Response to comments from reviewer 1

We would like to thank Renji Naruse for the comments on our manuscript and suggested improvements.

The review called for considerable rewriting of the manuscript to improve the clarity of purpose of the study, and we have made every effort to do this, as detailed below. In particular we focused on clearly stating the purpose, and improving the readability, and believe theta the changes detailed below have significantly improved the manuscript.

Reviewer comments are given in green, authors reply in black and revised text sections included in blue italics. The revised manuscript and figure captions are appended to this reply highlighting all changes made, and including updated versions of the figures.

The purpose of this paper is unclear, and the manuscript itself is quite long with lots of lengthy paragraphs and sentences (e.g., L74-78, L79-84, L111-114, and others: very hard to read).

The aims of the paper have been stated more clearly at the end of the introduction as follows:
"*In this study a Microsoft Xbox Kinect sensor is used as a close-range mobile distance ranger to produce a series of small-scale digital surface models (DSMs). The method of DSM generation is evaluated against standard terrestrial laser scanning and the Kinect-derived DSMs of the penitentes are used to (i) perform the first detailed examination of the morphometry of natural penitentes over the course of an ablation season; (ii) compare the volume change computed from DSM differencing with estimates based on manual measurements of surface lowering and (iii) examine the geometrical roughness properties of the sampled penitentes*."
The sequencing of the results and discussion has also been reordered to follow the numerical order of these 3 aims.

The manuscript has been re-edited to break long sentences into shorter ones to aid readability. As illustration, the first two examples listed have been changed as follows (the third section has been deleted):

- "*While penitentes are a relatively rare form of linearized surface feature in many glacierized environments, in contrast linear crevasses are widespread, and although the impact of wind direction on roughness and the resultant turbulent heat fluxes is generally not treated in glaciology, penitentes offer a unique test bed for investigating the significance of linearized features on effective surface roughness for various wind directions*." Now reads: "*While penitentes are a relatively rare form of linearized surface feature in many glacierized environments, linear crevasses are widespread, and penitentes offer a unique test bed for investigating the significance of linearized features on effective surface roughness for various wind directions.*"
- *"In general, the physical roughness of snow and ice surfaces are particularly prone to varying in space and time (e.g. Smeets et al., 1999; Brock et al., 2006; Fassnacht et al., 2009), it is desirable to be able to replace relatively logistically and technologically challenging methods of determining roughness parameters from atmospheric profile or eddy covariance measurements, with methods based on more readily measurable surface terrain properties (e.g. Kondo and Yamazawa, 1986; Munro, 1989; Andreas, 2011), or properties such as radar backscatter that can be derived from spaceborne instruments (e.g. Blumberg and Greeley, 1993)."*

now reads "*As it is logistically challenging to deploy instrumentation to determine roughness parameters from atmospheric profile or eddy covariance measurements on glacier surfaces, efforts have been made to instead use methods based on properties such as radar backscatter (e.g. Blumberg and Greeley, 1993) or more readily measurable surface terrain properties (e.g. Kondo and Yamazawa, 1986; Munro, 1989; Fassnacht et al., 2009a; Andreas, 2011).*"

Abstract should state in principle very concisely, the purpose (in a short sentence), methods, results (findings), interpretations (discussion), and conclusions within one paragraph of 200-300 words. In the present manuscript, the first nine lines (L10-L18) may be moved to Introduction, and the last 12 lines (L27-L39) emphasizes only aerodynamic roughness parameters.

Thanks for this; we fully agree that the initial abstract was not of sufficient brevity, or clarity. However, it remains the case that half of the abstract still refers to surface roughness as this part of the analysis is harder to condense than the morphometrical observations. The abstract has now been significantly reduced in length (from 492 to 364 words) following the suggestions and now reads as follows: "*In this study, the first small-scale digital surface models (DSMs) of natural penitentes on a glacier surface were produced using a Microsoft Xbox Kinect sensor on Tapado Glacier, Chile (30°08'S; 69°55'W). The surfaces produced by the complete processing chain were within the error of standard terrestrial laser scanning techniques, but insufficient overlap between scanned sections that were mosaicked to cover the sampled areas can result in three-dimensional positional errors of up to 0.3 m. Between November 2013 and January 2014 penitentes become fewer, wider, deeper, and the distribution of surface slope angles becomes more skewed to steep faces. Although these morphological changes cannot be captured by manual point measurements, mean surface lowering of the scanned areas was comparable to that derived from manual measurements of penitente surface height at a minimum density of 5 m*$^{-1}$ *over a 5 m transverse profile. Roughness was computed on the 3D surfaces by applying two previously published geometrical formulae; one for a 3D surface and one for single profiles sampled from the surface. Morphometric analysis shows that skimming flow is persistent over penitentes, providing conditions conducive for the development of a distinct microclimate within the penitente troughs. For each method a range of ways of defining the representative roughness element height was used, and the calculations were done both with and without application of a zero displacement height offset to account for the likelihood of skimming air flow over the closely-spaced penitentes. The computed roughness values are in the order of 0.01-0.10 m during the early part of the ablation season, increasing to 0.10-0.50 m after the end of December, in line with the roughest values previously published for glacier ice. Both the 3D surface and profile methods of computing roughness are strongly dependent on wind direction. However, the two methods contradict each other in that the maximum roughness computed for the 3D surface coincides with airflow across the penitente lineation while maximum roughness computed for sampled profiles coincides with airflow along the penitente lineation. These findings highlight the importance of determining directional roughness and wind direction for strongly aligned surface features and also suggest more work is required to determine appropriate geometrical roughness formulae for linearized features.*"

As expressed in the first part of Introduction (L41-L60), it is known that sublimation from the tips of penitentes and concentrated solar radiation in the hollows are essential to the formation of penitentes. On the other hand, turbulent heat flux, which is related with aerodynamic roughness heights, may play negative roles for penitent developments. In Introduction, following the albedo effect (L63-69), roughness parameters are described in detail from L70 to L96.

The section about methods of determining surface roughness has been moved to the methods section immediately prior to introducing the geometrical approach applied in this work. This makes the introduction more streamlined and is both more in balance with, and leads the reader more smoothly to, the goals of the paper.

I guess that the authors' largest interest may be the derivation and properties of roughness parameters. If so, the structure and the way of writing should be significantly modified in order for readers to understand easily the authors' statements. Issues on the penitent morphology and the aerodynamic roughness are not well harmonized in the present paper. Thus, I suggest now to divide the manuscript into two papers, such as, for example (only for authors' information):

a) "3D surface properties of snow penitentes and their evolutions in an ablation season 2013-14, at Tapado Glacier in the Andes" - [Fig.1, Fig.4, Fig.10, Fig. (meteorological condition), Fig. (heat balance)]

b) "Aerodynamic roughness parameters over a field of glacier penitentes derived from measurements with a Microsoft Xbox Kinect" - [Fig.1, Fig.2, (Fig.3), Figs. 5, 6, 7, 8, (9)] The manuscript b) needs to be reviewed by (an) expert(s) on boundary layer micrometeorology.

We prefer not to separate the paper into two, as the surface roughness properties fall under the umbrella of the 'surface properties' covered by the title. Additionally, we are keen to include within this paper at least one way in which the surfaces generated by the Kinect scanning can have valuable scientific applications.

However we have tried to respond to the comment that the component parts needed to be better integrated than they were in the initial submission and accordingly a number of changes were made to improve the relationship between the morphology and the roughness parts of the paper. For example:

- L67: "Measurements of natural penitentes required to examine their morphometry and roughness are rare (e.g. Naruse and Leiva, 1997), and …"
- L75: clearly stated the threefold aims "*… are used to (i) perform the first detailed examination of the morphometry of natural penitentes over the course of an ablation season; (ii) compare the volume change computed from DSM differencing with estimates based on manual measurements of surface lowering and (iii) examine the geometrical roughness properties of the sampled penitente surfaces*."
- These aims are now tackled consistently in this order throughout the paper.
- In keeping with this order, Figure 10 was moved up the order to become Figure 5.
- L470: "*The changing morphometry of the penitentes alters the geometrical surface roughness as they develop over the ablation season*."

3D surface properties of glacier penitentes over an ablation season, measured using a Microsoft Xbox Kinect.

Abstract. ~~Penitentes are a common feature of snow and ice surfaces in the semi-arid Andes where very low humidity, in conjunction with persistently cold temperatures and sustained high solar radiation favour their development during the ablation season. As penitentes occur in arid, low latitude basins where cryospheric water resources are relatively important to local water supply, and atmospheric water vapor is very low, there is potential value in understanding how penitentes might influence the runoff and atmospheric humidity.~~

~~The complex surface morphology of penitentes makes it difficult to measure the mass loss occurring within them because the (i) spatial distribution of surface lowering within a penitente field is very heterogeneous, and (ii) steep walls and sharp edges of the penitentes limit the line of sight view for surveying from fixed positions and (iii) penitentes themselves limit access for manual measurements.~~ In this study, ~~we solved these measurement problems by using a Microsoft Xbox Kinect sensor to generate~~the first small-scale digital surface models (DSMs) of ~~small sample areas of snow and ice~~natural penitentes on a glacier surface were produced using a Microsoft Xbox Kinect sensor on Tapado Glacier~~ in~~, Chile (30°08'S; 69°55'W~~) between November 2013 and January 2014.~~). The surfaces produced by the complete processing chain were within the error of standard terrestrial laser scanning techniques~~. However, in our study~~, but insufficient overlap between scanned sections that were mosaicked to cover the ~~studied sites~~ sampled areas can result in three-dimensional positional errors of up to 0.3 m.

~~Mean surface lowering of the scanned areas was comparable to that derived from point sampling of penitentes at a minimum density of 5 m^{-1} over a 5 m transverse profile. Over time the~~Between November 2013 and January 2014 penitentes become fewer, wider, deeper, and the distribution of surface slope angles becomes more skewed to steep faces. ~~These~~Although these morphological changes cannot be captured by ~~the interval sampling by~~ manual point measurements~~.~~, mean surface lowering of the scanned areas was comparable to that derived from manual measurements of penitente surface height at a minimum density of 5 m^{-1} over a 5 m transverse profile. Roughness was computed on the 3D surfaces by applying two previously published geometrical formulae; one for a 3D surface and one for single profiles sampled from the surface. Morphometric analysis shows that skimming flow is persistent over penitentes, providing conditions conducive for the development of a distinct microclimate within the penitente troughs. For each method a range of ways of defining the representative roughness element height ~~required by these formulae~~ was used, and the calculations were done both with and without ~~using~~application of a zero displacement height offset to account for the likelihood of skimming air flow over the closely~~-~~-spaced penitentes. The computed roughness values are in the order of 0.01-0.10 m during the early part of the ablation season, increasing to 0.10-0.50 m after the end of December, in line with the roughest values previously published for glacier ice. Both the 3D surface and profile methods of computing roughness are strongly dependent on wind direction. However, the two methods contradict each other in that the maximum roughness computed for the 3D surface coincides with airflow across the penitente lineation while maximum roughness computed for sampled profiles coincides with airflow along the penitente lineation. These findings highlight the importance of determining directional roughness and wind

direction for strongly aligned surface features and also suggest more work is required to determine appropriate geometrical roughness formulae for linearized features.

1. Introduction

Penitentes are spikes of snow or ice, ranging from a few centimetres up to several metres in height that can form during the ablation season on snowfields and glaciers~~ under the right conditions. The conditions required for penitentes to form~~. They are ~~dew point below 0°C, persistently low air temperatures and sustained strong solar insolation (Lliboutry, 1954). These conditions are frequently met at~~a common feature of high elevation, low-latitude glaciers and snowfields~~, such as in the subtropical Andes~~ (e.g. Hastenrath and Koci, 1981; Corripio and Purves, 2005; Winkler et al., 2009~~),~~) where ~~penitentes are widespread during the ablation~~very low humidity, persistently cold temperatures and sustained high solar radiation favour their development (Lliboutry, 1954). As cryospheric water resources are relatively important to local dry season~~.~~ water supply in arid mountain ranges (Kaser et al., 2010), there is potential value in understanding how penitentes might influence both runoff and atmospheric humidity.

~~Observations show that penitente~~Penitentes form linearized, inclined fins of snow or ice on the surface. Both the latitudinal range (within 55° of the equator on horizontal surfaces) and geometry ~~is~~ (aligned with the arc of the sun across the sky, and tilted toward the sun at local noon~~, highlighting the importance~~) of penitentes are governed by solar~~ radiation in penitente formation~~-to-surface geometry (Lliboutry, 1954; Hastenrath and Koci, 1981; Bergeron et al., 2006~~). Indeed, the alignment and restricted latitudinal range of penitentes (within 55° of the equator on horizontal surfaces) can be explained by solar-to-surface geometry alone (~~; Cathles et al., 2014). ~~The process~~During the initial stages of penitente ~~growth involves geometric focusing of incident solar radiation~~ development, ablation is thought to proceed by ~~surface~~sublimation alone driven by the low atmospheric humidity. Surface irregularities ~~that causes~~focus reflected solar radiation within depressions ~~to receive more radiation than surrounding peaks~~ (Amstutz, 1958; Corripio and Purves, 2005; Lhermitte et al., 2014; Claudin et al., 2015~~). Consequently,~~) such that the energy receipts, and consequently ablation, are ~~initially~~ enhanced in the hollow ~~due to multiple reflection of irradiance,~~ and the surface irregularity becomes amplified. ~~However for substantial penitente growth it is crucial that, at the tips of penitentes, ablation occurs by sublimation and the snow/ice temperature remains below the melting point, while in the troughs between penitentes, melting can occur once~~Subsequently, as the surface relief increases, a more humid microclimate is ~~established within the hollow~~thought to develop in the hollows between penitentes, supressing sublimation and allowing melting in the depressions. Meanwhile, the penitentes tips continue to ablate by sublimation alone (Lliboutry, 1954; Drewry, 1970; Claudin et al., 2015~~). Once the snow/ice in the hollows has reached the melting point, the spatial differentiation of ablation processes serves to further amplify the penitente relief as melting only~~) and, as melting requires approximately an eighth of the energy of sublimation to remove the same amount of ice, the spatial differentiation of ablation process between penitente trough and tip is very effective at amplifying the penitente surface relief.

The altered partitioning of ablation between sublimation and melting that occurs in penitente fields, as compared to surfaces without penitentes (e.g. Lliboutry, 1998; Winkler et al., 2009; Sinclair and MacDonell, 2015~~The impact of penitentes on the surface energy balance and ablation of snow and ice is of interest in arid mountains catchments, where penitentes are widespread and meltwater can be a substantial contribution to local hydrological resources (Kaser et al., 2010). Previous studies have shown that penitentes alter the surface energy balance of snow and ice surfaces by reducing~~), is expected to alter the rate of mass loss and meltwater production of snow and icefields during the ablation season, but this has not yet been fully quantified. Previous studies, based on modelling idealized penitente surfaces, have investigated the impact of penitentes on the shortwave radiative balance, and suggest that penitentes reduce effective albedo by up to 40% compared to flat surfaces (Warren et al, 1998; Corripio and Purves, 2005; MacDonell et al., 2013; Cathles et al., 2014; Lhermitte et al., 2014~~) as well~~). In addition to altering the ~~partitioning of ablation between sublimation and melting (e.g. Lliboutry, 1998; Winkler et al., 2009; Sinclair and~~

~~MacDonell, 2015~~). ~~Thus, the presence of penitentes is expected to alter the rate of mass loss and meltwater production of snow and icefields during the ablation season, and, on the basis of the~~ radiative ~~balance it has been postulated that they will accelerate the snow and ice mass loss rates (Cathles et al., 2014). However~~properties of the surface, the development of penitentes ~~on the surface will~~ also ~~alter the roughness properties in both space and time, but this, as well as its impact on the resultant turbulent fluxes is not quantified. The wind direction-dependence of~~ manifestly alters the surface roughness properties, but neither the impact of penitentes on surface roughness, nor the associated impact on turbulent energy fluxes has been investigated. The roughness of snow and ice surfaces is particularly prone to varying in space and time (e.g. Smeets et al., ~~over linearized surface features has been previously observed in wind~~1999; Brock et al., 2006; Fassnacht et al., 2009b). Wind profile measurements over ~~snow~~linearized sastrugi~~, for which~~ surface features shows that the derived aerodynamic roughness length varied from 1–70 mm over a 120° range of impinging wind direction (Jackson and ~~Carol~~Carroll, 1978). While penitentes are a relatively rare form of linearized surface feature~~ in many glacierized environments, in contrast,~~ linear crevasses are widespread, and ~~although the impact of wind direction on roughness and the resultant turbulent heat fluxes is generally not treated in glaciology,~~ penitentes offer a unique test bed for investigating the significance of linearized features on effective surface roughness for various wind directions.

