

Reply to editor's comments to the manuscript:

We have accepted most of the 153 suggestions provided by the editor in the pdf-file, and corrected the manuscript accordingly. We have also made changes in the abstract and conclusions, according to the suggestions from the editor. A list of all minor corrections is not included as a point-by-point reply, but all changes are highlighted in the following manuscript. Below we provide a response to the most important suggestions made by the editor, and describe our changes.

Editors comments are marked in bold, our answer in normal font, and *changes made in the manuscript in italics*.

The abstract could be more concisely written (I have made some suggestions to shorten sentences) and should present more of the key findings. In such a condensed abstract I would also include your key findings on (i) model sensitivity, (ii) model validation with logger and borehole data and (iii) the importance of lognormal vs. gamma distribution, all of which might be important teasers for other scientists to read the paper.

We have changed the abstract according to the suggested changes, and have now included the following additional sentences:

The mean modelled temperature of the grid cell reproduces the observations with an accuracy of 1.5°C or better. The observed sub-grid variations in ground surface temperatures from two field sites are very well reproduced, with estimated fractions of sub-zero MAGST within $\pm 10\%$. We also find that snow distributions within areas of 1km² in Norwegian mountain environments are closer to a gamma than to a lognormal theoretical distribution. The modelled permafrost distribution seems to be more sensitive to the choice of distribution function than to the fine-tuning of the coefficient of variation of the distribution. When incorporating the small-scale variation of snow, the modelled total permafrost area of mainland Norway is nearly twice as large compared to the area obtained with grid-cell average snow depths without a sub-grid approach.

I would also check the conclusion, which could be more concisely written and present main points in two lines each.

We have now divided and shortened the bullet points, so that each of the points now consists of only one sentence over two-three lines:

- *The total modelled permafrost area in an equilibrium with the average climate for the period 1981 – 2010 is 25 400 km². This corresponds to 7.8 % of the Norwegian mainland.*
- *The model simulation without a sub-grid representation of snow produces almost 50 % less permafrost.*

- *Due to the non-linear insulating effect of snow in combination with asymmetric snow distributions within each grid cell, the spatial average ground temperature in a 1km² area cannot be determined based on the average snow cover for that area.*
- *Observed variations in ground surface temperatures from two logger arrays with 26 and 41 loggers, respectively, are very well reproduced, with estimated fractions of sub-zero MAGST within $\pm 10\%$.*
- *94 % of the observed mean annual temperature at top of permafrost in the boreholes are within the modelled ground temperature range for the corresponding grid cell, and mean modelled temperature of the grid cell reproduces the observations with an accuracy of 1.5°C or better.*
- *The sensitivity of the model to the coefficient of variation of snow (CV_{sd}) is relatively low, compared to the choice of theoretical snow distribution function. Both are minor effects compared to the effect of running the model without a sub-grid distribution.*
- *The observed CV_{sd} of snow within 1 km² grid cells in the Hardangervidda mountain plateau varies from 0.15 to 1.15, with an average CV_{sd} of 0.6. The observed CV_{sd} values are nearly identical at the end of the accumulation seasons in 2008 and 2009.*
- *The distributions are generally closer to a theoretical gamma distribution than to a lognormal distribution, in particular in areas of very rough topography, thicker snow cover and higher average winter wind speeds.*

Page 1, line 16: What is a land surface model? - energy, topography.... specify "surface temperature models". Land surface or permafrost models refer to both land surface models AND permafrost models. The first includes the full surface energy balance and feedbacks to the atmosphere, while a permafrost model normally is restricted to ground temperatures. However, we think both terms are well known for the reader, and decided to leave it as it is.

Page 6, line 22: Explain the variety of processes included in one sentences for those who don't want to read the referenced papers. A short summary of the processes is given in the following paragraph, and we have therefore not extended this part with an additional sentence.

Page 9, line 25: Explain shortly. Here we have corrected the sentence into "*For these areas wind speeds in the forcing dataset have been linearly increased by 60 %*".

Small-scale variation of snow in a regional permafrost model

Abstract

The strong winds prevalent in high altitude and arctic environments heavily redistribute the snow cover, causing a small-scale pattern of highly variable snow depths. This has profound implications for the ground thermal regime, resulting in highly variable near-surface ground temperatures on the meter scale. Due to Asymmetric snow distributions combined with the non-linear insulating effect of snow, also mean that the spatial average ground temperature in a 1km² area can not necessarily be determined based on the average snow cover for that area. Land surface or permafrost models employing a coarsely classified average snow depth will therefore not yield a realistic representation of ground temperatures. In this study we employ statistically derived snow distributions within 1km² grid cells as input to a regional permafrost model in order to represent sub-grid variability of ground temperatures. This is shown to improve the representation of both the average and the total range of ground temperatures. The model results show that we reproduce observed sub-grid ground temperature variations of up to 6°C, with and 98% of borehole observations within match the modelled temperature range. The mean modelled temperature of the grid cell reproduces the observations with an accuracy of 1.5°C or better. The observed sub-grid variations in ground surface temperatures from two field sites are very well reproduced, with estimated fractions of sub-zero MAGST within ±10%. We also find that snow distributions within areas of 1km² in Norwegian mountain environments are closer to a gamma than to a lognormal theoretical distribution.

The modelled permafrost distribution seems to be more sensitive to the choice of distribution function than to the fine-tuning of the coefficient of variation of the distribution. When incorporating the small-scale variation of snow, the modelled total permafrost area of mainland Norway is nearly twice as large compared to the area obtained with grid-cell average snow depths without a sub-grid approach.

~~Based on this more faithful representation of ground temperatures, we find the total permafrost area of mainland Norway to be nearly twice as large as what is modelled without a sub-grid approach.~~

1 Introduction

High altitude and arctic environments are exposed to strong winds and drifting snow can create a small-scale pattern of highly variable snow depths. Seasonal snow cover is a crucial factor for the ground thermal regime in these areas (e.g. Goodrich, 1982; Zhang et al., 2001). This small-scale pattern of varying snow depths results in highly variable ground surface temperatures on the meter scale of; up to 6 °C ~~within~~ areas of less than 1 km² (e.g. Gubler et al., 2011; Gislås et al., 2014). ~~In general,~~ grid-based numerical land surface and permafrost models operate on scales too coarse to resolve the variability of snow depths, and are not capable of representing such small-scale variability. For the Norwegian mainland, permafrost models have been implemented with a spatial grid resolution of 1 km² (Gislås et al., 2013; Westermann et al., 2013), and do therefore only represent the larger scale patterns of ground temperatures. As a consequence, ~~As a consequence,~~ they usually represent the lower limit of permafrost as a sharp boundary, where the average ground temperature of a grid-cell crosses the freezing temperature (0°C). In reality, the lower permafrost boundary is a fuzzy transition. ~~Several~~ local parameters, such as snow cover, solar radiation, vegetation, soil moisture and soil type cause a pronounced sub-grid variation of ground temperature. Different approaches have been developed to address this mismatch of scales, such as the TopoSub (Fiddes and Gruber, 2012), ~~which~~ accountings for the variability of a range of surface parameters using k-means clustering. At high latitudes and altitudes, one of the principal controls on the variability of ground temperature is the effect of sub-grid variation in snow cover (e.g. Langer et al., 2013). ~~Gislås et al. (2014) show that~~ The observed variability in ground surface temperatures within 1 km x 1 km areas is to a large degree reproduced by only accounting for the variation in snow depths (Gislås et al., 2014). Therefore, ~~Therefore~~ procedures capable

1 | of resolving the small scale variability of snow depths ~~will have the potential to~~could
2 | considerably improve the representation of the ground thermal regime.

3 | The spatial variation of snow is a result of several mechanisms operating on different scales in
4 | different environments (Liston et al. 2004). In tundra and alpine areas, wind-affected
5 | deposition is the dominant control on the snow distribution at distances below 1 km (Clark et
6 | al., 2011). Physically-based snow distribution models are useful over smaller areas, but are
7 | not applicable on a regional scale. The coefficient of variation (CV), defined as the ratio
8 | between the standard deviation and the mean, ~~can be used as~~is a measure of the extent of
9 | spread in a distribution. ~~Previous studies suggest that the~~The coefficient of variation of snow
10 | depths (CV_{sd}), typically ~~ranging range~~ from low spread at 0.2 to high spread at 0.8, ~~is well~~
11 | ~~suited to reflect~~which suits snow distributions in a range of environments (e.g. Liston, 2004;
12 | Winstral and Marks, 2014). Liston (2004) assigned individual values of CV_{sd} to different land
13 | use classes in order to address sub-grid variability of snow in land surface schemes.
14 | According to this scheme, non-forested areas in Norway, as well as most of the permafrost
15 | areas in northern Europe ("*high-latitude alpine areas*"), would have been allocated a CV_{sd} of
16 | 0.7. A review of observed CV_{sd} from a large number of snow surveys in the northern
17 | hemisphere shows a large spread of CV_{sd} values, in particular within this land use class,
18 | ranging from 0.1 to 0.9 (Clark et al., 2011). This illustrates the need for improved
19 | representation of snow distribution within this land use class.

