to
15 overestimation of LCrRE along the continental edges and in mountainous regions like the
16 Himalayas. Some of the differences along the continental edges (especially of Greenland),
17 depicted in Fig. 9 at 1 degree resolution, are likely due to poor resolution of land cover
18 fraction in the AVHRR snow cover data used by *Flanner et al* (2011), and possibly also the
19 influence of land-fast sea-ice. Snow in mountainous regions is difficult to resolve in any
20 model because of irregular topography, and is uncertain in both datasets. The annual mean
21 LCrRE time-series (Fig. 10) of both datasets show similar patterns and exhibit a correlation
22 coefficient of 0.78, lending confidence in the application of longer-term AVHRR data to
23 derive estimates of large-scale LCrRE trends. We expect that the current analysis will be
24 useful in determining correction algorithms for biases in the Himalayas and along the coastal
25 margins of Greenland that may result from use of coarse-resolution AVHRR data.

26 **4 Conclusions**

27 We have estimated a global land-based CrRE (LCrRE) of about -2.6 Wm^{-2} during 2001-2013,
28 with about 59% of the effect originating from Antarctica. For a particular region, LCrRE can
29 vary significantly (e.g., from 0 to -250 Wm^{-2} over Antarctica; Fig. 5) depending on the
30 season. Due to a large contribution from seasonal snow, northern hemisphere LCrRE peaks
31 during April, whereas southern hemisphere LCrRE peaks during the December solstice.
32 About 78% of Northern Hemisphere LCrRE originates from seasonal or non-glaciated snow
33 while about 99.9% of Southern Hemisphere LCrRE comes from glaciated areas.

1 Mountainous region provide a small (-0.037 Wm^{-2}) yet consistent contribution towards
2 LCrRE throughout the year. Higher resolution data has improved the LCrRE estimates
3 relative to previous studies by better resolving the snow impact in mountainous regions and
4 in coastal areas, leading to a 18% smaller estimate of northern hemisphere LCrRE during
5 2001-2008 in this study than in *Flanner et al.* (2011). Inter-annual variations between these
6 two studies are well correlated ($r=0.78$), indicating that these data are useful in determining
7 longer term trends in LCrRE.

8 Snow cover, however, is patchy on substantially smaller spatial scales than the 0.05 degree
9 resolution analysis applied here. No significant trend over time has been observed in global
10 annual LCrRE values between 2001 and 2013, though significant reductions in cryospheric
11 influence are evident over large areas of northern Eurasia, especially during spring. Slightly
12 negative LCrRE trends (indicating increased albedo) are evident over Antarctica, possibly
13 due to increased snowfall frequency. LCrRE primarily depends on albedo contrast induced by
14 snow and the propagation of surface albedo anomalies to top-of-atmosphere energy fluxes. A
15 slight variation in either of the two can cause a major impact on LCrRE estimates. Sensitivity
16 analysis shows a secondary dependency of LCrRE on MODIS snow flag and global
17 climatology derived using MODIS surface albedo product, and changing either of those drops
18 the LCrRE estimates by about 8% globally. Using different MODIS data quality flags (Q2 &
19 Q4) does not have a significant effect on our LCrRE estimates. Using different radiative
20 kernels can cause a variation of about 3-16% in global LCrRE as compared to LCrRE with
21 the CAM4 kernel, depending on the atmospheric attenuation present in each particular model
22 due to cloud cover and aerosols.

23 For the consistency, we tried not use any partial year data available at the time of analysis.
24 Also, adding another year of the data (year 2014) would not have made any significant
25 impact on the results. However, it would be beneficial to look into long term trends (about
26 20-30 years) and comparison with previous research, with more MODIS data available in
27 future.

28 **Appendix A: Snow-covered albedo climatology by land classification**

29 Definitions for different land classes used in the MODIS MCD12C1 product are provided by
30 the International Geosphere-Biosphere Programme (IGBP). Table A.1 provide mean (μ) and
31 standard deviation (σ) of surface albedo for each land class type using section 2.2 algorithm.