~~In general, the physical roughness of snow and ice surfaces are particularly prone to varying in space and time (e.g. Smeets et al., 1999; Brock et al., 2006; Fassnacht et al., 2009), it is desirable to be able to replace relatively logistically and technologically challenging methods of determining roughness parameters from atmospheric profile or eddy covariance measurements, with methods based on more readily measurable surface terrain properties (e.g. Kondo and Yamazawa, 1986; Munro, 1989; Andreas, 2011), or properties such as radar backscatter that can be derived from spaceborne instruments (e.g. Blumberg and Greeley, 1993). The most comprehensive surface of methods to determine apparent aerodynamic properties from surface morphometry was carried out by Grimmond and Oke (1999) who tested several methods in urban environments, which are among the roughest surface conditions encountered in boundary layer atmospheric studies. The morphometric estimates of roughness properties were compared with those from aerodynamic methods from numerous field and laboratory studies. Many of the aerodynamic studies were found to be flawed, and the study demonstrates that, despite the considerable effort in obtaining such measurements, their reliability in complex and rough terrain is contested as the computations rely upon theory that is developed for flat homogenous terrain, and in general the aerodynamic results show a similar amount of spread as the various geometrical methods tested. Although, Grimmond and Oke (1999) consider that direct measurements of fluxes over complex terrain are most likely the 'best' way of determining surface properties, the difficulties of deploying the expensive and relatively delicate instruments over glacier surfaces makes a geometric determination even more appealing. However, in the case of penitentes, such studies are impeded by a scarcity of information on real penitente geometry.~~

Measurements of natural penitentes ~~(e.g.~~ required to examine their morphometry and roughness are rare (e.g. Naruse and Leiva, 1997~~) are rare as they are generally found in relatively inaccessible areas and the complex surface relief poses a considerable impediment to movement and measurement, for example preventing~~), and difficult to obtain because the complex, and partially overhanging, surface prevents the use of simplified automated tools such as photogrammetric determination of surface profile heights (e.g. Fassnacht et al., ~~2010~~2009a; Manninen et al., 2012~~). Furthermore, accurately measuring the convoluted penitente surface is in itself a significant challenge, as it includes overhanging surfaces, which is problem for immobile~~) or line-of-sight surveying ~~equipment. However,~~from fixed positions. Recent advances in close-range mobile depth-of-field sensors and efficient feature tacking software used in interactive computer gaming offer potentially useful tools that can be applied to ~~generate small-scale digital surface models to~~ resolve such problems in earth science (e.g. Mankoff ~~et al.,~~and Russo, 2013). In this study ~~sample plots of penitentes in snow on a glacier surface are scanned using~~ a Microsoft Xbox Kinect sensor is used as a close-range mobile distance ranger to produce a series of small-scale digital surface models (DSMs). ~~These surface models are used to perform (i)~~ The method of DSM generation is evaluated against standard terrestrial laser scanning, and the Kinect-derived DSMs of the penitentes are used to (i) perform the first detailed examination of the

~~geometry~~morphometry of natural penitentes ~~and how they change~~ over the course of ~~the core~~an ablation season; (ii) ~~an examination of the geometrical roughness properties of penitentes and (iii)~~ compare the volume ~~changes~~change computed from DSM differencing ~~the DSMs~~ with ~~the volume changes estimated from~~estimates based on manual measurements of surface lowering ~~within a penitente field. These measurements enable evaluation of how accurately simplified~~and (iii) examine the geometrical roughness properties of the sampled penitente surfaces ~~used in theoretical modelling represent the true surfaces found in nature, improved parameterization of surface roughness in energy balance models applied to glacier and snowfields with penitentes, and the performance of energy balance models over penitente surfaces to be evaluated against mas loss derived from the measured surface changes~~.

2. Methods

2.1 Description of fieldsite

Tapado Glacier (30°08'S; 69°55'W) lies in the upper Elqui Valley of the semi-arid Andes of the Coquimbo Region of Chile (Figure 1). ~~This~~The glacier is relatively ~~easily~~ accessible and ~~previous research indicates that the glacier surface develops~~is known to develop penitentes every summer (Sinclair and MacDonell, 2015). Two separate study areas were analysed. Firstly, a test site was established at a patch of snow penitentes within a dry stream bed at 4243 m a.s.l. in the glacier foreland (Figure ~~1b~~1). This site was used to (i) ~~trial~~test instrumental setups in order to optimize the field operation of the Kinect sensor, and (ii) compare the performance of the Kinect sensor against a Terrestrial Laser ~~Scanning~~Scanner (TLS~~) system.~~). This location was chosen due to the logistical difficulties of transporting the TLS to the glacier. Subsequently, two study plots were established at an elevation of 4774 m a.s.l. ~~within~~on the glacier ablation zone~~.~~ (Figure 1). These ~~surfaces at these~~ sites were ~~measured~~scanned repeatedly ~~using~~with the Xbox Kinect (see section 2.3) during the core ablation season between the end of November 2013 and the beginning of January 2014. ~~An automatic weather station on a free-standing tripod was installed beside the two plots to provide meteorological context for the measurements.~~

The location and layout of the two glacier sites is shown in Figure ~~1~~1a. Site A (5 m by 2 m) was measured four times, on 25 November, 11 December, 20 December and 3 January. Site B (2 m by 2 m~~, Figure 1c~~) was only measured on the last three dates ~~(Figure 1c).~~. The corners of the study sites were marked with 2 m lengths of plastic plumbing piping hammered vertically into the snow, or drilled into the ice~~.~~ (Figure 1c). In order to locate the study sites in space and to provide a common reference ~~frame~~ for each survey date, marker stake positions were measured using a Trimble 5700 differential GPS with Zephyr antenna on the 25th November, with a base station in the glacier foreland. On each visit to the glacier, when possible, the stakes were hammered further into the snow and the resultant lowering of the stake top was noted. The maximum standard deviations of the GPS stake positions were < 1.0 cm, 1.1 cm and 1.7 cm in easting, northing and elevation respectively, with combined XYZ standard deviation < 2.0 cm for all stakes (Supplement A). Error on the manual measurements of height offsets of the marker stakes on subsequent survey dates is conservatively estimated to be 2.0 cm. This results in total positional errors of the ground control points at each scan date of between 2.3 and 2.7 cm depending on the stake. Manual measurements of surface lowering were made along the eastern long side of site A. All surfaces heights were referenced to the elevation of the glacier surface at the upglacier end of this cross profile at the date of installation. An automatic weather station (AWS) on a free-standing tripod was installed beside the two glacier plots to provide meteorological context for the measurements (Figure 1).

2.2 Terrestrial laser scanning

~~Surface scans of snow penitentes at~~At the test site ~~were undertaken with both a terrestrial laser scanner (TLS) and the Kinect sensor in order to compare the~~ surface scans produced by the ~~well-established TLS method and the~~ relatively new Kinect sensor ~~application~~were compared with those produced by the well-established TLS method. The TLS system used was an Optech ILRIS-LR scanner, which is a long-range terrestrial laser scanner especially

suitable for surveying snow and ice surfaces ~~thanks to~~as it has a shorter wavelength laser beam (1064 nm) than other models. This equipment surveys surface topography based on time-of-flight measurement of a pulsed laser beam reflected to a given angle by a system of two rotating mirrors. It has a raw range accuracy of 4 mm at 100 m distance, raw angular accuracy of 80 µrad, beam diameter of 27 mm at 100 m distance and beam divergence of 250 µrad. The instrument was placed in five locations around the surveyed snow patch and boulder, overlooking it from different directions. Positions of the TLS were measured with ~~the~~ Trimble 5700 differential GPS with Zephyr ~~antenna~~antennae in static mode. Seventeen point clouds were obtained with nominal resolution of 0.11-0.75 cm. Resulting point clouds were corrected for atmospheric conditions (pressure, temperature and humidity) and trimmed with ILRIS Parser software, aligned with Polyworks IMAlign software into a common local coordinate system and georeferenced with differential GPS measurements using Polyworks IMInspect software. The alignment error of the point clouds as estimated by this software is 0.36-0.87 cm and comparison with ground control points gives an error of 5.65 cm. The TLS scan of the snow penitentes is presented as an example of the nature of the DSM that can be obtained within a penitente field using TLS (Figure 2). Unfortunately, the scans of snow penitentes could not be carried out with both the TLS and Kinect on the same day, so direct comparison of the TLS and Kinect scans is instead performed on a reference boulder ~~lying on the ground beside~~within the test site, whose surface is assumed unchanged between different scan dates.~~ The TLS scan of the snow penitentes is presented as an example of the nature of the DSM that can be obtained within a penitente field using a TLS (Figure 2).~~

2.3 Kinect ~~scans of~~ surface ~~change~~scanning

The Kinect sensor emits a repeated pattern of structured infra-red (IR) beams, and records the pattern distortion with an ~~onboard~~ IR camera. The depth~~-~~-of~~-~~-field calculation is performed via a proprietary algorithm and a distance map is the raw data output. Using the standard calibration the static raw depth field resolution of the Kinect is 1 mm and the ~~Kinect measured~~ distance ~~at the center of the field of view is within 1% of the real distance (Mankoff et al., 2013), implying an~~ error ~~of~~is < 1.0 cm at the distance range of the penitente scans~~.~~ (Mankoff and Russo, 2013).

For its original gaming usage, the Kinect is in a fixed position and proprietary software uses feature tracking to track the movements of players moving within the field of view of the Kinect. However, the inverse of this workflow can also be applied ~~wherein~~whereby the Kinect sensor is moved interactively around a static surface or 3D body, using the same feature tracking to compute the position of the sensor relative to the object and thereby allowing a point cloud reconstruction of the object~~ to be constructed.~~. In this work we apply the second work flow ~~sampling~~and sample Kinect data using the ReconstructMe™ 2.0 software package. In common with alternative reconstruction packages that are compatible with the Kinect, ReconstructMe™ performs bilateral filtering on the output depth map frame and converts the pixel version of each depth map frame to 3D coordinate maps of vertices and normals. An iterative closest point (ICP) alignment algorithm is then applied frame by frame at three scales to repeatedly rotate and translate the depth field to determine camera position and an aligned surface, giving weighted preference to portions of the surface that are perpendicular to the line of sight. ~~This~~The ReconstructMe™ software has the advantage of producing surface meshes in real-time, so that the operator can~~ visibly~~ check the scan quality and coverage at the time of capture, but the disadvantage that the raw point cloud is not saved and if the real-time tracking is lost a new scan ~~sample~~ must be started.

The Xbox Kinect was connected via a 5m powered USB extension cord to an MSI GE60 gaming laptop, powered using a 240V 600W inverter connected to the ~~12V~~ 160Ah 12V battery of the automatic weather station on the glacier. Scans were carried out by two people; one moving the Kinect across the penitente field and the other monitoring the quality of the surface being generated~~. The~~ on screen. In bright conditions, the return IR signal of the Kinect is swamped by natural radiation ~~in bright conditions, and this is especially true over bright, rough~~over snow and ice surfaces, which reflect ~~the~~a high proportion of incident shortwave radiation, and absorb or scatter much of the longwave radiation signal. ~~To solve this~~Therefore, scanning was carried out at twilight or just after nightfall. Sudden movements caused by the operator slipping or the snow compacting underfoot ~~can result~~resulted in the

ReconstructMe software losing its tracking of common reference points~~ used to generate the continuous surface mesh.~~. Consequently, each study site was scanned in small sections and three to thirteen ~~separate~~overlapping surface meshes were used to cover the area of each study site.

2.4 ~~Mesh processing~~

~~Freely available Meshlab software was used to initially align the~~ **Kinect surface** ~~meshes covering each study site using a pairwise alignment procedure.~~ **mesh processing**

The full mesh processing procedure using the freely available Meshlab software is presented in Supplement B, and briefly described here. Small surface components, unreferenced and duplicated vertices were removed from the meshes using inbuilt filters. ~~The Meshlab alignment~~The component meshes that cover each sampling date at a single site were aligned using an iterative closest point (ICP) algorithm ~~was applied to objectively optimize the alignment and compute~~which distributes the alignment error~~. This alignment procedure uses an ICP algorithm to iteratively align the component meshes and distribute the alignment errors~~ evenly across the resultant mosaicked surface mesh. Alignment solutions consistently had mean distributed error < 4 mm (Supplement B). The aligned meshes were flattened into a single layer, remeshed using a Poisson filter and ~~finally~~ resampled to reduce the point density by setting a minimum vertex spacing of 2.5mm.

The surface mesh for each scan date was georeferenced in Polyworks software using the known coordinates of the base of the marker stakes at the time of each scan because the upper portions of the symmetrical stakes are often poorly captured by the meshing software. The local elevation zero was set to be the north-east corner of site A. The mismatch evident in the georeferencing step (Table 1) is much larger than the mesh alignment error (Supplement B). ~~stakes are often poorly represented in the scans due to the fact that ReconstructMe™ does not handle symmetrical objects well. It proved difficult in some cases to locate the surfaces in space such that the locations of all marker stakes were consistent with the ground control points.~~ This is most likely an artifact of a combination of (i) reduced mesh quality at the margins of the component scans and (ii) insufficient overlap between some scan sections producing distortion within the mesh alignment. ~~The mismatch evident in the georeferencing step (Table 1) is much larger than the mesh alignment error (Supplement B).~~

To eliminate the marker stakes and any data gaps near the margins of the study areas, each surface mesh was sub-sampled within the staked area. The sub-sampled area for site A is a 2.0 by 3.5 m horizontal area (7.00 m^2), and site B is a 1.5 x 1.5 m horizontal area (2.25 m^2) shown in the examples in Figure 3. Mesh vertices and an index file of the vertices comprising each face were exported from Meshlab for subsequent analysis in Matlab software.

2.5 Calculations of surface geometrical properties

The geo2d and geo3d toolboxes (available from the Matlab File Exchange) were used ~~in Matlab™~~ to compute the ~~triangle~~face areas and normals of the mesh, from which ~~the~~ surface height distribution, aspect and dip of the sampled surface ~~can be determined~~were calculated, weighted by the ~~triangle~~ratio of each face area ~~as a function of~~to the total surface area of all faces. ~~Volume change between~~As the surfaces ~~was~~contain overhanging parts, DSM differencing cannot be performed by simple subtraction. Instead volumes for all surfaces were computed ~~by projecting each triangle area onto~~ relative to a baselevel horizontal reference~~ surface.~~. Volumes relative to this horizontal reference for upward-facing triangles were computed column-wise~~ from these projected areas~~, by projecting the area of each triangular face onto the reference surface and using the height coordinate of the triangle centroid as the height dimension for each column. These were summed and volumes for overhanging triangles, calculated in the same way~~ as the up-ward facing volumes~~, were subtracted to derive ~~a~~the total volume between the reference surface and ~~the~~each scanned penitente surface. Successive volumes were subtracted to obtain the volume change over each measurement interval.