20 | An accurate representation of the small scale snow variation ~~highly~~ influences the timing and
21 | magnitude of runoff in hydrological models, and a detailed picture of the sub-grid variability
22 | is of great value for the hydropower industry and ~~in~~ flood forecasting. Adequate
23 | representations of the snow covered fraction in land surface schemes ~~are important for~~
24 | ~~enhanced realism of~~improve simulated near surface air temperatures, ground temperatures and
25 | evaporation due to the considerable influence of snow cover on the duration of melt season
26 | and the surface albedo.

27 | In this study we derive functional dependencies between distributions of snow depth within
28 | 1x1 km grid cells and CV_{sd} , based on an extensive in-situ data set from Norwegian alpine
29 | areas. In a second step, we employ the resulting snow distributions as input to the permafrost
30 | model CryoGRID1, a spatially distributed, equilibrium permafrost model (Gisnås et al.,
31 | 2013). ~~From the~~Using a sub-grid representation of ground temperatures, permafrost
32 | probabilities are derived, hence enabling a more realistic, fuzzy permafrost boundary instead

of a binary, sharp transition. With this approach, we aim to improve permafrost distribution modelling in inhomogeneous terrains.

2 Setting

The model is implemented for the Norwegian mainland, extending from 58° to 71°N. Both the topography and climate in Norway is dominated by the Scandes, ~~the a~~ mountain range stretching south-north through Norway, separating the coastal western part with steep mountains and deep fjords from the eastern part where the mountains gradually decrease in height. The maritime climate of the west coast is dominated by low-pressure systems from the Atlantic Ocean resulting in heavy precipitation, while the eastern parts of the Scandes have a more continental and drier climate. Mountain permafrost is present all the way to the southern parts of the Scandes, with a gradient in the lower limit of permafrost from c. 1400 to 1700 m from east to west in central southern Norway, and from c. 700 to 1200 m from east to west in northern Norway (Gisnås et al., 2013). While permafrost is also found in mires at lower elevations both in southern and northern Norway, most of the permafrost is located in exposed terrain above the tree line where. ~~This environment is dominated by~~ strong winds resulting in heavy redistribution of snow.

~~The~~ In-situ records of snow depth data used to establish the snow distribution scheme were collected at the Hardangervidda mountain plateau in the southern part of the Scandes (Fig. 1). It is the largest mountain plateau in northern Europe, located at elevations from 1000 to above 1700 meters a.s.l., with occurrences of permafrost in the highest mountain peaks. The terrain is open and slightly undulating in the east, while in the west it is more complex with steep mountains divided by valleys and fjords. The mountain range represents a significant orographic barrier for the prevailing westerly winds from the Atlantic Ocean, giving rise to large variations in precipitation and strong winds, two agents promoting a considerably wind-affected snow distribution. Mean annual precipitation varies from 500 to more than 3000 mm over distances of a few tens of kilometres, and maximum snow depths can vary from ~~zero~~ 0 to more than 10 meters over short distances (Melvold and Skaugen, 2013).

3 Model description

3.1 A statistical model for snow depth variation

The Winstral terrain-based approach (Winstral et al., 2002) is applied over the entire Norwegian mainland using the 10-meter national digital terrain model from the Norwegian Mapping Authority (available at Statkart.no), with wind data from the NORA10 dataset (Section 4.1) used to indicate the distribution of prevailing wind directions during the accumulation season.

The terrain-based exposure parameter (S_x), described in detail in (Winstral et al., 2002), quantifies the extent of shelter or exposure of the considered grid-cell~~considered~~. S_x is determined by the slope between the grid-cell and the cells of greatest upward slope in the upwind terrain. The upwind terrain is defined as a sector towards the prevailing wind direction d constrained by the maximum search distance ($d_{max} = 100$ m) and a chosen width (A) of 30° with the two azimuths extending 15° to each side of d (see Fig. 2). The cell of the maximum upward slope is identified for each search vector, separated by 5° increments. This gives in total seven search vectors for each of the eight 30° wide sectors. S_x for the given grid-cell is finally calculated as the average of the maximum upward slope gradient of all seven search vectors:

$$S_{x_{d,A,d_{max}}}(x_i y_i) = \max \left[\tan \left(\frac{Z(x_v, y_v) - Z(x_i, y_i)}{[(x_v - x_i)^2 + (y_v - y_i)^2]^{0.5}} \right) \right] \quad (1)$$

where d is the prevailing wind direction, (x_i, y_i) are the coordinates of the considered grid-cell, and (x_v, y_v) are the sets of all cell coordinates located along the search vector defined by (x_i, y_i) , A and d_{max} . This gives the degree of exposure or shelter in the range -1 to 1, where negative values indicate-correspond to exposure.

To estimate a realistic degree of exposure based on the observed wind pattern at a local site, S_x was computed for each of the eight prevailing wind directions $d = [0^\circ, 45^\circ, 90^\circ, 135^\circ, 180^\circ, 225^\circ, 270^\circ, 315^\circ]$, and weighted based on the wind fraction (wf_d). wf_d accounts for the amount of different exposures in the terrain at various wind directions, and represents the fraction of hourly wind direction observations over the accumulation season for the eight wind directions. The selected period of wind directions influencing the redistribution of snow is here-chosen-as January to March. Wind speeds below a threshold of 7 ms^{-1} are excluded, as this threshold is considered a lower limit required for wind drifting of dry snow (Li and

Pomeroy, 1997; Lehning and Fierz, 2008). We assume that the snow distribution at snow maximum is highly controlled by the terrain and the general wind exposure over the winter season, and we do not account for the variation in snow properties over the season that controls how much snow is available for transport at a given time.

The calculated S_x parameter values are used as predictors in different regression analyses to describe the CV_{sd} within 1 x 1 km derived from an Airborne Laser Scanning (ALS) of snow depths (see Sect. 4.1). The coefficient of variation of exposure degrees (CV_{Sx}) within each 1x1 km grid cell is computed by aggregating the S_x map from 10 meter to 1 km resolution according to:

$$cV_{Sx} = \text{std}(e^{Sx})/\text{mean}(e^{Sx}) \quad (2)$$

S_x -values below the 2.5th and above 97.5th percentiles of the S_x -distributions are excluded, giving $S_x \approx [-0.2, 0.2]$. Three regression analyses were performed to reduce the RMS between CV_{Sx} and observed CV_{sd} , where additional predictors such as elevation above treeline (z) and maximum snow depth (μ) ~~successively~~ have been included (Table 1). ~~Elevation above treeline is chosen as predictor to account for the increased wind exposure with elevation.~~ Ideally, wind speed should be included as predictor. However, the NORA10 dataset (Section 4.1) does not sufficiently reproduce the local variations in wind speeds over land, especially not at higher elevations and for terrain with increased roughness. Elevation above treeline is chosen as predictor to account for the increased wind exposure with elevation. ~~Because of the~~ There is a strong gradient in treeline and general elevation of mountain peaks from high mountains in the south to lower topography in the north of Norway. ~~Therefore,~~ applying only elevation, ~~not adjusted for the local treeline,~~ as predictor would result in an underestimation of redistribution in the north.

3.2 CryoGRID 1 with an integrated sub-grid scheme for snow variation

The equilibrium permafrost model CryoGRID 1 (Gisnås et al., 2013; Westermann et al., 2015) provides an estimate for the *MAGST* (Mean annual ground surface temperature) and *MAGT* (Mean Annual Ground Temperature at the top of the permafrost or at the bottom of the seasonal freezing layer) from freezing (FDD_a) and thawing (TDD_a) degree days in the air according to

$$MAGST = \frac{TDD_a \times nT - FDD_a \times nF}{P} \quad (3)$$

1 and

$$2 \quad MAGT = \begin{cases} \frac{(TDD_a * nT * r_k - FDD_a * nF)}{P} & \text{for } K_t TDD_s \leq K_f FDD_s \\ \frac{(TDD_a * nT - \frac{1}{r_k} FDD_a * nF)}{P} & \text{for } K_t TDD_s \geq K_f FDD_s \end{cases} \quad (4)$$

3 where P is the period that FDD_a and TDD_a are integrated over, r_k is the ratio of thermal
4 conductivities of the ground in thawed and frozen states (assuming that heat transfer in the
5 ground is entirely governed by heat conduction), while nT and nF are semi-empirical transfer-
6 functions which aim to capture a-including-a-variety of key processes in one single variable
7 (see Gisl  s et al., 2013; Westermann et al., 2015 for details).

8 The winter nF -factor relates the freezing degree days at the surface to the air and thus
9 accounts for the effect of the winter snow cover, and likewise the nT -factor relates the
10 thawing degree days at the surface to the air and accounts for the surface vegetation cover:

$$11 \quad FDD_s = nF * FDD_a \quad \text{and} \quad TDD_s = nT * TDD_a \quad (5)$$

12 Variation in observed n -factors for forests and shrubs are relatively small, with nT -factors
13 typically in the range 0.85 to 1.1, and nF -factors in the range 0.3 to 0.5 (Gisl  s et al., 2013).
14 ~~Following Gisl  s et al. (2013) for~~ forest, shrubs and mires are assigned nT -factors 0.9/1.0/0.85
15 and nF -factors 0.4/0.3/0.6, respectively (Gisl  s et al., 2013).

16 Observed variations in nT and nF within the open non-vegetated areas are comparably large,
17 with values typically in the range 0.4 – 1.2 for nT and 0.1 – 1.0 for nF . The variability is
18 related to the high impact and high spatial variability of snow depths (Gisl  s et al., 2014).
19 While nF accounts for the insulation from snow due to low thermal conductivity, nT
20 indirectly compensates for the shorter season of thawing degree days at the ground surface in
21 areas with a thick snow cover. Relationships between n -factors for open areas and maximum
22 snow depths are established based on air and ground temperature observations together with
23 snow depth observations at the end of accumulation season at the 13 stations in southern
24 Norway, presented in Hipp (2012) and at arrays of nearly 80 loggers at Finse and Juvvassh  e
25 (Gisl  s et al., 2014) (Fig. 3):

$$26 \quad nF = -0.17 * \ln(\mu) + 0.25 \quad (6)$$

$$27 \quad nT = -0.13 * \mu + 1.1 \quad (7)$$

The relationships between n -factors and snow cover in open areas are shown to be consistent within the two sites in southern Norway (Gisnås et al., 2014). Due to lack of field observations including all required variables at one site in northern Norway, the relation is not tested for this area. However, it fits very well with a detailed study with 107 loggers recording the variation in ground surface temperature at a lowland site in Svalbard (Gisnås et al. 2014). Other factors, such as solar radiation and soil moisture, have minor effects on the small-scale variation in ground surface temperatures in these areas. Gisnås et al (2014) demonstrated that most of the sub-grid variation in ground temperatures within 1 km x 1 km areas in Norway and Svalbard was reproduced by including only the sub-grid variation of snow depths. In other areas other parameters than snow depth might have a larger effect on the ground surface temperatures, and should be accounted for in the derivation of n -factors.

We assume that the distribution of maximum snow depths within a grid cell with a given CV_{sd} and average maximum snow depth (μ) follows a *gamma* distribution with a probability density function (PDF) given by:

$$f(x; \alpha, \beta) = \frac{1}{\beta^\alpha \Gamma(\alpha)} x^{\alpha-1} e^{-\frac{x}{\beta}} \quad (8)$$

with a *shape* parameter $\alpha = CV_{sd}^{-2}$ and a *rate* parameter $\beta = \mu * CV_{sd}^2$ (e.g. Skaugen et al., 2004; Kolberg and Gottschalk, 2006). The average maximum snow depth corresponds to the coarse scale snow observation, and the original coarse scale snow depth is therefore conserved in the sub-grid snow distribution. Corresponding n -factors are computed for all snow depths (x) based on Eq. 6 and 7, and related to the PDF (Eq. 8). The model is run for each nF from 0 to 1 with 0.01 spacing, giving 100 model realizations. Each realization corresponds to a unique snow depth, represented with a set of nF and nT factors. Based on the 100 realizations, a α -distribution of $MAGST$ and $MAGT$ are calculated for each grid cell, where the potential permafrost fraction is derived as the percentage of sub-zero $MAGT$. A schematic overview of the model chain and the evaluation is shown in Fig. 4. To assess the sensitivity of the choice of the theoretical distribution function, the model was also run with PDFs following a *lognormal* distribution, ~~given by~~ (e.g. Liston, 2004):

$$f(x; \lambda, \zeta) = \frac{1}{x\zeta\sqrt{2}} e^{\left\{-\frac{1}{2}\left[\frac{\ln(x)-\lambda}{\zeta}\right]^2\right\}} \quad (9)$$

where

$$\lambda = \ln(\mu) - \frac{1}{2}\zeta^2, \quad \zeta^2 = \ln(1 + CV_{sd}) \quad (10)$$

3.3 Model evaluation

The CV_{sd} was derived for 0.5 km x 1 km areas based on the ALS snow depth data (Section 4.1) resampled to 10 x 10 meter resolution. Each 0.5 x 1 km area includes 500 to 5000 grid cells 10 x 10 m, depending on the area masked out due to lakes or measurement errors. There were > 4000 grid cells in 70% of the areas. Goodness of fit evaluations for the theoretical *lognormal* and *gamma* distributions applying the Anderson-Darling test in MATLAB [adtest.m (Stephens, 1974)] were conducted for each distribution. Parameters for gamma (*shape* and *rate*) and lognormal (*mu*, *sigma*) distributions were estimated by maximum likelihood as implemented in the MATLAB functions gamfit.m and lognfit.m.

The results of the permafrost model are evaluated with respect to the average *MAGST* and *MAGT* within each grid cell, as well as the fraction of sub-zero *MAGST*. For the evaluation runs, the model is forced with climatic data for the hydrological year corresponding to the observations. The performance in representing fractional permafrost distribution is evaluated at two field sites where arrays of 26 (Juvvasshøe) and 41 (Finse) data loggers have measured the distribution of ground surface temperatures at 2 cm depth within 500 x 500 meter areas for the hydrological year 2013 (Gisnås et al., 2014). The general lower limits of permafrost are compared to permafrost probabilities derived from BTS (basal temperature of snow) - surveys (Haeberli, 1973; Lewkowicz and Ednie, 2004), conducted at Juvvasshøe and Dovrefjell (Isaksen et al., 2002). The model performance of *MAGST* is evaluated with data from 128 temperature data loggers located a few cm below the ground surface in the period 1999 - 2009 (Farbrot et al., 2008; Isaksen et al., 2008; Ødegaard et al., 2008; Farbrot et al., 2011; Isaksen et al., 2011; Farbrot et al., 2013). The loggers represent all vegetation classes used in the model, and *cover* spatially large parts of Norway (Fig. 2). Four years of data from 25 boreholes (Isaksen et al., 2007; Farbrot et al., 2011; Isaksen et al., 2011; Farbrot et al., 2013) are used to evaluate modelled *MAGT* (Fig. 1). Tables of ground surface temperature loggers (Table S1) and boreholes used for validation (Table S2) are included in the supplementary material.

4 Data

4.1 Forcing and evaluation of the snow distribution scheme

Wind speeds and directions during the snow accumulation season are calculated from the boundary layer wind speed and direction at 10 meter above surface in the Norwegian Reanalysis Archive (NORA10) wind dataset. NORA10 is a dynamically downscaled dataset of ERA -40 to a spatial resolution of 10-11 km, with hourly resolution of wind speed and direction (Reistad et al., 2011). The dataset is originally produced for wind fields over sea, and underestimates the wind speeds at higher elevation over land (Haakenstad et al., 2012). Comparison with weather station data revealed that wind speeds above the tree line are underestimated by about 60% (Haakenstad et al., 2012). For these areas ~~wind speeds in the~~ forcing dataset has ~~been~~ linearly increased by 60 %.

The snow distribution scheme is derived from an ALS snow depth over the Hardangervidda mountain plateau in southern Norway (Melvold and Skaugen, 2013). The ALS survey is made along six transects, each covering a 0.5 x 80 km area with nominal 1.5 x 1.5 m ground point spacing. The survey was first conducted between 3rd and 21st of April 2008, and repeated in the period 21st-24th April 2009. The snow cover was at a maximum during both surveys. A baseline scan was performed 21st of September 2008 to obtain the elevation at minimum snow cover. The ALS data are presented in detail in Melvold and Skaugen (2013). Distributions of snow depth, represented as CV_{sd} , are calculated for each 0.5 x 1 km area, based on the snow depth data resampled to 10 x 10 meter resolution. About 400 cells of 0.5 x 1 km exist for each year, after lakes and areas below treeline are excluded.

The snow distribution scheme is validated with snow depth data obtained by ground penetrating radar (GPR) at Finse (60°34'N, 7°32'E, 1250-1332 m a.s.l.) and Juvvasshøe (61°41'N, 8°23'E, 1374-1497 m a.s.l.). The two field sites are both located in open, non-vegetated alpine landscapes with major wind re-distribution of snow. ~~However,~~ they differ with respect to mean maximum snow depth (~2 m / ~1 m), average winter wind speeds (7-8 / 10-14 m/s) and topography (very rugged at Finse, while steep, but less rugged at Juvvasshøe). ~~The timing of the~~ Snow surveys were conducted late March to April (2009, 2012-2014) around maximum snow depth, but when the snow pack was still dry. The GPR surveys at Finse are constrained to an area of 1x1 km, while at Juvvasshøe they cover several square kilometres, but with lower observation density. The GPR data from the end of the

accumulation season in 2013 are presented in Gisnås et al. (2014), and the data series from the other years are obtained and processed following the same procedures, described in detail in Dunse et al. (2009). The propagation speed of the radar signal in dry snow was derived from the permittivity and the speed of light in vacuum, with the permittivity obtained from snow density using an empirical relation (Kovacs et al., 1995). The snow depths were determined from the two-way travel time of the reflection from the ground surface and the wave-speed. Observations were averaged over 10 x 10 meter grid cells, where grid cells containing less than three samples were excluded. The CV_{sd} for 1x1 km areas are computed based on the 10-meter resolution data.