~~2.6~~2.6 Manual measurements of surface change

Traditional single-point stake measurements of glacier surface lowering are unreliable within the inhomogeneous surface of a penitente field. One alternative is to measure surface lowering at intervals along a profile perpendicular to the main axis of alignment of the penitentes. Such a reference was installed along the 5 m-long eastern margin of site A, between two longer corner stakes drilled 3 m into the ice using a Kovacs hand drill. The distance between a levelled string and the glacier surface was measured using a standard tape measure at 0.2 m intervals on 23 November. Subsequent measurements, on the 12 and 21 December and on 4 January, were made at 0.1 m intervals. All measurements were recorded to the nearest centimetre, and the error on each measurement is estimated to be 2.0 cm, which is assumed to capture the error associated with the horizontal position of the measurements along the reference frame and the vertical measurements of the distance to the surface beneath.

2.7 Calculations of geometric surface roughness

The aerodynamic roughness length (z_0) is the distance above the surface at which an extrapolation of a logarithmic windspeed profile under neutral conditions ~~would be extrapolated down through~~towards the surface ~~layer and~~would reach zero. Over taller roughness elements the level~~ of action~~ of momentum transfer between the airflow and the surface roughness elements is displaced upwards by a distance, termed the zero-plane displacement (z_d). Above particularly rough surfaces, a roughness sub-layer is formed in the lowest part of the surface layer within which surface roughness elements create a complex 3D flow that is almost chaotic. Where roughness elements are widely spaced, the separated flow over obstacles reattaches to the surface before the subsequent obstacle is reached. More closely packed roughness elements experience a wake interference regime, and in the most densely packed arrays of roughness elements skimming flow occurs (Grimmond and Oke, 1999). At the top of the roughness sublayer individual wakes caused by surface obstacles are smeared out and the flow is independent of horizontal position, and thus, observations at this level represent the integrated surface rather than individual surface obstacles. This level is known as the blending height (z_r). All these properties are dependent on the size and arrangement of surface roughness elements.

As it is logistically challenging to deploy instrumentation to determine roughness parameters from atmospheric profile or eddy covariance measurements on glacier surfaces, efforts have been made to instead use methods based on properties such as radar backscatter (e.g. Blumberg and Greeley, 1993) or more readily measurable surface terrain properties (e.g. Kondo and Yamazawa, 1986; Munro, 1989; Fassnacht et al., 2009a; Andreas, 2011). Grimmond and Oke (1999) tested several methods of determining apparent aerodynamic properties from surface morphometry in urban environments, which are among the roughest surface conditions encountered in the atmospheric boundary layer, and found that morphometric determinations of surface roughness do not clearly underperform in comparison with aerodynamic methods, suggesting that morphometric measurements of roughness are worth pursuing.

There are a number of formulations for deriving z_0 from geometrical measurements. For example, the simplest approach is to take the standard deviation of the surface elevations as a measure of roughness (Thomsen et al., 2015). In this work, the surface meshes were analysed for roughness on the basis of a widely-used relationship established by Lettau (1969), initially developed for isolated, regular obstacles distributed over a plane:

$$z_0 = 0.5\, h \left(\frac{s}{S}\right) \qquad (1)$$

where h is the height of the obstacles, s is the upwind silhouette area of each obstacle and S is the specific area occupied by each roughness element obstacle, also referred to as its lot area. The roughness values computed using Equation 1 over 3D snow surfaces has been shown to vary widely depending on the methods of surface interpolation used (Fassnacht et al., 2014), due to the influence on interpolation method on the unit surface area occupied by each roughness element. However in this work the high resolution meshes used can be expected to adequately capture the

surface properties as no extrapolation or interpolation procedure is needed. Isolated roughness elements of regular geometry distributed over a horizontal plane are a poor analogy for the irregular surface topography of a penitente field, and the applicability of this formulation over penitentes has not been established. Nevertheless, we apply the analysis as an illustration of the nature of the results generated from such an approach over penitentes and hope that future aerodynamic roughness lengths obtained from micrometeorological measurements can be compared to these ~~geometrically~~ morphometrically-derived ones. Macdonald and others (1998) state that for irregular obstacles h can be replaced by average obstacle height, s with the sum of all the upwind silhouette areas, and S with the total area covered by the obstacles. While the upwind silhouette area, and indeed surface area in any direction, is relatively easily defined for each surface mesh area using trigonometry, it is difficult to define individual roughness elements and their representative heights, due to the lack of an apparent base level. Here we first detrend the surfaces to remove any general surface slope at the site, then compute the roughness for the detrended 3D meshes assuming that the roughness elements cover the whole surface area (i.e S = plot area), and for four possible representations of average obstacle height (h) as follows: (i) the maximum range of the detrended mesh; (ii) twice the standard deviation of the detrended surface mesh; (iii) mean mesh height above the mesh minimum; and (iv) median mesh height above the minimum.

These data are computed for illustrative purposes only as it is reported that Equation 1 fails when the roughness element density exceeds 20-30~~%,~~% (Macdonald et al., 1998), as is expected for penitente fields~~ (Macdonald et al., 1998).~~. High density roughness elements means that they interfere with the airflow around each other, and upwards displacement of the zero wind velocity level ~~is displaced upwards, and~~means that effective roughness is a result of the roughness elements above this zero velocity displacement plane~~. The~~, and the zero displacement height~~ in this sense~~, gives an indication of the penetration depth of effective turbulent mixing into the penitente field. Accordingly, we additionally present sample calculations of three-dimensional roughness on the detrended surface meshes using three possible realizations of z_d, as, like h, z_d is also unknown in the case of the penitente fields being sampled. In the first case, z_d is taken to be h, in the second 2/3 h, which is a widely used standard in forests and other complex terrain applications (~~Brutseart~~Brutsaert, 1975), and in the third 1/3 h~~ for comparison, both~~. Each z_d case is computed for the four realizations of h used as before. Equation 1, (for irregular obstacles) is then applied to the roughness elements remaining above the plane of the general surface slope offset by a distance z_d above the minimum height of the surface mesh. The representative height h for this portion of the mesh exceeding the plane is taken to be the mean area-weighted height of all triangles above this plane, s is the summed frontal area of all mesh triangles above z_d that face into the chosen wind direction and S is the total horizontal area of the surface components above z_d.

Munro (1989, 1990) modified the formula of Lettau (1969) to be applied to a single irregular surface cross-section of length X, sampled perpendicular to the wind direction. This modified formulation is easier to work with on a glacier where the roughness elements are irregular, closely spaced, and generally poor approximations of objects distributed over a plane. Instead of having to define an obstacle height above the plane, h is replaced with an effective height h^* expressed as twice the standard deviation from the standardized mean profile height; s is replaced with $h^*X/2f$, in which f is the number of profile sections that are above the mean elevation; and S is replaced with $(X/f)^2$. This approach approximates the surface elevation profile as rectangular elements of equal size, and has been shown to give results within 12% of the silhouette area determined by integrating between true topographic minima (Munro, 1989). Importantly, roughness values derived this way over snow, slush and ice surfaces show reasonable agreement with roughness values derived from wind profiles (Brock et al., 2006). To investigate the nature of the roughness computed this way for north-south and east-west impinging wind directions, cross profiles longer than 1.5 m at 0.~~1m~~1 m intervals orientated E-W and N-S were extracted from each scanned surface. Cross-sections were detrended to remove the influence of any general surface slope at the site, and roughness was computed on each of these cross-sectional profiles following the modifications of Munro~~ for each detrended surface profile~~. Mean profile roughness for these two wind directions are presented for each sampled surface.

~~**2.7 Manual measurements of surface change**~~

~~Traditional stake measurements of glacier surface lowering made at a single point are unreliable within the inhomogeneous surface of a penitente field, as multiple measurements are required to characterize the complex surface. One alternative is to measure surface lowering at intervals along a profile perpendicular to the main axis of alignment of the penitentes. Such a reference was installed along the 5 m-long eastern margin of site A, between two longer corner stakes drilled 3 m into the ice using a Kovacs hand drill. The distance between a levelled string and the glacier surface was measured using a standard tape measure at 0.2 m intervals on 23 November. Subsequent measurements, on the 12 and 21 December and on 4 January, were made at 0.1 m intervals. All measurements were recorded to the nearest centimetre, and the error on each measurement is conservatively estimated to be 2.0 cm, which is assumed to capture the error associated with the horizontal position of the measurements along the reference frame and the vertical measurements of the distance to the surface beneath.~~

3. Results

3.1 Evaluation of the quality and suitability of penitente scans by TLS and Kinect

~~At the~~The test site~~, the~~ was well-developed snow penitentes ~~were well-developed and between~~ 0.5 ~~and~~ - 1.0 m in height in a channel (Figure 1b). TLS scans ~~were made~~ of these penitentes ~~to illustrate the capabilities of this more conventional scanning system in capturing the penitente surfaces. TLS scans~~ were taken from five different vantage points ~~positioned~~ above the penitentes. The penitente surface produced by the TLS had surface slope ranging between -30 and 90 degrees, indicating that overhanging surfaces within the penitente field ~~are~~can be captured~~, however~~. However the limitations of this conventional fixed-point scanning system in capturing the penitente surfaces is illustrated by the fact that only 58% of the total surveyed horizontal area could be scanned, as the deepest parts of the troughs were obscured from the view ~~of TLS~~ by the surrounding penitentes (Figure 2a). By comparison, the hand-held, mobile nature of the Kinect means that ~~100% of~~ the whole surface of the penitente field can be captured as the field of view can be adjusted into almost limitless close-range positions~~. The long range of the TLS makes it easier to cover large areas in comparison to~~, although the close range Kinect sensor~~, but as only penitente tips are scanned the utility of this larger areal coverage~~ is ~~limited~~impractical to apply over large areas.

~~The Kinect scan~~For the direct comparison of the two methods on a reference boulder, the Kinect-derived surface, produced from three mosaicked meshes was aligned to ~~that~~the surface produced from the TLS point clouds. The TLS scan was incomplete, with parts of the top and overhanging surfaces of the boulder missing due to being obscured from the TLS survey positions, while the Kinect scan achieved complete coverage of the boulder. The difference between the two aligned meshes where overlapping data existed was always < 2 cm (Figure 2b), which is well within the error of the georeferenced TLS surface model. Larger differences in Figure 2b, up to 5 cm, occur only where there are holes in ~~one of~~ the surfaces being compared.

It is difficult to formally assess the total error of the surfaces produced by the Kinect scans because the ~~proprietary software, ReconstructMe™ and Poisson surface reconstruction in Meshlab, are all~~workflow involves several black box processing steps ~~in the workflow~~. The mean alignment errors of the mesh mosaicking step in Meshlab is < 0.4 cm and quantifiable errors associated with the GPS positions, subsequent measurement of the stake bottom positions relative to the GPS positions are all < 2.0 cm. However, ~~in this study~~ the three-dimensional georeferencing error in this study is large (Table 1) compared to the other sources and ~~can be~~is therefore taken as a reasonable value for the error of the total process chain. Errors given on the seasonal mass, volume and surface changes are based on summing the squares of the mean elevation difference between the marker stakes and ground control points (GPCs) at each site on the first and last survey dates.

3.2 Meteorological conditions

During the study period one significant snowfall event occurred on the 8th December 2013, when the sonic ranger recorded ~~an increase of~~ a surface height increase of 0.09 m over the course of the day~~, and temperature and incoming longwave radiation increase progressively~~ (Table 2). ~~The surface conditions of~~Surface albedo and ~~surface~~ temperature are derived from radiation measurements that ~~integrate the signal from a~~ sample an area beneath the instrument. Surface temperature was calculated from measured surface longwave emissions, assuming ~~a surface longwave~~ emissivity of 1. Over the study period, air temperature and atmospheric longwave receipts increase, while albedo decreases and derived surface temperature increases (Table 2). Thus, over the course of the study, ~~the~~ atmospheric energy supply increases and ~~the~~ surface properties become ~~gradually~~ more conducive to melting. ~~In the three measurement periods 22, 38 and 43% of hourly values of surface temperature exceed the melting point and the~~The warming atmosphere is clearly expressed in the positive degree days of the three periods which are 3.7, 2.2 and 31.5 over the 16, 9 and 14 day-long periods respectively. ~~The height change difference~~Hourly surface temperatures exceed the melting point in 22, 38 and 43% of cases in each period respectively. Daily surface lowering rates calculated between the hourly mean sensor-to-surface distance recorded by the AWS sonic ranger at midnight at the end of the survey days indicates lowering rates of 17, 37 and 56 mm d~~ay~~$^{-1}$ over the ~~same~~three measurement intervals, ~~indicating~~confirming that the increasing energy receipts translate into increasing rates of surface lowering at the AWS.

3.3 Areal scans of penitente surfaces

Surface lowering rates derived from the ~~computed~~calculated volume changes per unit area are 21, 41 and 70 mm d~~ay~~$^{-1}$ over each interval at site A, and 57 and 61 mm d~~ay~~$^{-1}$ over the last two intervals at site B. Surface lowering calculated as the difference between successive hypsometric mean mesh elevation for each site were within a few millimetres of the volume computations: 22, 38 and 69 mm d~~ay~~$^{-1}$ for the three measured intervals at site A, and 54 and 60 mm d~~ay~~$^{-1}$ for the last two intervals at site B. The total surface lowering over the whole available period computed by volume change (hypsometric mean height change) was 1.68 (1.77) ± 0.11 m at site A and 1.37 (1.32) ± 0.38 m at site B. Surface height changes recorded at site A over the same period as at site B were 1.35 (1.31) ± 0.21 m, indicating that the values were repeatable ~~across~~at both sites. The volume loss was converted to mass loss ~~on the basis of~~using the mean snow density of 426 kg m^{-3} (with an assumed error of ± 5%) measured in a 1.10 m snow pit excavated on 22 November 2013 beside the ~~weather station.~~AWS. Mass loss at site A computed from mesh volume ~~changes~~change (hypsometric height ~~changes~~change) between 25 November and 3 January was 716 ± 58 (754 ± 59) kg m^{-2}~~, indicating an underestimation of mass loss but that the two computation methods are within error of each other~~. Mass loss at site B from mesh volume changes (hypsometric height changes) between 11 December and 3 January was 582 (562) ± 166 kg m^{-2}. Measurements at site A over the same period give mass loss of 573 (558) ± 95 kg m^{-2}, so again, measurements at both sites are within error of each other.

The morphometry of the sampled penitentes changed visibly over the measured intervals (Figures 3 and 4). The strong east-west ~~preferential orientation~~lineation and preferred north and south surface aspect predicted from theory developed early and was maintained throughout study period. ~~The expression of this alignment is more convoluted in the stages of development studied here than the parallel rows of penitentes used in model representations (Corripio and Purves, 2005; Lhermitte et al., 2014).~~ Over time ~~the~~ penitente troughs became fewer in number, but wider and deeper ~~inkeeping with the increasing surface relief evident in the manual measurements.~~. This ~~is reflected by increasing~~causes total surface area~~, with the penitente surfaces~~ to increase; at site A ~~providing~~the true surface is between 1.7 and 4.0 times the ~~surface area of the~~ horizontal equivalent area, ~~and at site B providing~~ between 2.1 and 3.7 times the horizontal surface area equivalent and at site B (Figure 4 a & b). Snowfall during the first measurement interval decreases the surface area at site A over that interval. ~~The surface~~Surface relief, expressed by the vertical range of the mesh, also increases through time, except when snowfall partially filled the developing penitentes~~,~~ ~~reducing~~ and reduces both the range of the surface and the general slope angle. ~~Nevertheless, the morphometric~~

~~properties of the meshes broadly meet the properties of simplified surfaces.~~ The largest part of the surface is facing southwards, and the predominant angle generally steepens over time, though again this trend is reversed by snowfall (Figure 4 c & d). From the onset of measurements the surface aspect distribution is strongly dominated by north and south facing components and this becomes more pronounced in the latter measurements and the preferred orientation rotates slightly over the course of the season (Figure 4 e & f).