4.2 Permafrost model setup

The climatic forcing of the permafrost model is daily gridded air temperature and snow depth data, called the *seNorge* dataset, provided by the Norwegian Meteorological Institute and the Norwegian Water and Energy Directorate. The dataset, available for the period 1961 – 2015, is based on air temperature and precipitation data collected at the official meteorological stations in Norway, interpolated to 1 x 1 km resolution applying Optimal Interpolation as described in Lussana et al. (2010). Snow depths are derived from the air temperature and precipitation data, using a snow algorithm accounting for snow accumulation and melt, temperature during snow fall and compaction (Engeset et al., 2004; Saloranta, 2012). Freezing- (FDD_a) and thawing (TDD_a) degree days in the air are calculated as annual accumulated negative (FDD) and positive (TDD) daily mean air temperatures, and maximum annual snow depths (μ) are derived directly from the daily gridded snow depth data. The CryoGRID 1 model is implemented at 1 x 1 km resolution over the same grid as the *seNorge* dataset.

Soil properties and surface cover is kept as in Gisnås et al. (2013), with five land cover classes; *forest*, *shrubs*, *open non-vegetated areas*, *mires* and *no data*, based on CLC level 2 in the Norwegian Corine Land Cover map 2012 (Aune-Lundberg and Strand, 2010). Sub-grid distributions of snow are only implemented for *open non-vegetated areas*.

5 Results

5.1 Observed snow distributions in mountain areas of Norway

CV_{sd} within 1 x 1 km areas in the ALS snow survey at Hardangervidda ranged from 0.15 to 1.14, with mean and median of respectively 0.58 and 0.59. According to the Anderson-Darling goodness of fit evaluations 70 out of 932 areas had a snow distribution within the 5% significance interval of a *gamma* distribution, while only 1 area was within the 5% significance interval of a *lognormal* distribution. Although the null hypothesis rejected more than 90% of the sample distributions, the *Anderson-Darling Test Score* was all over lower for the *gamma* distribution, indicating that the observed snow distributions are closer to a *gamma* than to a *lognormal* theoretical distribution (Fig. 5). For lower lying areas with less varying topography and shallower snow depths, in particular in the eastern parts of Hardangervidda, the observed snow distributions were similarly close to ~~a *lognormal* as to a *gamma*~~ both distributions. In higher elevated parts with more snow to the west of the plateau the snow distributions were much closer to a *gamma* distribution. Based on these findings a *gamma* distribution was used in the main model runs, while a model run with *lognormal* distributions of snow was made to evaluate the sensitivity towards the choice of the distribution function (Section 3.2).

5.2 Evaluation of the snow distribution scheme

Three regression models for CV_{sd} as a function of the terrain-based parameter S_x , elevation (z) and mean maximum snow depth (μ) were calibrated with the snow distribution data from the ALS snow survey over the Hardangervidda mountain plateau (Table 1). *Model 1* results in a root mean square error (*RMSE*) of only 0.14. However, the correlations of the distributions are significantly improved by including *elevation* as predictor (*Model 2*; $R^2 = 0.52$). By including *maximum snow depth* as additional predictor (*Model 3*) the model improves slightly to $R^2 = 0.55$ (Fig. 6). The distribution of CV_{sd} (example of *Model 3* in Fig. 8, left) shows increased values in areas of rougher topography (western side of Norway) and higher elevations (central part following the Scandes), with maximum CV_{sd} up to 1.2 in the Lyngen Alps and at peaks around Juvvasshøe (Fig. 1, site 2 and 4). The lowest values of 0.2-0.3 are modelled in larger valleys in south eastern Norway, where elevations are lower and topography gentler.

The regression models for CV_{sd} are validated with data from GPR snow surveys at Juvvasshøe and Finse (Table 1). The correlation for *Model 1* is poor, with $R^2 = 0.04$ and Nash-Sutcliffe model efficiency (ME) = -0.7 (Table 1). *Model 2* improves the correlation significantly, while the best fit is obtained with *Model 3* (Fig. 6, $RMSE = 0.094$, $R^2 = 0.62$ and $ME = 0.61$). The improvement in *Model 3* compared to *Model 2* is more pronounced in the validation than in the fit of the regression models, and is mainly a result of better representation of the highest CV_{sd} -values. The validation area at Juvvasshøe is located at higher elevations than what is represented in the ALS snow survey data set and undergoes extreme redistribution by wind. The representation of extreme values, therefore, has a high impact in the validation run.

5.3 Modelled ground temperatures for mainland Norway

The main results presented in this section are based on the model run with 100 realizations per grid cell, applying *gamma* distributions over the CV_{sd} from *Model 3*. The main results are given as averages over the 30-year period 1981 – 2010. According to the model run, in total 25 400 km² (7.8 %) of the Norwegian mainland is underlain by permafrost in an equilibrium situation with the climate over the 30-years period 1981-2010 (Fig. 1). 12 % of the land area features sub-zero ground temperatures in more than 10% of a 1 km grid cell, and is classified as sporadic (4.4 %), discontinuous (3.2 %) or continuous (4.3 %) permafrost (Fig. 1). In comparison, the model run without a sub-grid variation results in a permafrost area of only 13460 km², corresponding to 4.1% of the model domain (Table 2). The difference is illustrated for Juvvasshøe (Fig. 7, a) and Dovrefjell (c), where the sub-grid model very well reproduces the observed lower limit of permafrost based on borehole temperatures and BTS-surveys. In contrast, the model without sub-grid variability indicates a hard line for the permafrost limit at much higher elevations (Fig. 7, b and d). At Juvvasshøe, the model without sub-grid distribution still reproduces the permafrost limit to some extent because of the large elevation gradient. At Dovrefjell, where the topography is much gentler, the difference between the models is much larger and the approach without sub-grid distribution is not capable of reproducing the observed permafrost distribution. The modelled permafrost area for model runs applying the other models for CV_{sd} and theoretical distribution functions are summarized in Table 2.

The standard deviations of the modelled sub-grid distribution of MAGT range from 0 °C to 2.5 °C (Fig. 8, right). The highest *standard deviation* values are found in the Jotunheimen

area, where modelled sub-grid variability of MAGT is up to 5 °C. Also at lower elevations in south eastern parts of Finnmark *standard deviations* exceed 1.5 °C. Here, the CV_{sd} values are below 0.4, but because of cold ($FDD_a < -2450$ °C) and dry (max SD < 0.5 meters) winters even small variations in the snow cover ~~result in~~have large effects on the ground temperatures.

Close to 70% of the modelled permafrost is situated within open, non-vegetated areas above treeline, classified as mountain permafrost according to Gruber and Haeberli (2009). This is the major part of the permafrost extent both in northern and southern Norway. In northern Norway the model results indicate that the lower limit of continuous ~~and~~ sporadic mountain permafrost decreases eastwards from 1200 ~~and~~ 700 meters a.s.l.; ~~respectively~~, in the west, to 500 ~~and~~ 200 meters in the east, respectively. In southern Norway, the southernmost location of continuous mountain permafrost is in the mountain massif of Gaustatoppen at 59.8°N, with continuous permafrost above 1700 meters a.s.l. and discontinuous permafrost down to 1200 m a.s.l. In more central southern Norway the continuous mountain permafrost reaches down to 1600 meters a.s.l. in the western Jotunheimen and Hallingskarvet, and down to 1200 meters a.s.l. in the east at the Swedish border. The sporadic mountain permafrost extends around 200 meters further down both in the western and eastern parts.

5.4 Evaluation of CryoGRID 1 with sub-grid snow distribution scheme

The observed and modelled CV_{sd} values at the field sites were 0.85 and 0.80 at Juvvasshøe, and 0.71 and 0.77 at Finse. At Juvvasshøe the observed fraction of loggers with *MAGST* below 0°C was 77 %, while the model result indicates an aerial fraction of 64 %. Similarly, at Finse the observed negative *MAGST* fraction was 30 %, while the model indicates 32 %. The measured ranges of *MAGST* within the 1 km x 1 km areas were relatively well reproduced by the model (Table 3). The average *MAGST* within each field area was also improved compared to a model without a sub-grid representation of snow (Table 3, in parenthesis).

58% of the observed *MAGSTs* are captured by the modelled range of *MAGST* for the corresponding grid cell, and 87% within 1°C outside the range given by the distribution. The overall correlation between observed *MAGST* and average modelled *MAGST* for a grid cell is fairly good with *RMSE*, R^2 and *ME* of 1.3°C, 0.65 and 0.37, respectively (Fig. 9, left). The measured *MAGT* was within the range of modelled *MAGT* in all boreholes except ~~of~~ one, where *MAGT* deviates~~this being~~ 0.2°C outside the range. All the average modelled *MAGT* are

within $\pm 1.6^{\circ}\text{C}$ of observations, while 90 % are within 1°C . The *RMSE* between the observed and modelled average *MAGT* is 0.6°C (Fig. 9, right).

The evaluation of the model runs with all three *CV_{sd}*-models, as well as *lognormal* instead of *gamma* distribution functions are summarized in Table 2. The highest correlation between observed and mean *MAGST* and *MAGT* was obtained by *Model 3*, but *Model 2* yielded similar correlations. All three model runs capture 58 % of the observed *MAGST* and more than 98 % of the observed *MAGT* within the temperature range of the corresponding grid cell. The total area of modelled permafrost is 9% less when applying the simplest snow distribution model (*Model 1*) compared to the reference model (*Model 3*), while the same model without any sub-grid distribution results in 47 % less permafrost area. With a *lognormal* distribution the modelled permafrost area is 18 % less (*Model 3*) than with a *gamma* distribution.

6 Discussion

6.1 The effect of a statistical representation of sub-grid variability in a regional permafrost model

The total distribution of modelled permafrost with the sub-grid snow scheme corresponds to 7.8% of the Norwegian land area, while the modelled permafrost area without a sub-grid representation of snow ~~e-only comprises~~ 4%. This large difference in total modelled permafrost area stems exclusively from differences in the amount of modelled permafrost in mountains above the treeline. In these areas the snow distribution is highly asymmetric ~~with~~ ~~and~~ a majority of the area having ~~inge~~ below average snow depths. Because of the non-linearity in the insulating effect of snow cover, the mean ground temperature of a grid cell is not ~~the same as, and is or even often~~ far from, ~~the same as~~ the ground temperature below the average snow depth. Often, the majority of the area in high, wind exposed mountains is nearly bare blown with most of the snow blown into terrain hollows. Consequently, most of the area experiences significantly lower average ground temperatures than with an evenly distributed, average depth snow cover. In mountain areas with a more gentle topography and relatively small spatial temperature variations, an evenly distributed snow depth will result in large biases in modelled permafrost area, as illustrated at Dovrefjell in Fig. 7. This study ~~is-provides~~ clear evidence that the sub-grid variability of snow depths should be ~~accounted-for~~ ~~included~~ in model approaches targeting the ground thermal regime and permafrost distribution.

1 The model reproduces the large range of variation in sub-grid ground temperatures, with
2 standard deviations up to 2.5 °C, ~~coincident. This is in accordance with to~~ the observed small-
3 scale variability of up to 6 °C within a single grid cell (Gubler et al., 2011; Gislén et al.,
4 2014). Inclusion of sub-grid variability of snow depths in ~~the model—approaches~~
5 ~~providesallows for~~ a more adequate representation of the gradual transition from permafrost
6 to permafrost-free areas in alpine environments, and thus a better estimation of permafrost
7 area. ~~With In~~ a warming ~~g of the~~ climate, a model without such a sub-grid representation
8 would respond with an abrupt decrease in permafrost extent. In reality, bare blown areas with
9 mean annual ground temperatures of -6 °C need a large temperature increase to thaw.
10 Increased precipitation as snow would also warm the ground; however, bare blown areas may
11 still be bare blown with increased snow accumulation during winter. A statistical snow
12 distribution reproduces this effect, also with an increase in mean snow depth.

13 CryoGRID1 is a simple modelling scheme delivering a mean annual ground temperature at
14 the top of the permanently frozen ground based on near-surface meteorological variables,
15 under the assumption that the ground thermal regime is in equilibrium with the applied
16 surface forcing. This is a simplification, and the model cannot reproduce the transient
17 evolution of ground temperatures, and is therefore not suitable for future climate predictions.
18 However, it has proven to capture the regional patterns of permafrost reasonably well (Gislén
19 et al., 2013; Westermann et al., 2013). Because of the simplicity it is computationally
20 efficient, and suitable for doing test-studies like the one presented in this paper and in similar
21 studies (Westermann et al., 2015).

22 For the model evaluation with measured ground temperatures in boreholes (Section 5.4), the
23 modelled temperatures are forced with data for the hydrological year corresponding to the
24 observations. Because of the assumption of an equilibrium situation in the model approach,
25 such a comparison can be problematic as many of the boreholes have undergone warming
26 during the past decades. However, with the majority of the boreholes located in bedrock or
27 coarse moraine material with relatively high conductivity, the lag in the climate signal is
28 relatively small at the ~~depth of the~~ top of ~~the~~ permafrost. The lag will also vary from borehole
29 to borehole, depending on the ground thermal properties. Since we use data distributed over
30 larger areas and longer time periods, including a large range of situations, the effect ~~is~~ mainly
31 ~~shows-evident~~ in terms of a larger statistical spread and not a systematic error.

The large amount of field observations used for calibration and evaluation in this study is mainly conducted in alpine mountain areas. The large spatial variation in winter snow depths is a major controlling factor also of the ground temperatures in peat plateaus and palsa mires, and is a driving factor in palsa formation (Seppälä, 2011). The sub-grid effect of snow should therefore also be implemented for mire areas, where comparable data sets are lacking.

6.2 Model sensitivity

The sensitivity of CV_{sd} -model to the modelled ground temperatures is relatively low, with only 9 % variation in permafrost area, although the performance of the snow distribution scheme varies significantly between the models when evaluated with GPR snow surveys (Table 1). In comparison, a *lognormal* instead of a *gamma* distribution function reduces the permafrost area by 18% (Table 2). The choice of distribution function therefore seems to be of greater importance than the fine tuning of a model for CV_{sd} . This result contradicts the conclusions by Luce and Tarboton (2004), which suggest that the parameterization of the distribution function is more important than the choice of distribution model. With a focus on hydrology and snow cover depletion curves, equal importance was given to both the deeper and shallower snow depths in the mentioned study. In contrast, an accurate representation of the shallowest snow depths is crucial for modelling the ground thermal regime. The low thermal conductivity of snow results in a disconnection of ground surface and air temperatures at snow packs thicker than 0.5 – 1 m, depending on the physical properties of the snow pack and the surface roughness (Haeberli, 1973). In wind exposed areas prone to heavy redistribution, large fractions of the area will be entirely bare blown (Gisnås et al., 2014). These are the areas of greatest importance for permafrost modelling. In order to reproduce the gradual transition in the discontinuous permafrost zone, where permafrost is often only present at bare blown ridges, shallow snow covers must be satisfactorily represented. Compared to a *gamma* function, a *lognormal* distribution function to a larger degree underestimates the fraction of shallow snow depths, resulting in a less accurate representation of this transition.

Several studies include statistical representations of the sub-grid variability of snow in hydrological models, most commonly applying a two- or three-parameter *lognormal* distribution (e.g. Donald et al., 1995; Liston, 2004; Pomeroy et al., 2004; Nitta et al., 2014). Observed snow distributions within 1x1 km in the ALS snow survey presented in this paper

are closer to a *gamma* than to a *lognormal* distribution, supporting the findings by Skaugen (2007) and Winstral and Marks (2014) which were both conducted in non-forested alpine environments. However, the difference is not substantial in all areas; the two distributions can provide near-equal fit in eastern parts of the mountain plateau where the terrain is gentler and the wind speeds are lower. We suggest that the choice of distribution function of snow is important in model applications for the ground thermal regime, and recommend the use of *gamma* distribution for non-vegetated high alpine areas prone to heavy redistribution of snow.

While a *gamma* distribution offers improvements over a *lognormal* distribution, the bare blown areas are still not sufficiently represented. One attempt to solve this is to include a third parameter for the “snow free fraction” (e.g. Kolberg et al., 2006; Kolberg and Gottschalk, 2010). We made an attempt to calibrate such a parameter for this study, however, no correlations to any of the predictors were found. It is also difficult to determine a threshold depth for “snow free” areas in ALS data resampled to 10 meter resolution, where the uncertainty of the snow depth observations are in the order of ten centimetres (Melvold and Skaugen, 2013).

In this study a high number of realizations could be run per grid cell because of the low computational cost of the model. To evaluate the sensitivity of sampling density, the number of realizations was reduced from 100 to 10 per grid cell. This resulted in a 2.6 % increase in total modelled permafrost area relative to the reference model run. This demonstrates that a statistical downscaling of ground temperatures as demonstrated in this study is robust and highly-significantly improves the model results with only a few additional model realizations per grid cell.

7 Conclusions

We present a modelling approach to reproduce the variability of ground temperatures within the scale of 1 km² grid cells based on probability distribution functions over corresponding seasonal maximum snow depths. The snow distributions are derived from climatic parameters and terrain parameterizations at 10 meter resolution, and are calibrated with a large scale data set of snow depths obtained from laser scanning. The model results are evaluated with independent observations of snow depth distributions, ground surface temperature distributions and ground temperatures. From this study the following conclusions can be drawn:

- ~~The te-model results indicate a total~~ modelled permafrost area in an equilibrium with the average climate for the period 1981 – 2010 ~~area is of~~ 25 400 km². ~~This, corresponding corresponds~~ to 7.8 % of the Norwegian mainland, ~~in an equilibrium situation with the average climate over 1981-2010. 4 % of the model domain features permafrost for all snow depths.~~
- ~~The same permafrost model~~ model simulation without a sub-grid representation of snow produces almost 50 % less permafrost.
- ~~Because of the~~ Due to the non-linearity ~~in the~~ insulating effect of snow ~~cover~~ in combination with ~~the highly~~ asymmetric snow distributions within each grid cell, the spatial average ground temperature in a 1km² area cannot be determined based on the average snow cover for that area. ~~sub-grid variability of snow depths must be accounted for in models representing the ground thermal regime.~~
- —
- Observed variations in ground surface temperatures from two logger arrays with 26 and 41 loggers, respectively, are very well reproduced, with estimated fractions of sub-zero MAGST within $\pm 10\%$.
- 94 % of the observed mean annual temperature at top of permafrost in the boreholes are within the modelled ground temperature range for the corresponding grid cell, and mean modelled temperature of the grid cell reproduces the observations with an accuracy of 1.5°C or better.
- The sensitivity of the model to the coefficient of variation of snow (CV_{sd}) is relatively low, compared to the choice of theoretical snow distribution function. ~~B~~ However, both are minor effects compared to the effect of running the model without a sub-grid distribution.
- The observed CV_{sd} of snow within 1 km² grid cells in the Hardangervidda mountain plateau varies from 0.15 to 1.15, with an average CV_{sd} of 0.6. The observed CV_{sd} values are nearly identical at the end of the accumulation seasons in 2008 and 2009.
- The distributions are generally closer to a theoretical *gamma* distribution than to a *lognormal* distribution, in particular in areas of very rough topography, thicker snow cover and higher average winter wind speeds. ~~The observed CV_{sd} values are nearly identical at the end of the accumulation seasons in 2008 and 2009.~~