~~3.4~~3.4 Manual measurements of reference cross-profile

The surface properties from manual measurements were computed on data sampled at 0.2 m over 5.0 m. Maximum relief of the sampled penitente profile, defined as the range of the distance from the horizontal reference to the surface, increased over time from 0.76, through 0.83 and 1.00 to 1.38 m on each measurement date. The standard deviation of the surface remained relatively unchanged with values of 0.24, 0.26, 0.28 and 0.32 m at each measurement date. Surface lowering rate calculated by differencing the mean surface height along the profile on each measurement data was 13, 57 and 61 mm d^{-1} over the three sampled intervals, giving a total mean surface lowering of 1.61 ± 0.14 m between 23 of November and 4 January. These manual measurements along the cross-profile compare well to the aerially-averaged lowering rates from the scanned surfaces, despite the fact that the manual measurements are made in only 2 dimensions, do not visually represent the complexity of the penitente surfaces, and individual points are sometimes out of the range of error of the Kinect (Figure 5). The computed mass loss over the same period is 688 ± 70 kg m^{-2}, which underestimates, but is within error of, the value for site A derived from volume changes.

To investigate the impact of sampling resolution, maximum elevation range, mean surface height compared to the horizontal reference and mean surface lowering were calculated from manual measurements at 0.1 (n = 52), 0.2 (n = 26), 0.4 (n = 14) and 1.0 m (n = 6) intervals on the last three measurement dates. The highest resolution sample was taken as a reference against which to evaluate coarser sampling. Surface relief differed from that measured at 0.1 m by maxima of 0.13, 0.29 and 0.41 m for 0.2, 0.4 and 1.0 m sampling intervals respectively. Mean measured surface height was within 0.03 m of the highest resolution measurements at 0.2 m and 0.4 m intervals, and within 0.12 m at 1.0 m resolution. Mean lowering rates at 0.1, 0.2 and 0.4 m sampling intervals were all within 3 mm d^{-1}. This increased to a maximum of 12 mm d^{-1} when the sampling resolution was decreased to 1.0 m. Decreasing the length of the sampled profile down to 2 m alters the mean lowering rate by less than 5 mm d~~ay~~$^{-1}$ at sampling resolutions of 0.1, 0.2 and 0.4 m.

Probing of the snow depth on 25 November indicated mean snow depth of 1.83 m (standard deviation 0.56 m). The underlying ice surface does not appear to be influencing the structure of the overlying snow penitentes (Figure 5). However, it is difficult to draw a firm conclusion based on these measurements, particularly as, while the surface of the penitentes was still snow on the 3 January, in several instances the surface had lowered below the level of the ice interface suggested by the initial probing.

3.5 Surface roughness assessments

Given that aerodynamic measurements to determine the most suitable representative height and zero displacement level for penitentes are thus far unavailable, the approach taken here was to do an exploratory study and compute geometric surface roughness values using various ways of expressing h and z_d. As a consequence the results are purely illustrative and while patterns can be drawn from them that have meaning for understanding the nature of the computation, the applicability of these values in turbulent exchange calculations remains to be established. The representative height, h, used in the calculations increases over time in all cases, and is bounded by the maximum case, taking h ~~to be the~~as range of the detrended surfaces ~~(maximum)~~, and the minimum case, taking h as twice the standard deviation of the detrended surface (Figure ~~5~~6). For clarity, the ~~other~~ two ~~case~~intermediate values are not included in ~~the plots shown here.~~Figure 6. Differences ~~within a single~~in h computed by the same method ~~between~~

~~the two sites~~ can reach as much as 0.2 m between the two sites, although the pattern of change over time is consistent.

The application of ~~Lettaus~~Lettau's (1969) formula is considered to be invalid if the ratio of the frontal area to the planar area of the obstacles exceeds 0.2 – 0.3, with 0.25 often being chosen as a single value. ~~In~~This ratio is greater than 0.2 for all ~~cases~~ of the penitente surfaces~~ this ratio exceeds 0.2~~, and ~~only 6% of cases computed at 10° intervals of bearing over all dates are below 0.3, and these are all early in the season, before~~after the 20th December is always greater than 0.3. Exceeding this threshold implies that the obstacles are so closely packed that 'skimming' airflow will occur. Ignoring this issue, calculated z_0 values increase with time and show a strong dependence on the impinging wind direction, with values peaking for wind directions perpendicular to the alignment of the penitentes (Figure ~~6~~7). Calculated z_0 ranges from 0.01 – 0.90 m, depending on the way in which the representative height is expressed, the ~~time of year~~date and the wind direction (Figure ~~7~~8). However, given the close spacing of the penitentes it ~~seems appropriate~~is likely more valid to~~ also~~ explore what the calculated z_0 would be ~~like~~ when ~~applying~~ a zero displacement height offset~~, although again~~ is applied. Again, in the absence of validation data ~~these numbers~~from independent measurements, calculated values can be only indicative of the pattern of roughness computed by these methods. Introducing the zero displacement height reduces the maximum calculated roughness by about half, and also reduces the variability between different representative heights (Figure ~~7~~8), as a smaller h value translates into a smaller z_d so that the calculation is performed on a larger portion of the mesh.

Surface roughness assessments on the basis of calculations following Munro's modification for single profile measurements were applied to cross profiles longer than 1.5 m yielding 20 (6) profiles orientated N-S and 33 (7) E-W at site A (B). Surface amplitude increases over time, and the amplitude of the N-S running cross profiles is generally larger than the E-W running cross profiles, as illustrated in the example of site B (Figure ~~8). The~~9). Table 3 shows the calculated roughness values at each survey date, revealing that while profile-computed roughness length increases monotonically over time at site B, ~~but shows a reduction~~it reduces over the first period at site A, associated with snowfall during this period. Both the range and relative increase in roughness over time is larger for the N-S running profiles. The computed roughness at both sites is 4.3 to 6.8 times larger for airflow impinging on the penitente field in an E-W direction than for airflow in the N-S direction. This is contrary to the results computed on the full 3D mesh surface, but is understandable because this formulation relies on the amplitude of the surface, which is generally larger in the N-S orientated cross profiles than the E-W running cross profiles.

4. Discussion

4.1 Penitente morphology

Although the natural penitentes sampled here are more convoluted than the parallel rows of penitentes used in model representations (Corripio and Purves, 2005; Lhermitte et al., 2014), the morphometric properties of the meshes broadly meet the properties of simplified surfaces. The penitente surface represents a much larger total surface area than the equivalent non-penitente surface and the control of solar radiation on penitente morphology means that the vast majority of the surface consistently dips steeply to the north and south at all stages of development. This means that the angle of incidence of direct solar radiation is reduced, decreasing both the intensity of the solar beam and the proportion of it that is absorbed. Although these effects are counteracted by multiple reflections of solar radiation within the penitente (Corripio and Purves, 2005; Lhermitte et al., 2014; Claudin et al., 2015) modeled mean net shortwave at sampled points in an example penitente field at the summer solstice at 33°S is about half of that of a level surface (Corripio and Purves, 2005). However, given the larger surface area of the penitente field compared to a flat surface, the total absorbed shortwave is a third higher in the modeled penitentes, broadly in line with the observed effect of penitentes on spatially-averaged albedo (Warren et al, 1998; Corripio and Purves, 2005; MacDonell et al., 2013; Cathles et al., 2014; Lhermitte et al., 2014). For idealized penitentes at 33°S during summer solstice, modeled increase in net shortwave radiation over penitentes is not compensated by modelled changes in net

longwave radiation, meaning that the excess energy receipts must be compensated by either turbulent energy fluxes or consumption of energy by melting (Corripio and Purves, 2005).

Unless a snowfall event occurs to partially fill the troughs, surface relief, slope angle, penitente spacing and total surface area all increase over time as the penitentes develop and deepen. Thus the impact of penitentes on surface properties will also change along with the morphological changes. At Tapado Glacier, penitentes are initially overhanging to the north, and the southfacing sides are convex compared to the northfacing overhanging faces. Over the season the penitentes become more upright as the noon solar angle gets higher. Idealized modelling based on measurements at Tapado Glacier, shows that concave and convex slopes, as well as penitente size have been shown to impact the apparent albedo as measured by ground and satellite sensors (Lhermitte, et el., 2014), and there may be some value in assessing the impact of these morphometry changes on albedo over time. In the context of the numerical theory of Claudin and others (2015), penitente spacing controls the atmospheric level at which water vapor content is representative of the bulk surface properties. Simultaneous field or laboratory measurements of penitente spacing evolution and vapor fluxes above the surface would be required to solidly confirm this, but the spacing from the field measurements provided here can be used as an indication of the level at which measurements would need to be made in order to capture the bulk surface fluxes rather than fluctuations governed by the small-scale surface terrain.

4.2~~Prevailing wind direction differs only slightly in each period with an increasing northwesterly component in the second two periods compared to the first. This may be related to the occurrence of snow during the first period, which can be expected to alter the thermally driven valley wind systems. Over the whole study period wind direction is predominantly from the south-westerly sector, but swings through southerly to easterly thereby encompassing both extreme wind angles used in the roughness calculations here (Figure 9). This indicates that the effective roughness can be expected to differ significantly depending on the wind direction.~~

~~3.5 Manual measurements of reference cross-profile~~

~~Using data sampled at 0.2 m over 5.0 m, the maximum relief of the sampled penitente profile, defined as the range of the maximum and minimum distance from the horizontal reference to the surface, increased through time, from 0.76, 0.83, 1.00 to 1.38 m on each measurement date. The standard deviation of the surface remained relatively unchanged over time with values of 0.24, 0.26, 0.28 and 0.32 m at each measurement date. The difference in the mean surface height measured at the ablation frame profile at site A indicates mean lowering rates of 13, 57 and 61 mm day^{-1} over the three sampled intervals resulting in a total mean surface lowering of 1.61 ± 0.14 m between 23 of November and 4 January. The manual measurements at the cross profile compare well to the aerially-averaged lowering rates from the scanned surfaces, despite the fact that the manual measurements are only made in 2 dimensions, do not visually represent the complexity of the penitente surfaces, and individual points are sometimes out of the range of error of the Kinect (Figure 10). The computed mass loss over the same period is 688 ± 70 kg m^{-2}, which underestimates the value for site A derived from volume changes but is within error, even accounting for the two extra days measurement interval.~~

~~Values of maximum elevation range and standard deviation along the profile, mean surface height compared to the horizontal reference and mean lowering were computed from the manual measurements for available data at 0.1 (n = 52), 0.2 (n = 26), 0.4 (n = 14) and 1.0 m (n = 6) intervals to investigate the impact of sampling resolution. The highest resolution sample was taken as a reference against which to evaluate the values from coarser resolution sampling. Calculated surface relief differed from that measured at the highest resolution by maxima of 0.13, 0.29 and 0.41 m for 0.2, 0.4 and 1.0 m sampling intervals respectively. Mean measured surface height was within 0.03 m of the highest resolution measurements at 0.2 m and 0.4 m intervals, and within 0.12 m at 1.0 m resolution. Mean lowering rates at 0.1, 0.2 and 0.4 m sampling intervals were all within 3 mm day^{-1} with the difference increasing to a maximum of 12 mm day^{-1} when the sampling resolution was decreased to 1.0 m. Decreasing the length of the~~

~~sampled profile down to 2 m alters the mean lowering rate by less than 5 mm day^{-1} at sampling resolutions of 0.1, 0.2 and 0.4 m.~~

~~Probing of the snowdepth on 25 November indicated a mean snow depth of 1.83 m (standard deviation 0.56 m). The underlying ice surface identified by the snow probing, does not appear to be influencing the structure of the snow penitentes developing in the current season. However, it is difficult to draw a firm conclusion based on measurements at only 0.2 m spacing, particularly as, while the surface of the penitentes was still snow on the 3 January, in several instances the surface had lowered below the level of the ice interface indicated by the initial probing.~~

~~4. Discussion~~

~~4.1~~ Methods of measuring change of rough glacier surface elements

The test site for scanning penitentes with a TLS was chosen as ~~it provided the most optimal viewing angles possible from scanning positions, as the penitentes lay in a river bed and~~ scanning positions could be established on the surrounding ~~river banks to look down into~~higher ground overlooking the penitente field~~.~~, thereby offering the best viewing angles possible. Nevertheless, the terrestrial laser scanning could only capture the ~~tips rather than the whole surface~~upper portions of the penitentes ~~and, as~~. As ablation is at its maximum in the troughs, TLS data is therefore not able to determine the true volume change ~~ongoing in~~of penitentes. The coverage would be increased if a higher viewing angle could be achieved, but the steep, dense nature of penitente fields makes it difficult to imagine where sufficient suitable locations can be found surrounding glaciers or snowfields with penitentes. In contrast, the mobile Kinect sensor can be moved across the complex relief of the penitente field to make a complete surface model. Although it is in principle possible to capture a large area with the ReconstructMe software used here, and it offers the advantage of providing real time feedback on the mesh coverage, it proved difficult to capture the study sites in a single scan given (i) the reduced signal range of the sensor over snow and ice (Mankoff ~~et al.,~~and Russo, 2013), and (ii) the difficulty of moving around the penitente field. As a result, partial scans were obtained, with the disadvantage that subsequently combining these introduces a substantial degree of additional error associated with alignment if the component scans were not of high quality at the margins, or did not overlap adjacent scan areas sufficiently. A combination of these two techniques might allow the extrapolation of small-scale geometry changes and volume loss determined from a Kinect surface scan to be extrapolated usefully to the glacier or snowfield scale using measurements made with a TLS.

Despite not visually capturing the complex ~~surface properties~~morphology of the penitentes, manual measurements of surface height change in a penitente field along a profile cross-cutting the penitentes are robust for determining mean surface lowering rates, and show good agreement to the volume changes computed from differencing the digital surface models scanned in detail using a Kinect. Thus, the detailed surface geometry need not be known in order to reasonably calculate the total volume loss over time within penitente fields. Comparison of the manual sampling at different intervals ~~suggest~~suggests that five samples per meter is adequate to characterize surface change of penitentes~~.~~, but that data will be unreliable is the cross-profile is too short. Over the 39 days of the study, ~~the~~ mass loss calculated from 26 points spaced at 0.2 m intervals along a 5 m profile crosscutting the penitentes differed from that calculated from volume change computed on surface meshes consisting of over 1.3 million points and covering an area of 7 m^2 by only 28 kg m^{-2}. Although this difference was within the error of the two measurement types, the seasonal difference, assuming that this difference applies to a whole ablation season of 120 days would be 86 kg m^{-2}, and applied to the whole glacier (3.6 km^2) would amount to an underestimate of mass loss over an ablation season of 0.3 gigatonnes. As a side note, the probing of snowdepth carried out as part of this study highlights the difficulty in identifying the underlying ice surface, or summer ablation surface, ~~in this way~~ within a penitente field, suggesting that a single location must be sampled very densely to obtain a characteristic snowdepth ~~in~~by this ~~way~~method.

4.3 Surface roughness

~~4.2 Penitente~~The changing morphometry **~~and change in time~~**

~~The manual measurements at 0.2 m intervals are adequate to determine the mean surface lowering within a penitente field, giving confidence to this type~~ of ~~simplified measurement on seasonal timescales. However, the interval measurements cannot capture the surface morphometry, or how it changes in time.~~

~~At all times the penitente surface represents a much larger total surface area than the equivalent non-penitente surface. Over time the surface relief, and slope angle, increases as~~ the penitentes ~~deepen, unless a snowfall event occurs to partially fill the troughs, which also reduced the mean surface slope. The control of solar radiation on penitente morphology means that the vast majority of the surface consistently dips steeply to the north and south at all stages of development. This means that the angle of incidence of direct solar radiation is reduced, decreasing both the intensity of the solar beam and the proportion of it that is absorbed. Although these effects are counteracted by multiple reflections of solar radiation within the penitente (Corripio and Purves, 2005; Lhermitte et al., 2014; Claudin et al., 2015) modeled mean net shortwave in an example penitente field at the summer solstice at 33°S is about half of that of a level surface (Corripio and Purves, 2005). However, given the larger surface area of the penitente field compared to a flat surface, the total absorbed shortwave is a third higher in the modeled penitentes. At Tapado Glacier, penitentes are initially overhanging to the north, and the southfacing sides are convex compared to the northfacing overhanging faces. Over the season the penitentes become more upright as the noon solar angle gets higher. Idealized modelling based on measurements at Tapado Glacier, shows that concave and convex slopes, as well as penitente size have been shown to impact the apparent albedo as measured by ground and satellite sensors (Lhermitte, et el., 2014), and there may be some value in assessing the impact of these morphometry changes on albedo over time. For the idealized penitente surface at 33°S during summer solstice case, modeled increase in net shortwave radiation over penitentes is not compensated by modelled changes in net longwave radiation, meaning that the excess energy receipts must be compensated by either turbulent energy fluxes or consumption of energy by melting (Corripio and Purves, 2005).~~

~~In the context of the numerical theory of Claudin and others (2015), progressive widening of the penitente spacing, as observed at both site A and B, is indicative of changes in the atmospheric level at which water vapor content is unaffected by the vapor flux from the penitente surface. Simultaneous field or laboratory measurements of penitente spacing evolution and vapor fluxes above the surface would be required to solidly confirm this, but the field measurements provided here can be used as an indication of the level to which vapor flux from the surface is influencing the boundary layer vapor content.~~

alters the geometrical surface roughness as they develop over the ablation season. Values calculated using**~~4.3 Surface roughness~~**

~~In this work~~ a single, simple, geometric relationship (Lettau 1969) ~~was~~were investigated because a profile-based version of this formulation has previously been tested against aerodynamic measurements over glacier surfaces (Munro, 1989, 1990; Brock et al., 2006). Certainly other relationships could be explored in the context of linearized glacier features, but given the wide spread of values produced in previous comparisons such an analysis might be of limited value in the absence of simultaneous aerodynamical investigations (Grimmond and Oke, 1999). Furthermore, the results of Grimmond and Oke (1999) indicate that for the cities sampled, the Lettau method gives z_0 values that are in the middle of the range of all the methods. The analysis of geometric computations of roughness properties in Grimmond and Oke (1999) highlight the importance of correctly determining z_d, and limited sensitivity analyses show the computed z_d and z_0 to be strongly dependent on the dimensions of the obstacles. Lettau's (1969) formula, which does not account for z_d, overestimates roughness for densely packed obstacles, but this ~~overestimation~~ does not compensate sufficiently to reproduce values of $z_d + z_0$ ~~produced~~ for densely packed obstacles from formulations that include z_d in the computation of z_0. ~~This means that~~Thus, Lettaus formula is

expected to estimate the zero velocity point of a logarithmic wind profile to be lower than formulations that include z_d in ~~their computation of z_0. In this work however we computed z_d in a separate preceding step to explore the impact of z_d on the computed~~the computation of z_0.

~~As penitentes fields present very densely packed roughness elements, the frontal area of the surface tends to be large compared to the ground area, and the limits of the~~ The ratio of frontal to planar area ~~found in this study~~ of the penitentes implies that skimming flow ~~is almost always occurring over penitente fields~~prevails, such that turbulent airflow in the overlying atmosphere does not penetrate ~~to the full depth of the~~ penitente ~~fields~~troughs. This is in agreement with the theory of formation and growth of penitentes, in which the development and preservation of a humid microclimate within the penitente ~~hollows~~troughs is required to facilitate differential ablation between the trough and tip of the penitente. ~~As~~Although the ~~spacing between the~~data here shows that penitentes ~~also increases over the ablation season the features~~ become less densely packed over time, ~~although the~~ skimming flow regime persists over the study period, and available data ~~are~~is insufficient to determine if ~~the spacing increases sufficiently by the~~ this holds true to the end of the ~~season to comply with the applicable limits of the roughness calculation used here~~ablation season.

Application of geometrical roughness equations is made more problematic in penitente fields as it is not clear how an appropriate representative obstacle height should be expressed, nor how to define the zero displacement level during ~~presumed~~ skimming flow. Roughness calculated using a range of possible representations of these properties point towards roughness values in the order of 0.01-0.10 m during the early part of the ablation season and 0.10-0.50 m after the end of December. These values are in line with the roughest values previously published for glacier ice (Smeets et al., 1999; Obleitner, 2000). The topographic analysis clearly shows that in the absence of intervening snowfall events, this roughness increase is related to the deepening of the penitentes over time and an increase of the surface amplitude. The ~~patterns~~pattern of the computed roughness properties is consistent between the two neighbouring sites, but individual values can differ, suggesting that ~~local~~ relief varies substantially over short distances and sampling a ~~larger~~large area ~~would be beneficial in order~~is necessary to capture mean properties.

The strong alignment of penitentes means that ~~roughness~~ calculated roughness is strongly dependent on ~~the~~wind direction. Roughness calculated from 3D surface meshes ~~is~~are higher for wind impinging in a north-south direction, as the large faces of the penitentes form the frontal area in this case. In contrast, ~~if~~ roughness ~~is computed~~calculated for individual profiles extracted from the mesh to mimic manual transect measurements in the field, ~~roughness~~ is between 3 and 6 times larger for air flow ~~along the penitente lineation (E-W) than it is across the lineation (N-S). While clearly highlighting that the surface roughness of the strongly aligned penitente fields is dependent on wind~~impinging in an east-west direction, ~~this contradiction poses~~than in a ~~conundrum as neither~~north-south direction. Neither approach has been ~~specifically~~ evaluated against independent surface roughness derived from atmospheric profile measurements over penitentes. Consequently, although surface roughness calculations on the basis of profile geometry have been evaluated against aerodynamic roughness over rough ice surfaces, the available data is insufficient to distinguish if maximum aerodynamic roughness is associated with wind flowing across or along the penitente lineation. Thus it is not clear which ~~pattern is more~~method captures the appropriate relationship between wind direction and surface roughness for calculating turbulent fluxes over penitentes. It principle it sounds reasonable to expect airflow across the penitente lineation to maximize turbulence as the penitentes present a large surface area to the wind, yet, if skimming flow is established, with the result that only the tips of the penitentes are determining the structure of the turbulence then roughness in this direction would be strongly reduced, and perhaps even be less than for air flow along the penitente lineation, for which the smaller frontal area reduces the likelihood of skimming flow. Further investigation of this in order to quantify the impact of penitentes on turbulent fluxes for various airflow patterns requires measurement of turbulent fluxes using eddy covariance or atmospheric profile methods, which would demonstrate the nature of the directional roughness and establish the impact of penitentes on turbulent energy fluxes for different wind directions. Such measurements would be best implemented in a manner which can sample all wind directions equally, and eddy covariance systems for which analysis is limited to a sector

of airflow centred around the prevailing airflow source, might not be able to capture the nature of the directional dependence correctly.

Prevailing wind direction differs only slightly in each period with an increasing northwesterly component in the second two periods compared to the first. This may be related to the occurrence of snow during the first period, which is expected to alter thermally-driven valley wind systems. Over the whole study period wind direction is predominantly from the south-easterly and north-westerly sectors, and swings through both extreme wind angles used in the roughness calculations here (Figure 10). This indicates that the effective roughness at this site can be expected to differ significantly over time depending on the wind direction.

In this study we did not explicitly compute the blending height as available formulae are dependent upon z_0 and z_d. Estimates of the blending height independently from z_0 and z_d have been suggested to be 2.5 - 4.5 times h, as twice the mean element spacing, or as combination of the height and spacing (see examples within Grimmond and Oke, 1999). Given that only atmospheric measurements above the blending height give representations of integrated surface fluxes and conditions, the first approach would imply that aerodynamical or flux measurements over penitentes would have to be carried out at ~~some~~considerable height above the surface to capture mean surface properties rather than the effects of individual roughness elements. The mathematical model of Claudin and others (2015) ~~indicates that the~~ gives a characteristic length scale for the level at which the vapour flux ~~does not~~ is constant in horizontal space~~, and therefore is the product of mean surface properties,~~ that is related to the spacing of the penitentes. ~~Taking~~Interpreting this ~~to be representative of~~level as the blending height ~~would imply~~implies that ~~a formulation for~~ the blending height might be ~~possible~~determined on the basis of spacing of penitentes alone, and that this in turn might contain useful data for understanding the structure and efficiency of turbulence above penitentes. ~~However, exploring~~Exploring these ideas requires information from detailed meteorological measurements as well as the geometrical information offered in this paper.

5. Conclusion

Surface scanning technology and software is an area of rapid development, and a number of potentially superior alternative set-ups and data capture sensors and software is now available. This study demonstrates that the Microsoft Kinect sensor can work successfully at close range over rough snow and ice surfaces under low light conditions, and generate useful data for assessing the geometry of complex terrain and surface roughness properties.

The data collected offers the first detailed study of how the geometry of penitentes ~~evolves~~evolve through time, highlighting the rate of change of surface properties over an ablation season that can serve as a guideline for parameterizing surface properties required for energy and mass balance modelling of penitente surfaces.

The ~~measurements~~results confirm that even relatively crude manual measurements of penitente surface lowering are adequate for quantifying the seasonal mass loss, which is good news for the validity of measurements of surface change on glaciers with penitentes. However, further measurements and/or modelling studies are required to determine if the mass loss from the expanded and convoluted surface of penitentes is enhanced or inhibited compared to mass loss in the absence of penitentes.

Aerodynamical roughness properties and related metrics over very rough surfaces remain poorly quantified and both geometric and meteorological determinations of these values show a wide spread; consequently it remains unclear what the best methods to use are or what values modellers would be best to use (Grimmond and Oke, 1999). In this context ~~penitentes and~~ further study of ~~them~~penitentes offers a useful opportunity as (a) their morphometric evolution over time allows various geometries to be evaluated by ~~instrumenting and scanning~~monitoring a single site, and (b) they offer a bridge between wind tunnel and urban field experimentation of turbulence and roughness over extreme terrain. Although validity of surface roughness calculations based on surface geometry remains to be

established for penitentes, this study highlights that (i) skimming flow is expected to persist over penitentes field, but is more likely under wind directions perpendicular to the penitente alignment; (ii) z_d is certainly greater than zero, and while the depth of penetration of surface layer turbulence into a penitente field is not clearly established it is likely to evolve with the developing penitentes, and values of $z_d \sim 2/3h$ give results that are theoretically reasonable in the framework outlined by Grimmond and Oke (1999); (iii) the two methods of geometric computation of surface roughness applied here give conflicting results as to whether the effective surface roughness of penitentes is greater for airflow along or across the penitente lineation and (iv) more complete understanding of the impact of penitentes on the turbulent structure, its evolution in time, and its directional dependency, would require atmospheric measurements with no directional bias concurrent with measurements of penitentes morphology.

Potential future applications and analyses of the surfaces generated in this study include (i) using surface properties and roughness values as a guide for input into surface energy balance models; (ii) assessing the performance of models against the measured volume loss over time and (iii) evaluating how well simplified representations of penitente surfaces used in small scale radiation models and turbulence models capture the real-world complexity. Such studies would help establish the nature of the likely micro-climatic distribution of the surface energy balance within a real penitente field, and as a result the impact of penitentes on runoff and exchange of water vapour with the atmosphere.

Author contributions. L.N. designed the study. Fieldwork was carried out by L.N. and B.P. with M.P. providing the TLS. TLS and AWS equipment was provided by S.M. through collaboration with CEAZA. The data was analysed by L.N. and M.P. and L.N. ~~prepared~~led the preparation of the manuscript and figures.

Acknowledgements. Fieldwork for this study was funded by a National Geographic Waitt Grant. L.N. was supported by an Austrian Science Fund Elise Richter Grant (V309). M.~~-~~P. was supported within statutory activities No 3841/E-41/S/~~2015~~ 2016 of the Ministry of Science and Higher Education of Poland. International cooperation was supported by the Centre for Polar Studies from the funds of the Polish Leading National Research Centre (KNOW) in Earth Sciences (2014–18). Thanks are also due to Mathias Rotach for reading the paper prior to submission.

Figure 1: Map of Tapado Glacier in the Elqui catchment of the Coquimbo Region of Chile, showing the location of the measured sites and insets of (a) the glacier site layout, showing the location of the horizontal reference (black line) and ~~;~~ (b) the test site, ~~highlighting~~ indicating the boulder ~~(*)~~ (red star) at which the Kinect scans were compared against TLS~~, and (c) an example photograph of glacier site B at the time of installation.~~.

Figure 2: (a) Oblique view of the TLS~~-~~derived DSM of the test site highlights the patchy coverage of the penitentes obtained by this method. (b) Absolute differences between DSMs of the sample boulder produced using TLS and Kinect.

Figure 3: Shaded DSM meshes of N-S orientated DSMs for the 1.5m x 1.5m ~~subsample at~~ glacier site B on (a) 12.12.2013 (b) 20.12.2013 and (c) 03.01.2013 obtained using the Kinect.

Figure 4: Summary of the DSM properties through time at site A (left) and B (right). (a,b) Surface height distribution as a percentage of total surface area, in local coordinates [m] relative to the position of the northern end of ablation frame ~~(a & b).~~ .Inset tables show weighted mean mesh elevation, range, surface area and surface area as a function of the horizontal area of the sampled site. (c,d) Distribution of surface angles as a percentage of total surface area ~~(c & d).~~ ,(e,f) Aspect distribution as a percentage of total surface area ~~(e & f).~~.

Figure 5: Comparison of surface height through time extracted from the Kinect scan and measured manually along the horizontal reference. Vertical error on the Kinect cross profiles is given by a linear interpolation of total positional error between the bounding stakes. Solid black triangles indicate locations where snowdepth exceeded the length of the 3 m probe.

Figure ~~5~~6: Representative surface heights computed on detrended surface meshes for site A (solid) and site B (open) over time where h1-h4 refer to representative surface heights computed as range (h1), twice the standard deviation (h2), area weighted mean height above the minimum (h3), and area weighted median above the minimum mesh height (h4).

Figure ~~6~~7: 3D z_0 computed for 10° aspect intervals for all detrended DSMs highlighting peak roughness occurs in N-S airflow. Maximum values take h to be the detrended mesh elevation range, and minimum values take h to be twice the standard deviation of the detrended mesh.