1 In areas subject to snow redistribution, the average ground temperature of a 1 km² grid cell
2 must be determined based on the distribution, and not the overall average of snow depths
3 within the grid cell. ~~M~~Furthermore, modelling the full range of ground temperatures present
4 over small distances ~~enables~~facilitates a better representation of the gradual transition from
5 permafrost to non-permafrost areas and most likely a more accurate response to climate
6 warming. This study ~~is—demonstrates clear evidence—that~~ accounting for the sub-grid
7 variability of snow depths ~~should be accounted for in model approaches~~can strongly improve
8 model estimates of the ~~targeting the~~ ground thermal regime —and permafrost distribution
9 alpine conditions.

1 Figures:

2

3 Fig. 1: Modelled distribution of permafrost in Norway. Sites mentioned in the text: 1) Finse,
4 south of Hallingskarvet, 2) Juvvasshøe in Jotunheimen, 3) Dovrefjell, 4) The Lyngen Alps
5 and 5) Finnmark.

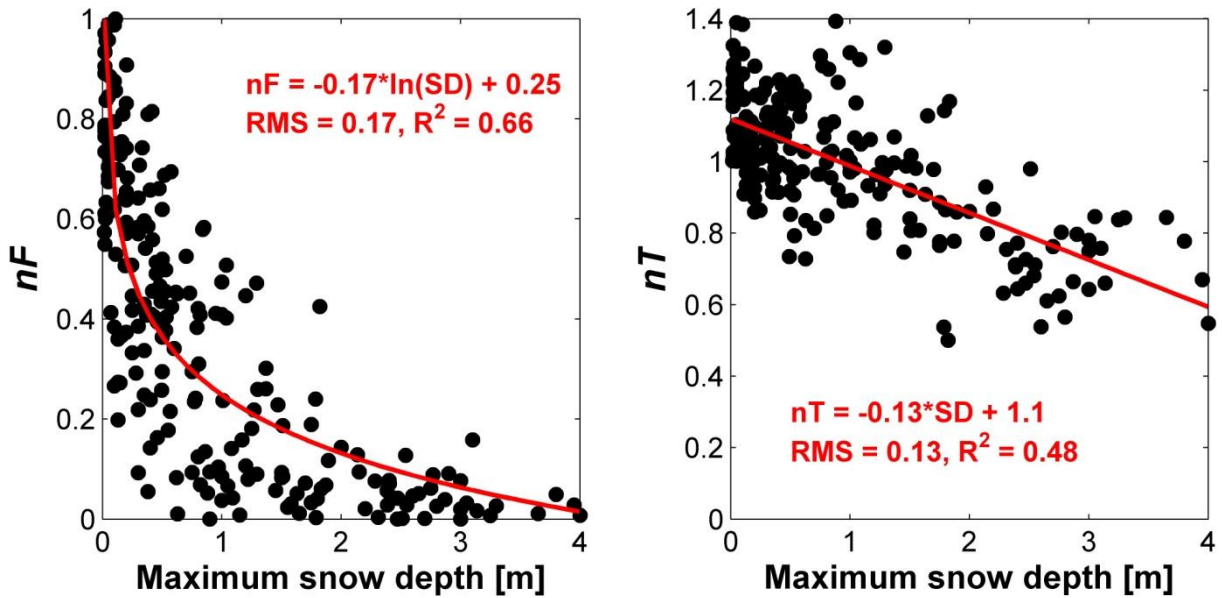

1

2

3 Fig. 2: The ~~figure illustrates the~~ area accounted for in each of the 8 runs of the Winstral
 4 terrain-based parameter, each of them with a prevailing wind direction d_n . The area accounted
 5 for when calculating the exposure of a grid cell is constrained by the search window (A) and
 6 the search distance d_{max} being 100 meters upwind.

7

8

9 Fig. 3: nF and nT related to maximum snow depth observed at more than 90 sites located
 10 above 1000 m a.s.l. in southern Norway.

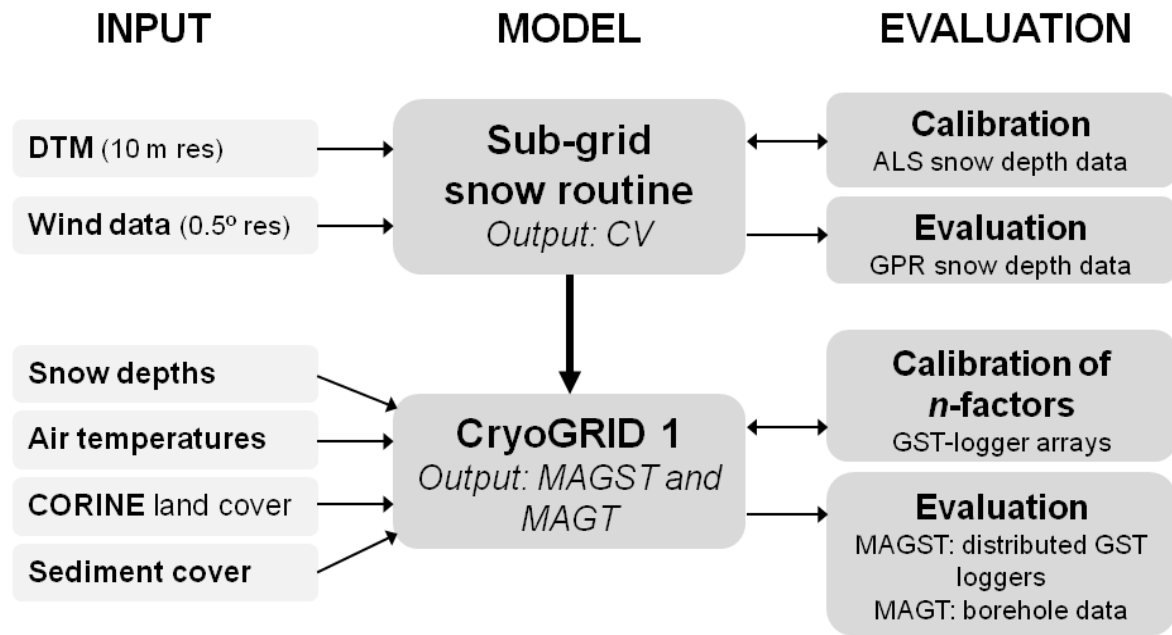

Fig. -4: Schematic of the model chain, including input data, and calibration and evaluation procedures.

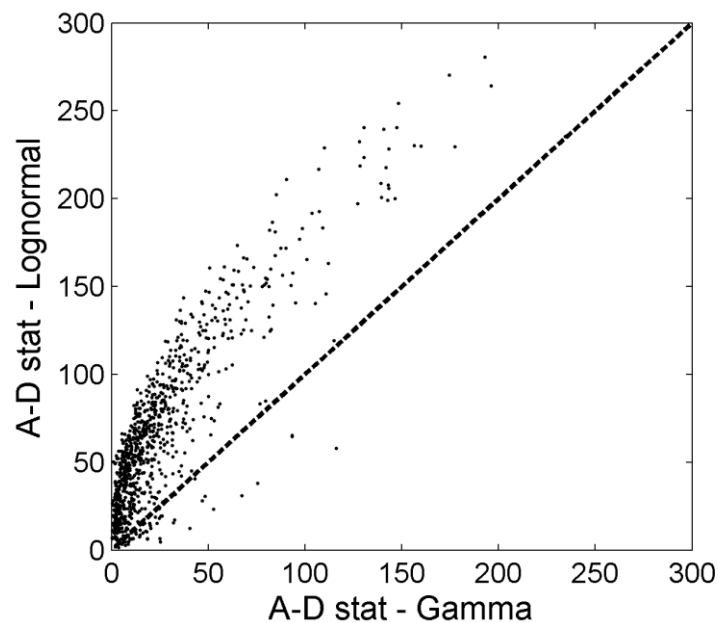

Fig. -5: Scores from the Anderson-Darling Test Statistics for Goodness-of-Fit between theoretical *gamma* and *lognormal* distributions and the observed distribution within each 1x1 km area in the ALS snow survey. Lower scores indicate better fit.