Figure ~~7~~8: Comparison of three-dimensional surface roughness through time, indicating the range of z_0 computed for all incident wind angles (at 10° intervals). Upper panels show the roughness with no zero level displacement and lower panels show values with a zero displacement offset d1 = h; d1 = 2/3h and d3 = 1/3h.As before, h1- h4 refer to representative surface heights computed as range, twice the standard deviation, area weighted mean height above the minimum, and area weighted median above the minimum mesh height respectively.

Figure ~~8~~9: Examples of (a) N-S, and (b) E-W orientated cross sections longer than 1.5 m, sampled at 0.1 m intervals ~~in local coordinates at site B~~ from which effective surface roughness properties were computed using the methods of Munro (1989, 1999).The local coordinates are relative to the NE corner marker of site A (Fig 1).

Figure ~~9~~10: Wind rose for the whole study period (26 Nov 2013 – 3 Jan 2014).

~~Figure 10: Comparison of surface height through time extracted from the Kinect scan and measured manually along the horizontal reference. Error ranges on the Kinect cross profiles are given by a linear interpolation of total positional error between the bounding stakes. Solid black triangles indicate locations where snowdepth exceeded the length of the 3 m probe.~~

B2: Detailed mesh-processing procedure used in this study.

- All processesing was carried out in Meshlab unsless otherwise stated
- Pairwise point alignment of the component surface meshes covering each study site
- Applied filter to remove mesh sections (vertices and faces) consisting of < XXX vertices
- Applied filter to remove unreferenced and duplicated vertices
- ICP alignment optimization of the mosaicked component surface meshes using the following parameters:
    - sample number of 1000 for each ICP iteration
    - minimal starting distance for chosen points of 10 mm at the first iteration reducing by 20% on each iteration
    - maximum of 50 iterations were performed
    - using rigid matching so that no stretching or warping of the mesh is permitted
    - export distributed alignment error
- Flattened mosaicked surface meshes into a single layer and remeshed using a Poisson filter with the following paramters:
    - Octreee depth (12)
    - Solver divide (7)
    - number of samples per node (1)
- Meshes were georeferenced with differential GPS measurements in Polywork
- Corner marker stakes, and parts of the mesh representing sensors installed within the sample site were manually removed from the georeferenced surface mesh and the mesh was cropped at the margins
- Triangle numbers were reduced by merging vertices closer than 2.5mm
- Resultant non-manifold features were removed
- Closed holes using a 20mm diameter filter. Inspected boundaries of resultant meshes to confirm that all remaining boundaries are on the edges of the sub-sampled area.
- Cropped horizontal areas to a consistent patch size: A 2 x 3.5m; B 1.5 x 1.5m
- Exported as .OBJ file from which the vertex coordinates and face indices and metadata were extracted for subsequent analysis in Matlab.

C: Comments and recommendations on the Kinect sampling strategy used in this study.

- Daylight swamps the signal of the Kinect. Over rock surfaces the Kinect worked perfectly as long as the surface was not in direct sunlight. Over snow and ice the effective range was reduced to about 1m and scanning could only be performed once the sun was below the horizon and was even better after darkness had fallen.
- This study used ReconstructMe as the capture software as it performs real time meashing so that the quality of the surface collected can be assessed at the time of capture. This is an advantage for:
    - observing if return signals had been obtained from the troughs of the penitentes as penetration into very narrow penitente troughs was only achieved over several passes and by re-orientating the sensor to be parallel with the trough.
- The disadvantages of ReconstructMe are that:
    - it does not save the raw depth data
    - it requires a computer with a powerful graphics processor as the real time processing is performed at the same 30Hz frequency as the depth-map frame production of the Kinect.
    - the powerful graphics processor tends to be power hungry
- Alternative systems for sampling Kinect data are numerous and growing, and the user must do some up to date research to discover the newest developments, but some existing options are to:
    - use the 'KinectFusion' algorithm (Izadi et al., 2011;Newcombe et al., 2011), implemented in the 'Kinfu' program (part of the Point Cloud Library (PCL); Rusu and Cousins, 2011), which allows one to move the Kinect and scan an area or object, automatically stitching together each frame into one large 3D model, while also capturing raw data.
    - for very large areas, the Kinfu implementation has been extended, named Kintinuous, and used to map paths more than 100m long (Whelan et al., 2012).
- When covering an area larger than $1m^2$ with a Kinect survey it would be advantageous to have a camera boom mounting for moving the Kinect smoothly over the glacier surface, as this would mean larger areas can be scanned in a single mesh. This would save significant work, and additional error involved in aligning and mosaicking the meshes.
- Ground control point markers which have fixed geometric surfaces with known alignment to x, y, z would have facilitated the alignment and mosaicking the component meshes of each scan. On the basis of this study a marker pole with cubes attached to it at fixed heights and known orientations would be ideal. As the surface lowers and more of the marker stake is revealed additional markers should be added at known distances below the previous marker cube.
- A higher number of ground control points to provide redundancy is advisable as in the case of poorly represented locations for georeferencing step, these could be excluded and the remaining points would still allow successful georeferencing.

Response to comments from Reviewer 2

We would like to thank the reviewer for their careful reading of this manuscript. All these minor comments have been remedied as detailed below.

Reviewer comments are given in green, authors reply in black and revised text sections included in blue italics. The revised manuscript and figure captions are appended to this reply highlighting all changes made, and including updated versions of the figures.

---

line 57. Drewry 1970 is missing from the reference list.

This has now been added.

line 74. Change Carol to Carroll.

Done

line 80. Fassnacht et al 2009. Do you mean 2009a or 2009b?

Now specifies Fassnacht et al., 2009b

line 85. Change “surface” to “survey”.

Done

line 100. Fassnacht et al 2010 is not in the reference list.

Sorry, ought to have been 2009a, and now has been corrected.

line 104-105. Change “Mankoff et al.” to “Mankoff and Russo”. Also on lines 165 and 455.

Corrected in all 3 places

lines 107-109. This sentence will be easier to read if written with parallel construction. Change to “(i) to perform the first . . . (ii) to perform an examination . . . (iii) to compare the volume . . .“

Now reads: “*The method of DSM generation is evaluated against standard terrestrial laser scanning, and the Kinect-derived DSMs of the penitentes are used to (i) perform the first detailed examination of the morphometry of natural penitentes over the course of an ablation season; (ii) compare the volume change computed from DSM differencing with estimates based on manual measurements of surface lowering and (iii) examine the geometrical roughness properties of the sampled penitente surfaces*.”

line 114. Change “mas” to “mass”

Done

line 121. Change “Figure 1b” to “Figure 1”

Done, and we also reference this figure for the other site features described.

line 267. Change Brutseart to Brutsaert.

Done

line 357. “strong east-west preferential orientation”. But Figures 4e and 4f show aspect orientation north-south, not east-west. You need to define “aspect”.

Now reads: “*The morphometry of the sampled penitentes changed visibly over the measured intervals (Figures 3 and 4). The strong east-west lineation and preferred north and south surface aspect predicted from theory developed early and was maintained throughout study period.*”

line 382. Change Lettaus to Lettau’s

Done

line 401. “at site A”. Figure 8 caption mentions only site B, not site A.

The sentence is not intended to refer to Figure 8. We have added the missing reference to Table 3 here that shows the change in calculated roughness properties over time.

line 409. “predominantly from the south-westerly sector”. On Figure 9 the wind direction is predominantly SE not SW.

Correct! This now reads: “*Over the whole study period wind direction is predominantly from the south-easterly and north-westerly sectors, and swings through both extreme wind angles used in the roughness calculations here (Figure 9).*”

lines 522-525. This is an important result; it should be included in the abstract.

Abstract now includes: “*Morphometric analysis shows that skimming flow is persistent over penitentes, providing conditions conducive for the development of a distinct microclimate within the penitente troughs.*”, and has been substantially shortened in response to comments from R1.

line 674. Breidamerkurjökull. (change h to k)

Done

line 682. Change “roughness of” to “roughness on”

Done

Table 2. Units of windspeed should be m/s. So change the exponent from -2 to -1.

Done

Table 3. This table is not referenced in the text.

Thank you. We now refer to this table as follows: “*Table 3 shows the calculated roughness values at each survey date, revealing that while profile-computed roughness length increases monotonically over time at site B, it reduces over the first period at site A, associated with snowfall during this period.*”

Figure 1. What are the units of the tick labels? They should be replaced with latitude and longitude, or else removed.

They were in UTM and have now been replaced with latitude and longitude

Figure 2. The labels on the color scale will be easier to read if given in mm instead of m. Then (for example) “0.0000” becomes “0” and “0.0500” becomes “50”.

This has been done

Figure 3 (a,b). Why are the heights negative?

In Figure 4 the heights are all plotted relative to the reference height of the uppermost stake marking out the horizontal reference for manual measurements of surface lowering. This is described in both the text and the figure caption: “*Figure 4: Summary of the DSM properties through time at site A (left) and B (right). Surface height distribution as a percentage of total surface area, in local coordinates [m] relative to the position of the northern end of ablation frame (a & b). Inset tables show weighted mean mesh elevation, range, surface area and surface area as a function of the horizontal area of the sampled site. Distribution of surface angles as a percentage of total surface area (c & d). Aspect distribution as a percentage of total surface area (e & f).”*

Figure 8. What do the colors mean? What does it mean that the green values are positive but the blue values are at -1m?

The colors refer to dates and these are now labelled on the figure. The height coordinate is relative to the NE corner marker of site A, and the caption now reads: “*Figure 9: Examples of (a) N-S, and (b) E-W orientated cross sections sampled at 0.1 m intervals in local coordinates at site B from which effective surface roughness properties were computed using the methods of Munro (1989, 1999).The surface height coordinate is relative to the NE corner marker of site A.”*

3D surface properties of glacier penitentes over an ablation season, measured using a Microsoft Xbox Kinect.

Abstract. ~~Penitentes are a common feature of snow and ice surfaces in the semi-arid Andes where very low humidity, in conjunction with persistently cold temperatures and sustained high solar radiation favour their development during the ablation season. As penitentes occur in arid, low latitude basins where cryospheric water resources are relatively important to local water supply, and atmospheric water vapor is very low, there is potential value in understanding how penitentes might influence the runoff and atmospheric humidity.~~

~~The complex surface morphology of penitentes makes it difficult to measure the mass loss occurring within them because the (i) spatial distribution of surface lowering within a penitente field is very heterogeneous, and (ii) steep walls and sharp edges of the penitentes limit the line of sight view for surveying from fixed positions and (iii) penitentes themselves limit access for manual measurements.~~ In this study, ~~we solved these measurement problems by using a Microsoft Xbox Kinect sensor to generate~~the first small-scale digital surface models (DSMs) of ~~small sample areas of snow and ice~~natural penitentes on a glacier surface were produced using a Microsoft Xbox Kinect sensor on Tapado Glacier~~ in~~, Chile (30°08'S; 69°55'W~~) between November 2013 and January 2014.~~). The surfaces produced by the complete processing chain were within the error of standard terrestrial laser scanning techniques~~. However, in our study~~, but insufficient overlap between scanned sections that were mosaicked to cover the ~~studied sites~~ sampled areas can result in three-dimensional positional errors of up to 0.3 m.

~~Mean surface lowering of the scanned areas was comparable to that derived from point sampling of penitentes at a minimum density of 5 m^{-1} over a 5 m transverse profile. Over time the~~Between November 2013 and January 2014 penitentes become fewer, wider, deeper, and the distribution of surface slope angles becomes more skewed to steep faces. ~~These~~Although these morphological changes cannot be captured by ~~the interval sampling by~~ manual point measurements~~.~~, mean surface lowering of the scanned areas was comparable to that derived from manual measurements of penitente surface height at a minimum density of 5 m^{-1} over a 5 m transverse profile. Roughness was computed on the 3D surfaces by applying two previously published geometrical formulae; one for a 3D surface and one for single profiles sampled from the surface. Morphometric analysis shows that skimming flow is persistent over penitentes, providing conditions conducive for the development of a distinct microclimate within the penitente troughs. For each method a range of ways of defining the representative roughness element height ~~required by these formulae~~ was used, and the calculations were done both with and without ~~using~~application of a zero displacement height offset to account for the likelihood of skimming air flow over the closely~~-~~-spaced penitentes. The computed roughness values are in the order of 0.01-0.10 m during the early part of the ablation season, increasing to 0.10-0.50 m after the end of December, in line with the roughest values previously published for glacier ice. Both the 3D surface and profile methods of computing roughness are strongly dependent on wind direction. However, the two methods contradict each other in that the maximum roughness computed for the 3D surface coincides with airflow across the penitente lineation while maximum roughness computed for sampled profiles coincides with airflow along the penitente lineation. These findings highlight the importance of determining directional roughness and wind

direction for strongly aligned surface features and also suggest more work is required to determine appropriate geometrical roughness formulae for linearized features.

1. Introduction

Penitentes are spikes of snow or ice, ranging from a few centimetres up to several metres in height that can form during the ablation season on snowfields and glaciers ~~under the right conditions. The conditions required for penitentes to form~~. They are ~~dew point below 0°C, persistently low air temperatures and sustained strong solar insolation (Lliboutry, 1954). These conditions are frequently met at~~a common feature of high elevation, low-latitude glaciers and snowfields~~, such as in the subtropical Andes~~ (e.g. Hastenrath and Koci, 1981; Corripio and Purves, 2005; Winkler et al., 2009~~),~~) where ~~penitentes are widespread during the ablation~~very low humidity, persistently cold temperatures and sustained high solar radiation favour their development (Lliboutry, 1954). As cryospheric water resources are relatively important to local dry season~~.~~ water supply in arid mountain ranges (Kaser et al., 2010), there is potential value in understanding how penitentes might influence both runoff and atmospheric humidity.

~~Observations show that penitente~~Penitentes form linearized, inclined fins of snow or ice on the surface. Both the latitudinal range (within 55° of the equator on horizontal surfaces) and geometry ~~is~~ (aligned with the arc of the sun across the sky, and tilted toward the sun at local noon~~, highlighting the importance~~) of penitentes are governed by solar ~~radiation in penitente formation~~-to-surface geometry (Lliboutry, 1954; Hastenrath and Koci, 1981; Bergeron et al., 2006~~). Indeed, the alignment and restricted latitudinal range of penitentes (within 55° of the equator on horizontal surfaces) can be explained by solar-to-surface geometry alone (~~; Cathles et al., 2014). ~~The process~~During the initial stages of penitente ~~growth involves geometric focusing of incident solar radiation~~ development, ablation is thought to proceed by ~~surface~~sublimation alone driven by the low atmospheric humidity. Surface irregularities ~~that causes~~focus reflected solar radiation within depressions ~~to receive more radiation than surrounding peaks~~ (Amstutz, 1958; Corripio and Purves, 2005; Lhermitte et al., 2014; Claudin et al., 2015~~). Consequently,~~) such that the energy receipts, and consequently ablation, are ~~initially~~ enhanced in the hollow ~~due to multiple reflection of irradiance,~~ and the surface irregularity becomes amplified. ~~However for substantial penitente growth it is crucial that, at the tips of penitentes, ablation occurs by sublimation and the snow/ice temperature remains below the melting point, while in the troughs between penitentes, melting can occur once~~Subsequently, as the surface relief increases, a more humid microclimate is ~~established within the hollow~~thought to develop in the hollows between penitentes, supressing sublimation and allowing melting in the depressions. Meanwhile, the penitentes tips continue to ablate by sublimation alone (Lliboutry, 1954; Drewry, 1970; Claudin et al., 2015~~). Once the snow/ice in the hollows has reached the melting point, the spatial differentiation of ablation processes serves to further amplify the penitente relief as melting only~~) and, as melting requires approximately an eighth of the energy of sublimation to remove the same amount of ice, the spatial differentiation of ablation process between penitente trough and tip is very effective at amplifying the penitente surface relief.