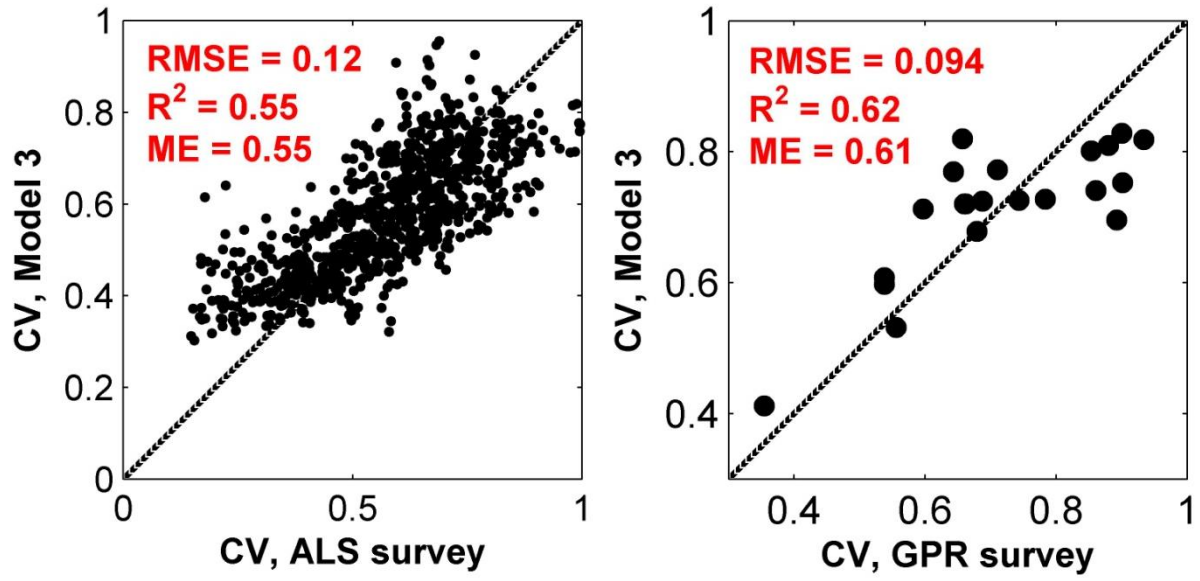

Fig. 6: Left: Fit ~~for~~of the regression *Model 3* for CV_{sd} , calibrated with CV_{sd} derived from the ALS snow survey. Right: The model performance is evaluated with independent ground penetrating radar (GPR) snow surveys from at Finse and Juvvasshøe.

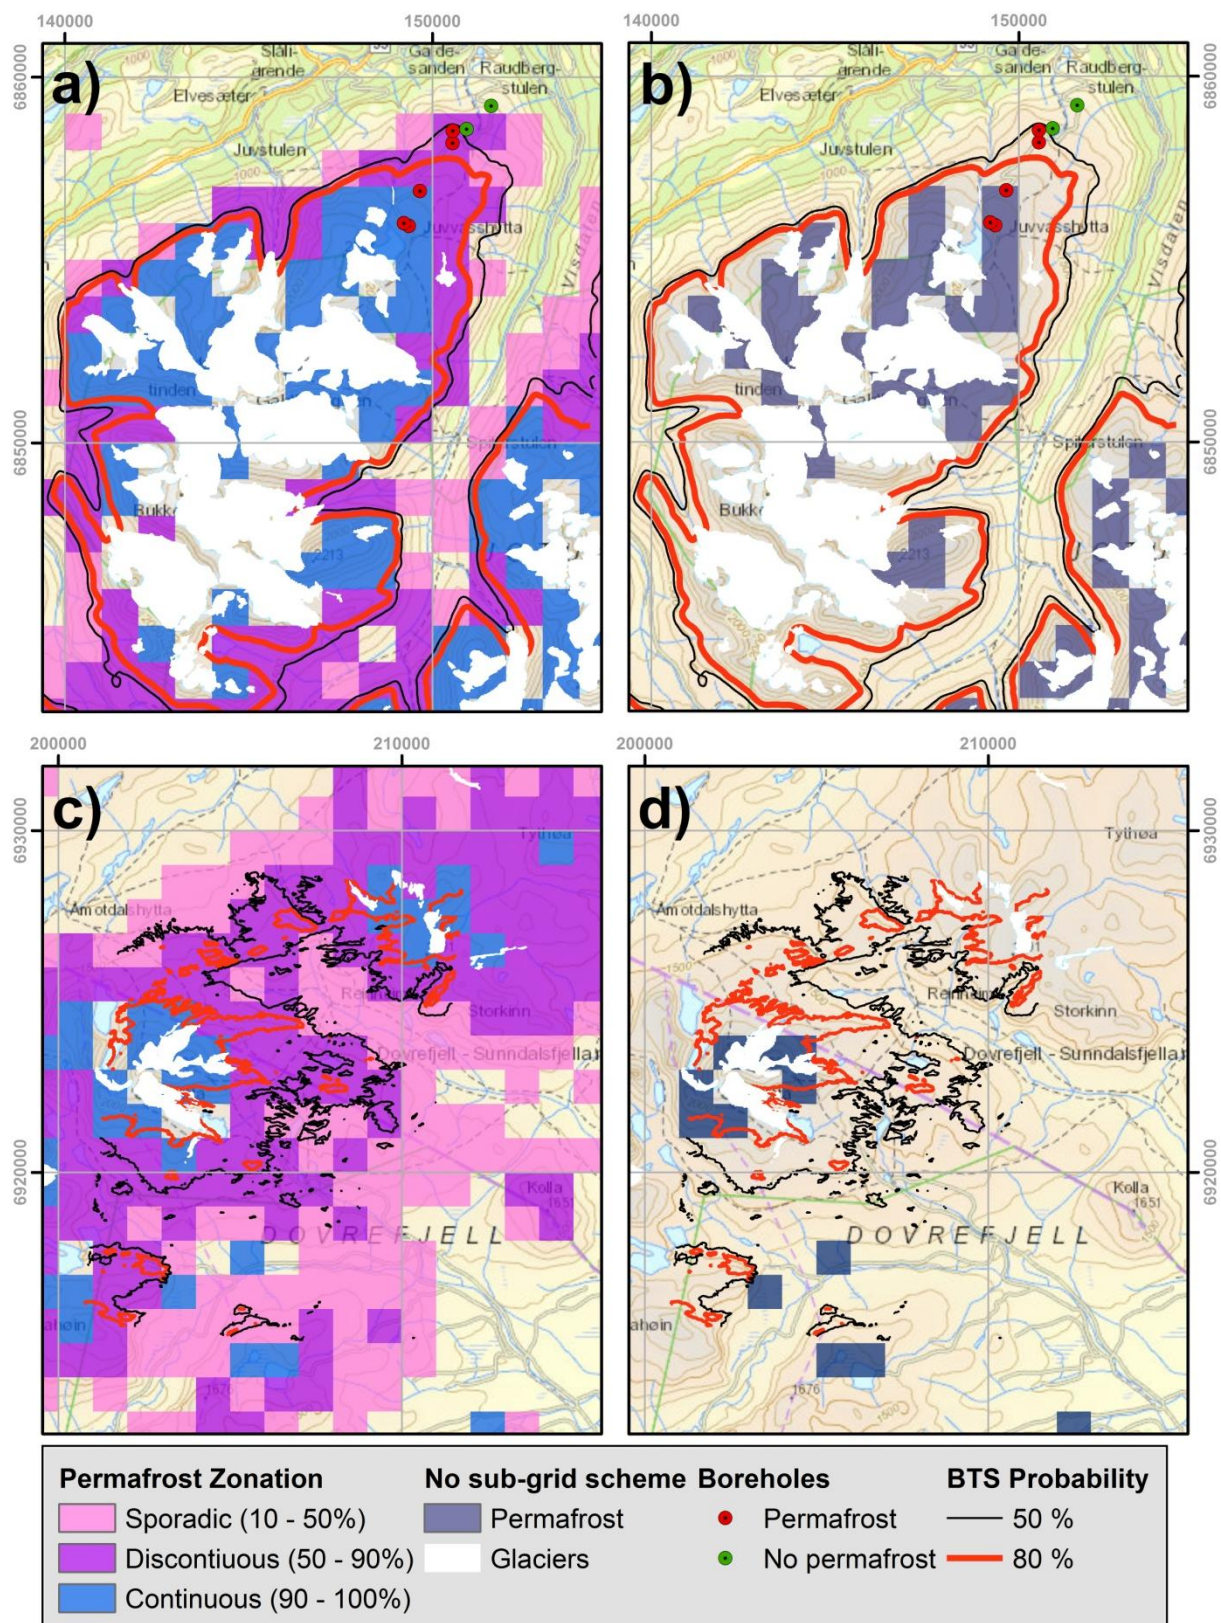

Fig. 7: Distribution of permafrost at Juvvasshøe in Jotunheimen (a and b), and at Dovrefjell (c and d) modelled as permafrost zones applying the sub-grid approach (left) compared to the modelled mean annual ground temperature (*MAGT*) without a sub-grid approach (right).

Lower limit of 50 % and 80 % probability of permafrost derived from BTS-surveys are shown as black and red contour lines, respectively. Borehole locations with permafrost (red) and seasonal frost (green) are shown as dots in the map at Juvvasshøe.