The altered partitioning of ablation between sublimation and melting that occurs in penitente fields, as compared to surfaces without penitentes (e.g. Lliboutry, 1998; Winkler et al., 2009; Sinclair and MacDonell, 2015~~The impact of penitentes on the surface energy balance and ablation of snow and ice is of interest in arid mountains catchments, where penitentes are widespread and meltwater can be a substantial contribution to local hydrological resources (Kaser et al., 2010). Previous studies have shown that penitentes alter the surface energy balance of snow and ice surfaces by reducing~~), is expected to alter the rate of mass loss and meltwater production of snow and icefields during the ablation season, but this has not yet been fully quantified. Previous studies, based on modelling idealized penitente surfaces, have investigated the impact of penitentes on the shortwave radiative balance, and suggest that penitentes reduce effective albedo by up to 40% compared to flat surfaces (Warren et al, 1998; Corripio and Purves, 2005; MacDonell et al., 2013; Cathles et al., 2014; Lhermitte et al., 2014~~) as well~~). In addition to altering the ~~partitioning of ablation between sublimation and melting (e.g. Lliboutry, 1998; Winkler et al., 2009; Sinclair and~~

~~MacDonell, 2015~~). ~~Thus, the presence of penitentes is expected to alter the rate of mass loss and meltwater production of snow and icefields during the ablation season, and, on the basis of the~~ radiative ~~balance it has been postulated that they will accelerate the snow and ice mass loss rates (Cathles et al., 2014). However~~properties of the surface, the development of penitentes ~~on the surface will~~ also ~~alter the roughness properties in both space and time, but this, as well as its impact on the resultant turbulent fluxes is not quantified. The wind direction-dependence of~~ manifestly alters the surface roughness properties, but neither the impact of penitentes on surface roughness, nor the associated impact on turbulent energy fluxes has been investigated. The roughness of snow and ice surfaces is particularly prone to varying in space and time (e.g. Smeets et al., ~~over linearized surface features has been previously observed in wind~~1999; Brock et al., 2006; Fassnacht et al., 2009b). Wind profile measurements over ~~snow~~linearized sastrugi~~, for which~~ surface features shows that the derived aerodynamic roughness length varied from 1–70 mm over a 120° range of impinging wind direction (Jackson and ~~Carol~~Carroll, 1978). While penitentes are a relatively rare form of linearized surface feature~~ in many glacierized environments, in contrast,~~ linear crevasses are widespread, and~~ although the impact of wind direction on roughness and the resultant turbulent heat fluxes is generally not treated in glaciology,~~ penitentes offer a unique test bed for investigating the significance of linearized features on effective surface roughness for various wind directions.

~~In general, the physical roughness of snow and ice surfaces are particularly prone to varying in space and time (e.g. Smeets et al., 1999; Brock et al., 2006; Fassnacht et al., 2009), it is desirable to be able to replace relatively logistically and technologically challenging methods of determining roughness parameters from atmospheric profile or eddy covariance measurements, with methods based on more readily measurable surface terrain properties (e.g. Kondo and Yamazawa, 1986; Munro, 1989; Andreas, 2011), or properties such as radar backscatter that can be derived from spaceborne instruments (e.g. Blumberg and Greeley, 1993). The most comprehensive surface of methods to determine apparent aerodynamic properties from surface morphometry was carried out by Grimmond and Oke (1999) who tested several methods in urban environments, which are among the roughest surface conditions encountered in boundary layer atmospheric studies. The morphometric estimates of roughness properties were compared with those from aerodynamic methods from numerous field and laboratory studies. Many of the aerodynamic studies were found to be flawed, and the study demonstrates that, despite the considerable effort in obtaining such measurements, their reliability in complex and rough terrain is contested as the computations rely upon theory that is developed for flat homogenous terrain, and in general the aerodynamic results show a similar amount of spread as the various geometrical methods tested. Although, Grimmond and Oke (1999) consider that direct measurements of fluxes over complex terrain are most likely the 'best' way of determining surface properties, the difficulties of deploying the expensive and relatively delicate instruments over glacier surfaces makes a geometric determination even more appealing. However, in the case of penitentes, such studies are impeded by a scarcity of information on real penitente geometry.~~

Measurements of natural penitentes ~~(e.g.~~ required to examine their morphometry and roughness are rare (e.g. Naruse and Leiva, 1997~~) are rare as they are generally found in relatively inaccessible areas and the complex surface relief poses a considerable impediment to movement and measurement, for example preventing~~), and difficult to obtain because the complex, and partially overhanging, surface prevents the use of simplified automated tools such as photogrammetric determination of surface profile heights (e.g. Fassnacht et al., ~~2010~~2009a; Manninen et al., 2012~~). Furthermore, accurately measuring the convoluted penitente surface is in itself a significant challenge, as it includes overhanging surfaces, which is problem for immobile~~) or line-of-sight surveying ~~equipment. However,~~from fixed positions. Recent advances in close-range mobile depth-of-field sensors and efficient feature tacking software used in interactive computer gaming offer potentially useful tools that can be applied to ~~generate small-scale digital surface models to~~ resolve such problems in earth science (e.g. Mankoff ~~et al.,~~and Russo, 2013). In this study ~~sample plots of penitentes in snow on a glacier surface are scanned using~~ a Microsoft Xbox Kinect sensor is used as a close-range mobile distance ranger to produce a series of small-scale digital surface models (DSMs). ~~These surface models are used to perform (i)~~ The method of DSM generation is evaluated against standard terrestrial laser scanning, and the Kinect-derived DSMs of the penitentes are used to (i) perform the first detailed examination of the

~~geometry~~morphometry of natural penitentes ~~and how they change~~ over the course of ~~the core~~an ablation season; (ii) ~~an examination of the geometrical roughness properties of penitentes and (iii)~~ compare the volume ~~changes~~change computed from DSM differencing ~~the DSMs~~ with ~~the volume changes estimated from~~estimates based on manual measurements of surface lowering ~~within a penitente field. 2. Methods

2.1 Description of fieldsite

Tapado Glacier (30°08'S; 69°55'W) lies in the upper Elqui Valley of the semi-arid Andes of the Coquimbo Region of Chile (Figure 1). ~~This~~The glacier is relatively ~~easily~~ accessible and ~~previous research indicates that the glacier surface develops~~is known to develop penitentes every summer (Sinclair and MacDonell, 2015). Two separate study areas were analysed. Firstly, a test site was established at a patch of snow penitentes within a dry stream bed at 4243 m a.s.l. in the glacier foreland (Figure ~~1b~~1). This site was used to (i) ~~trial~~test instrumental setups in order to optimize the field operation of the Kinect sensor, and (ii) compare the performance of the Kinect sensor against a Terrestrial Laser ~~Scanning~~Scanner (TLS~~) system.~~). This location was chosen due to the logistical difficulties of transporting the TLS to the glacier. Subsequently, two study plots were established at an elevation of 4774 m a.s.l. ~~within~~on the glacier ablation zone~~.~~ (Figure 1). These ~~surfaces at these~~ sites were ~~measured~~scanned repeatedly ~~using~~with the Xbox Kinect (see section 2.3) during the core ablation season between the end of November 2013 and the beginning of January 2014. ~~An automatic weather station on a free-standing tripod was installed beside the two plots to provide meteorological context for the measurements.~~

The location and layout of the two glacier sites is shown in Figure ~~1~~1a. Site A (5 m by 2 m) was measured four times, on 25 November, 11 December, 20 December and 3 January. Site B (2 m by 2 m~~, Figure 1c~~) was only measured on the last three dates~~ (Figure 1c).~~. The corners of the study sites were marked with 2 m lengths of plastic plumbing piping hammered vertically into the snow, or drilled into the ice~~.~~ (Figure 1c). In order to locate the study sites in space and to provide a common reference~~ frame~~ for each survey date, marker stake positions were measured using a Trimble 5700 differential GPS with Zephyr antenna on the 25th November, with a base station in the glacier foreland. On each visit to the glacier, when possible, the stakes were hammered further into the snow and the resultant lowering of the stake top was noted. The maximum standard deviations of the GPS stake positions were < 1.0 cm, 1.1 cm and 1.7 cm in easting, northing and elevation respectively, with combined XYZ standard deviation < 2.0 cm for all stakes (Supplement A). Error on the manual measurements of height offsets of the marker stakes on subsequent survey dates is conservatively estimated to be 2.0 cm. This results in total positional errors of the ground control points at each scan date of between 2.3 and 2.7 cm depending on the stake. Manual measurements of surface lowering were made along the eastern long side of site A. All surfaces heights were referenced to the elevation of the glacier surface at the upglacier end of this cross profile at the date of installation. An automatic weather station (AWS) on a free-standing tripod was installed beside the two glacier plots to provide meteorological context for the measurements (Figure 1).

2.2 Terrestrial laser scanning

~~Surface scans of snow penitentes at~~At the test site ~~were undertaken with both a terrestrial laser scanner (TLS) and the Kinect sensor in order to compare the~~ surface scans produced by the ~~well-established TLS method and the~~ relatively new Kinect sensor ~~application~~were compared with those produced by the well-established TLS method. The TLS system used was an Optech ILRIS-LR scanner, which is a long-range terrestrial laser scanner especially

suitable for surveying snow and ice surfaces ~~thanks to~~as it has a shorter wavelength laser beam (1064 nm) than other models. This equipment surveys surface topography based on time-of-flight measurement of a pulsed laser beam reflected to a given angle by a system of two rotating mirrors. It has a raw range accuracy of 4 mm at 100 m distance, raw angular accuracy of 80 μrad, beam diameter of 27 mm at 100 m distance and beam divergence of 250 μrad. The instrument was placed in five locations around the surveyed snow patch and boulder, overlooking it from different directions. Positions of the TLS were measured with ~~the~~ Trimble 5700 differential GPS with Zephyr ~~antenna~~antennae in static mode. Seventeen point clouds were obtained with nominal resolution of 0.11-0.75 cm. Resulting point clouds were corrected for atmospheric conditions (pressure, temperature and humidity) and trimmed with ILRIS Parser software, aligned with Polyworks IMAlign software into a common local coordinate system and georeferenced with differential GPS measurements using Polyworks IMInspect software. The alignment error of the point clouds as estimated by this software is 0.36-0.87 cm and comparison with ground control points gives an error of 5.65 cm. The TLS scan of the snow penitentes is presented as an example of the nature of the DSM that can be obtained within a penitente field using TLS (Figure 2). Unfortunately, the scans of snow penitentes could not be carried out with both the TLS and Kinect on the same day, so direct comparison of the TLS and Kinect scans is instead performed on a reference boulder ~~lying on the ground beside~~within the test site, whose surface is assumed unchanged between different scan dates. ~~The TLS scan of the snow penitentes is presented as an example of the nature of the DSM that can be obtained within a penitente field using a TLS (Figure 2).~~

2.3 Kinect ~~scans of~~ surface ~~change~~scanning

The Kinect sensor emits a repeated pattern of structured infra-red (IR) beams, and records the pattern distortion with an ~~onboard~~ IR camera. The depth~~-~~-of~~-~~-field calculation is performed via a proprietary algorithm and a distance map is the raw data output. Using the standard calibration the static raw depth field resolution of the Kinect is 1 mm and the ~~Kinect-measured~~ distance ~~at the center of the field of view is within 1% of the real distance (Mankoff et al., 2013), implying an~~ error ~~of~~is < 1.0 cm at the distance range of the penitente scans~~.~~ (Mankoff and Russo, 2013).

For its original gaming usage, the Kinect is in a fixed position and proprietary software uses feature tracking to track the movements of players moving within the field of view of the Kinect. However, the inverse of this workflow can also be applied ~~wherein~~whereby the Kinect sensor is moved interactively around a static surface or 3D body, using the same feature tracking to compute the position of the sensor relative to the object and thereby allowing a point cloud reconstruction of the object ~~to be constructed.~~. In this work we apply the second work flow ~~sampling~~and sample Kinect data using the ReconstructMe™ 2.0 software package. In common with alternative reconstruction packages that are compatible with the Kinect, ReconstructMe™ performs bilateral filtering on the output depth map frame and converts the pixel version of each depth map frame to 3D coordinate maps of vertices and normals. An iterative closest point (ICP) alignment algorithm is then applied frame by frame at three scales to repeatedly rotate and translate the depth field to determine camera position and an aligned surface, giving weighted preference to portions of the surface that are perpendicular to the line of sight. ~~This~~The ReconstructMe™ software has the advantage of producing surface meshes in real-time, so that the operator can ~~visibly~~ check the scan quality and coverage at the time of capture, but the disadvantage that the raw point cloud is not saved and if the real-time tracking is lost a new scan ~~sample~~ must be started.

The Xbox Kinect was connected via a 5m powered USB extension cord to an MSI GE60 gaming laptop, powered using a 240V 600W inverter connected to the ~~12V~~ 160Ah 12V battery of the automatic weather station on the glacier. Scans were carried out by two people; one moving the Kinect across the penitente field and the other monitoring the quality of the surface being generated~~. The~~ on screen. In bright conditions, the return IR signal of the Kinect is swamped by natural radiation ~~in bright conditions, and this is especially true over bright, rough~~over snow and ice surfaces, which reflect ~~the~~a high proportion of incident shortwave radiation, and absorb or scatter much of the longwave radiation signal. ~~To solve this~~Therefore, scanning was carried out at twilight or just after nightfall. Sudden movements caused by the operator slipping or the snow compacting underfoot ~~can result~~resulted in the

ReconstructMe software losing its tracking of common reference points~~ used to generate the continuous surface mesh.~~. Consequently, each study site was scanned in small sections and three to thirteen ~~separate~~overlapping surface meshes were used to cover the area of each study site.

2.4 ~~Mesh processing~~

~~Freely available Meshlab software was used to initially align the~~ **Kinect surface** ~~meshes covering each study site using a pairwise alignment procedure.~~ **mesh processing**

The full mesh processing procedure using the freely available Meshlab software is presented in Supplement B, and briefly described here. Small surface components, unreferenced and duplicated vertices were removed from the meshes using inbuilt filters. ~~The Meshlab alignment~~The component meshes that cover each sampling date at a single site were aligned using an iterative closest point (ICP) algorithm ~~was applied to objectively optimize the alignment and compute~~which distributes the alignment error~~. This alignment procedure uses an ICP algorithm to iteratively align the component meshes and distribute the alignment errors~~ evenly across the resultant mosaicked surface mesh. Alignment solutions consistently had mean distributed error < 4 mm (Supplement B). The aligned meshes were flattened into a single layer, remeshed using a Poisson filter and ~~finally~~ resampled to reduce the point density by setting a minimum vertex spacing of 2.5mm.

The surface mesh for each scan date was georeferenced in Polyworks software using the known coordinates of the base of the marker stakes at the time of each scan because the upper portions of the symmetrical stakes are often poorly captured by the meshing software. The local elevation zero was set to be the north-east corner of site A. The mismatch evident in the georeferencing step (Table 1) is much larger than the mesh alignment error (Supplement B). ~~stakes are often poorly represented in the scans due to the fact that ReconstructMe™ does not handle symmetrical objects well. It proved difficult in some cases to locate the surfaces in space such that the locations of all marker stakes were consistent with the ground control points.~~ This is most likely an artifact of a combination of (i) reduced mesh quality at the margins of the component scans and (ii) insufficient overlap between some scan sections producing distortion within the mesh alignment. ~~The mismatch evident in the georeferencing step (Table 1) is much larger than the mesh alignment error (Supplement B).~~

To eliminate the marker stakes and any data gaps near the margins of the study areas, each surface mesh was sub-sampled within the staked area. The sub-sampled area for site A is a 2.0 by 3.5 m horizontal area (7.00 m^2), and site B is a 1.5 x 1.5 m horizontal area (2.25 m^2) shown in the examples in Figure 3. Mesh vertices and an index file of the vertices comprising each face were exported from Meshlab for subsequent analysis in Matlab software.