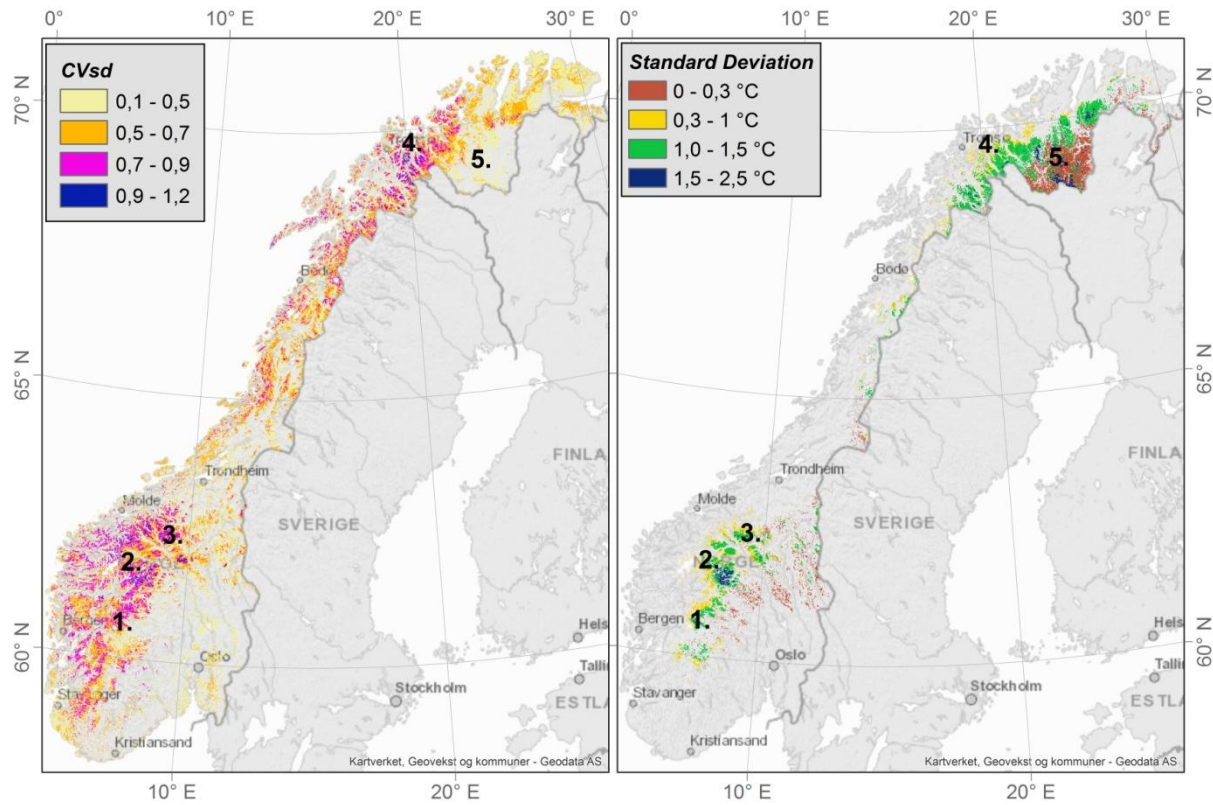

Fig. 8: Left: Distribution of modelled CV_{sd} in non-vegetated areas of Norway with *Model 3*. CV_{sd} increases in areas of rougher topography (western side of Norway) and higher elevations (central part following the Scandes). Right: Standard deviation of modelled $MAGT$ for areas of modelled permafrost. Sites mentioned in the text: 1) Finse, south of Hallingskarvet, 2) Juvvasshøe in Jotunheimen, 3) Dovrefjell, 4) The Lyngen Alps and 5) Finnmark.

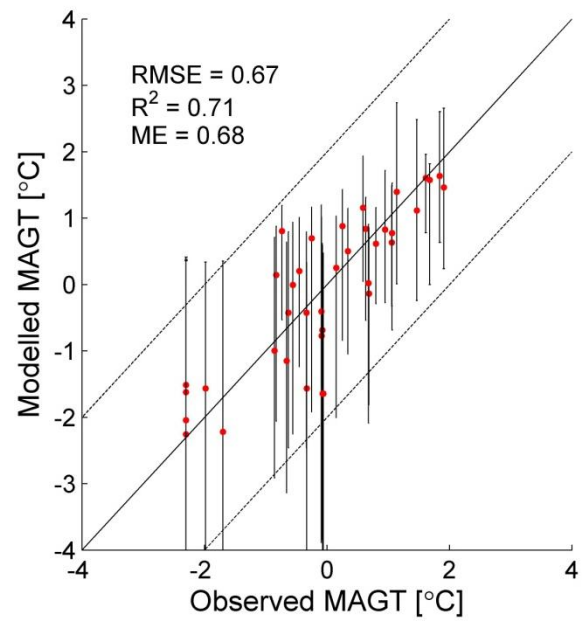

Fig. 9: ~~The figure shows the e~~Correlation between modelled and observed *MAGST* (left) and *MAGT* at the top of permafrost (right). The dotted line indicates ± 2 °C of the 1:1 line (black line). The vertical bars indicate the variation of modelled temperatures within the grid cell, and the red dots indicates the mean temperature.

Tables:

Table 1: The three regression models for CV_{sd} with in increasing number of predictors are calibrated with observed snow distributions from the ALS snow survey (left columns). P-values are $< 10^{-6}$. The isolated snow distribution scheme is validated with independent snow distribution data collected with GPR snow surveys (right columns). Root mean square error ($RMSE$), coefficient of determination (R^2) and Nash-Sutcliffe model efficiency (ME) are given for each model evaluation.

| 8 | $CV_{sd} =$ | Fit of regression | | | CV_{sd} GPR survey | | |
|----------------|--|-------------------|-------|------|----------------------|-------|-------|
| | | $RMSE$ | R^2 | ME | $RMSE$ | R^2 | ME |
| Model 1 | $0.39 + 3.4 * CV_{sx}$ | 0.14 | 0.36 | 0.36 | 0.20 | 0.04 | -0.71 |
| Model 2 | $0.31 + 3.1 * CV_{sx} + 4.05e-4 * z$ | 0.12 | 0.52 | 0.52 | 0.12 | 0.59 | 0.36 |
| Model 3 | $0.40 + 3.1 * CV_{sx} + 4.95e-04 * z - 0.0713 * \mu$ | 0.12 | 0.55 | 0.55 | 0.09 | 0.62 | 0.61 |

Table 2: The model performance is evaluated with respect to the mean annual ground surface temperatures ($MAGST$) and the mean annual temperature at the depth of the active layer or seasonal freezing layer ($MAGT$). Modelled average $MAGST$ or $MAGT$ over a grid cell is compared to more than 100 GST logger locations and 25 boreholes. The location of the GST loggers and boreholes are shown in Fig. 1. Modelled permafrost distribution is given in total areas, and as percentage of the model domain, corresponding to the Norwegian mainland area.

| | | Permafrost model evaluation | | | | | | Modelled permafrost area | |
|------------------------------|-----------------------------------|-----------------------------|-------------|-------------|-----------------|-------------|-------------|--------------------------|------------|
| | | MAGST, GST loggers | | | MAGT, boreholes | | | | |
| | | $RMSE$ | R^2 | ME | $RMSE$ | R^2 | ME | $[km^2]$ | $[%]$ |
| No sub-grid variation | | 1.57 | 0.65 | -0.56 | 1.19 | 0.62 | -1.90 | 13 462 | 4.1 |
| GAMMA | $CV_{sd} = 0.6$ | 1.37 | 0.64 | 0.06 | 0.77 | 0.66 | 0.22 | 23 571 | 7.3 |
| | Model 1 | 1.36 | 0.63 | 0.12 | 0.77 | 0.66 | 0.11 | 23 147 | 7.1 |
| | Model 2 | 1.29 | 0.65 | 0.31 | 0.65 | 0.71 | 0.62 | 23 674 | 7.3 |
| | Model 3* | 1.29 | 0.65 | 0.38 | 0.67 | 0.71 | 0.68 | 25 407 | 7.8 |
| LOGN | Model 1 | 1.40 | 0.64 | -0.06 | 0.87 | 0.67 | -0.25 | 19 975 | 6.2 |
| | Model 2 | 1.38 | 0.65 | 0.01 | 0.82 | 0.69 | 0.09 | 20 067 | 6.2 |
| | Model 3 | 1.36 | 0.65 | 0.06 | 0.78 | 0.69 | 0.22 | 20 889 | 6.2 |

*Reference model run.

Table 3: Observed and modelled values for the coefficient of variation for maximum snow depth (CV_{sd}) and spatial distributions of Mean Annual Ground Surface Temperatures (MAGST) at the field sites at Finse and Juvvasshøe. The MAGST modelled without a sub-grid distribution of snow is given in parenthesis.

| | Juvvasshøe | | Finse | |
|-----------------------------|------------|------------------|----------|-----------------|
| | Observed | Modelled | Observed | Modelled |
| CV_{sd} | 0.85 | 0.80 | 0.71 | 0.77 |
| MAGST < 0 °C | 77 % | 64 % | 30 % | 32 % |
| MAGST_{min} | -1.8 °C | -2.6 °C | -1.9 °C | -1.6 °C |
| MAGST_{max} | 1.0 °C | 0.8 °C | 2.7 °C | 1.0 °C |
| MAGST_{avg} | -0.5 °C | -0.5 °C (0.8 °C) | 0.8 °C | 0.2 °C (1.3 °C) |