2.5 Calculations of surface geometrical properties

The geo2d and geo3d toolboxes (available from the Matlab File Exchange) were used ~~in Matlab™~~ to compute the ~~triangle~~face areas and normals of the mesh, from which ~~the~~ surface height distribution, aspect and dip of the sampled surface ~~can be determined~~were calculated, weighted by the ~~triangle~~ratio of each face area ~~as a function of~~to the total surface area of all faces. ~~Volume change between~~As the surfaces ~~was~~contain overhanging parts, DSM differencing cannot be performed by simple subtraction. Instead volumes for all surfaces were computed ~~by projecting each triangle area onto~~ relative to a baselevel horizontal reference~~ surface.~~. Volumes relative to this horizontal reference for upward-facing triangles were computed column-wise~~ from these projected areas~~, by projecting the area of each triangular face onto the reference surface and using the height coordinate of the triangle centroid as the height dimension for each column. These were summed and volumes for overhanging triangles, calculated in the same way~~ as the up-ward facing volumes~~, were subtracted to derive ~~a~~the total volume between the reference surface and ~~the~~each scanned penitente surface. Successive volumes were subtracted to obtain the volume change over each measurement interval.

~~2.6~~2.6 Manual measurements of surface change

Traditional single-point stake measurements of glacier surface lowering are unreliable within the inhomogeneous surface of a penitente field. One alternative is to measure surface lowering at intervals along a profile perpendicular to the main axis of alignment of the penitentes. Such a reference was installed along the 5 m-long eastern margin of site A, between two longer corner stakes drilled 3 m into the ice using a Kovacs hand drill. The distance between a levelled string and the glacier surface was measured using a standard tape measure at 0.2 m intervals on 23 November. Subsequent measurements, on the 12 and 21 December and on 4 January, were made at 0.1 m intervals. All measurements were recorded to the nearest centimetre, and the error on each measurement is estimated to be 2.0 cm, which is assumed to capture the error associated with the horizontal position of the measurements along the reference frame and the vertical measurements of the distance to the surface beneath.

2.7 Calculations of geometric surface roughness

The aerodynamic roughness length (z_0) is the distance above the surface at which an extrapolation of a logarithmic windspeed profile under neutral conditions ~~would be extrapolated down through~~towards the surface ~~layer and~~would reach zero. Over taller roughness elements the level~~ of action~~ of momentum transfer between the airflow and the surface roughness elements is displaced upwards by a distance, termed the zero-plane displacement (z_d). Above particularly rough surfaces, a roughness sub-layer is formed in the lowest part of the surface layer within which surface roughness elements create a complex 3D flow that is almost chaotic. Where roughness elements are widely spaced, the separated flow over obstacles reattaches to the surface before the subsequent obstacle is reached. More closely packed roughness elements experience a wake interference regime, and in the most densely packed arrays of roughness elements skimming flow occurs (Grimmond and Oke, 1999). At the top of the roughness sublayer individual wakes caused by surface obstacles are smeared out and the flow is independent of horizontal position, and thus, observations at this level represent the integrated surface rather than individual surface obstacles. This level is known as the blending height (z_r). All these properties are dependent on the size and arrangement of surface roughness elements.

As it is logistically challenging to deploy instrumentation to determine roughness parameters from atmospheric profile or eddy covariance measurements on glacier surfaces, efforts have been made to instead use methods based on properties such as radar backscatter (e.g. Blumberg and Greeley, 1993) or more readily measurable surface terrain properties (e.g. Kondo and Yamazawa, 1986; Munro, 1989; Fassnacht et al., 2009a; Andreas, 2011). Grimmond and Oke (1999) tested several methods of determining apparent aerodynamic properties from surface morphometry in urban environments, which are among the roughest surface conditions encountered in the atmospheric boundary layer, and found that morphometric determinations of surface roughness do not clearly underperform in comparison with aerodynamic methods, suggesting that morphometric measurements of roughness are worth pursuing.

There are a number of formulations for deriving z_0 from geometrical measurements. For example, the simplest approach is to take the standard deviation of the surface elevations as a measure of roughness (Thomsen et al., 2015). In this work, the surface meshes were analysed for roughness on the basis of a widely-used relationship established by Lettau (1969), initially developed for isolated, regular obstacles distributed over a plane:

$$z_0 = 0.5\, h \left(\frac{s}{S}\right) \tag{1}$$

where h is the height of the obstacles, s is the upwind silhouette area of each obstacle and S is the specific area occupied by each roughness element obstacle, also referred to as its lot area. The roughness values computed using Equation 1 over 3D snow surfaces has been shown to vary widely depending on the methods of surface interpolation used (Fassnacht et al., 2014), due to the influence on interpolation method on the unit surface area occupied by each roughness element. However in this work the high resolution meshes used can be expected to adequately capture the

surface properties as no extrapolation or interpolation procedure is needed. Isolated roughness elements of regular geometry distributed over a horizontal plane are a poor analogy for the irregular surface topography of a penitente field, and the applicability of this formulation over penitentes has not been established. Nevertheless, we apply the analysis as an illustration of the nature of the results generated from such an approach over penitentes and hope that future aerodynamic roughness lengths obtained from micrometeorological measurements can be compared to these ~~geometrically~~ morphometrically-derived ones. Macdonald and others (1998) state that for irregular obstacles *h* can be replaced by average obstacle height, *s* with the sum of all the upwind silhouette areas, and *S* with the total area covered by the obstacles. While the upwind silhouette area, and indeed surface area in any direction, is relatively easily defined for each surface mesh area using trigonometry, it is difficult to define individual roughness elements and their representative heights, due to the lack of an apparent base level. Here we first detrend the surfaces to remove any general surface slope at the site, then compute the roughness for the detrended 3D meshes assuming that the roughness elements cover the whole surface area (i.e *S* = plot area), and for four possible representations of average obstacle height (*h*) as follows: (i) the maximum range of the detrended mesh; (ii) twice the standard deviation of the detrended surface mesh; (iii) mean mesh height above the mesh minimum; and (iv) median mesh height above the minimum.

These data are computed for illustrative purposes only as it is reported that Equation 1 fails when the roughness element density exceeds 20-30~~%,~~% (Macdonald et al., 1998), as is expected for penitente fields~~ (Macdonald et al., 1998).~~. High density roughness elements means that they interfere with the airflow around each other, and upwards displacement of the zero wind velocity level ~~is displaced upwards, and~~means that effective roughness is a result of the roughness elements above this zero velocity displacement plane~~. The~~, and the zero displacement height~~ in this sense~~, gives an indication of the penetration depth of effective turbulent mixing into the penitente field. Accordingly, we additionally present sample calculations of three-dimensional roughness on the detrended surface meshes using three possible realizations of z_d, as, like *h*, z_d is also unknown in the case of the penitente fields being sampled. In the first case, z_d is taken to be *h*, in the second 2/3 *h*, which is a widely used standard in forests and other complex terrain applications (~~Brutseart~~Brutsaert, 1975), and in the third 1/3 *h*~~ for comparison, both~~. Each z_d case is computed for the four realizations of *h* used as before. Equation 1, (for irregular obstacles) is then applied to the roughness elements remaining above the plane of the general surface slope offset by a distance z_d above the minimum height of the surface mesh. The representative height *h* for this portion of the mesh exceeding the plane is taken to be the mean area-weighted height of all triangles above this plane, *s* is the summed frontal area of all mesh triangles above z_d that face into the chosen wind direction and *S* is the total horizontal area of the surface components above z_d.

Munro (1989, 1990) modified the formula of Lettau (1969) to be applied to a single irregular surface cross-section of length *X*, sampled perpendicular to the wind direction. This modified formulation is easier to work with on a glacier where the roughness elements are irregular, closely spaced, and generally poor approximations of objects distributed over a plane. Instead of having to define an obstacle height above the plane, *h* is replaced with an effective height h^* expressed as twice the standard deviation from the standardized mean profile height; *s* is replaced with $h^*X/2f$, in which *f* is the number of profile sections that are above the mean elevation; and *S* is replaced with $(X/f)^2$. This approach approximates the surface elevation profile as rectangular elements of equal size, and has been shown to give results within 12% of the silhouette area determined by integrating between true topographic minima (Munro, 1989). Importantly, roughness values derived this way over snow, slush and ice surfaces show reasonable agreement with roughness values derived from wind profiles (Brock et al., 2006). To investigate the nature of the roughness computed this way for north-south and east-west impinging wind directions, cross profiles longer than 1.5 m at 0.~~1m~~1 m intervals orientated E-W and N-S were extracted from each scanned surface. Cross-sections were detrended to remove the influence of any general surface slope at the site, and roughness was computed on each of these cross-sectional profiles following the modifications of Munro~~ for each detrended surface profile~~. Mean profile roughness for these two wind directions are presented for each sampled surface.

~~2.7 Manual measurements of surface change~~

~~Traditional stake measurements of glacier surface lowering made at a single point are unreliable within the inhomogeneous surface of a penitente field, as multiple measurements are required to characterize the complex surface. One alternative is to measure surface lowering at intervals along a profile perpendicular to the main axis of alignment of the penitentes. Such a reference was installed along the 5 m-long eastern margin of site A, between two longer corner stakes drilled 3 m into the ice using a Kovacs hand drill. The distance between a levelled string and the glacier surface was measured using a standard tape measure at 0.2 m intervals on 23 November. Subsequent measurements, on the 12 and 21 December and on 4 January, were made at 0.1 m intervals. All measurements were recorded to the nearest centimetre, and the error on each measurement is conservatively estimated to be 2.0 cm, which is assumed to capture the error associated with the horizontal position of the measurements along the reference frame and the vertical measurements of the distance to the surface beneath.~~

3. Results

3.1 Evaluation of the quality and suitability of penitente scans by TLS and Kinect

~~At the~~The test site~~, the~~ was well-developed snow penitentes ~~were well-developed and between~~ 0.5 ~~and~~- 1.0 m in height in a channel (Figure 1b). TLS scans ~~were made~~ of these penitentes ~~to illustrate the capabilities of this more conventional scanning system in capturing the penitente surfaces. TLS scans~~ were taken from five different vantage points~~ positioned~~ above the penitentes. The penitente surface produced by the TLS had surface slope ranging between -30 and 90 degrees, indicating that overhanging surfaces within the penitente field ~~are~~can be captured~~, however~~. However the limitations of this conventional fixed-point scanning system in capturing the penitente surfaces is illustrated by the fact that only 58% of the total surveyed horizontal area could be scanned, as the deepest parts of the troughs were obscured from the view~~ of TLS~~ by the surrounding penitentes (Figure 2a). By comparison, the hand-held, mobile nature of the Kinect means that ~~100% of~~ the whole surface of the penitente field can be captured as the field of view can be adjusted into almost limitless close-range positions~~. The long range of the TLS makes it easier to cover large areas in comparison to~~, although the close range Kinect sensor~~, but as only penitente tips are scanned the utility of this larger areal coverage~~ is ~~limited~~impractical to apply over large areas.

~~The Kinect scan~~For the direct comparison of the two methods on a reference boulder, the Kinect-derived surface, produced from three mosaicked meshes was aligned to ~~that~~the surface produced from the TLS point clouds. The TLS scan was incomplete, with parts of the top and overhanging surfaces of the boulder missing due to being obscured from the TLS survey positions, while the Kinect scan achieved complete coverage of the boulder. The difference between the two aligned meshes where overlapping data existed was always < 2 cm (Figure 2b), which is well within the error of the georeferenced TLS surface model. Larger differences in Figure 2b, up to 5 cm, occur only where there are holes in ~~one of~~ the surfaces being compared.

It is difficult to formally assess the total error of the surfaces produced by the Kinect scans because the ~~proprietary software, ReconstructMe™ and Poisson surface reconstruction in Meshlab, are all~~workflow involves several black box processing steps~~ in the workflow~~. The mean alignment errors of the mesh mosaicking step in Meshlab is < 0.4 cm and quantifiable errors associated with the GPS positions, subsequent measurement of the stake bottom positions relative to the GPS positions are all < 2.0 cm. However, ~~in this study~~ the three-dimensional georeferencing error in this study is large (Table 1) compared to the other sources and ~~can be~~is therefore taken as a reasonable value for the error of the total process chain. Errors given on the seasonal mass, volume and surface changes are based on summing the squares of the mean elevation difference between the marker stakes and ground control points (GPCs) at each site on the first and last survey dates.

3.2 Meteorological conditions

During the study period one significant snowfall event occurred on the 8th December 2013, when the sonic ranger recorded ~~an increase of~~ a surface height increase of 0.09 m over the course of the day~~, and temperature and incoming longwave radiation increase progressively~~ (Table 2). ~~The surface conditions of~~Surface albedo and ~~surface~~ temperature are derived from radiation measurements that ~~integrate the signal from a~~ sample an area beneath the instrument. Surface temperature was calculated from measured surface longwave emissions, assuming ~~a surface longwave~~ emissivity of 1. Over the study period, air temperature and atmospheric longwave receipts increase, while albedo decreases and derived surface temperature increases (Table 2). Thus, over the course of the study, ~~the~~ atmospheric energy supply increases and ~~the~~ surface properties become ~~gradually~~ more conducive to melting. ~~In the three measurement periods 22, 38 and 43% of hourly values of surface temperature exceed the melting point and the~~The warming atmosphere is clearly expressed in the positive degree days of the three periods which are 3.7, 2.2 and 31.5 over the 16, 9 and 14 day-long periods respectively. ~~The height change difference~~Hourly surface temperatures exceed the melting point in 22, 38 and 43% of cases in each period respectively. Daily surface lowering rates calculated between the hourly mean sensor~~-~~-to~~-~~-surface distance recorded by the AWS sonic ranger at midnight at the end of the survey days indicates lowering rates of 17, 37 and 56 mm d~~ay~~$^{-1}$ over the ~~same~~three measurement intervals, ~~indicating~~confirming that the increasing energy receipts translate into increasing rates of surface lowering at the AWS.

3.3 Areal scans of penitente surfaces

Surface lowering rates derived from the ~~computed~~calculated volume changes per unit area are 21, 41 and 70 mm d~~ay~~$^{-1}$ over each interval at site A, and 57 and 61 mm d~~ay~~$^{-1}$ over the last two intervals at site B. Surface lowering calculated as the difference between successive hypsometric mean mesh elevation for each site were within a few millimetres of the volume computations: 22, 38 and 69 mm d~~ay~~$^{-1}$ for the three measured intervals at site A, and 54 and 60 mm d~~ay~~$^{-1}$ for the last two intervals at site B. The total surface lowering over the whole available period computed by volume change (hypsometric mean height change) was 1.68 (1.77) ± 0.11 m at site A and 1.37 (1.32) ± 0.38 m at site B. Surface height changes recorded at site A over the same period as at site B were 1.35 (1.31) ± 0.21 m, indicating that the values were repeatable ~~across~~at both sites. The volume loss was converted to mass loss ~~on the basis of~~using the mean snow density of 426 kg m^{-3} (with an assumed error of ± 5%) measured in a 1.10 m snow pit excavated on 22 November 2013 beside the ~~weather station.~~AWS. Mass loss at site A computed from mesh volume ~~changes~~change (hypsometric height ~~changes~~change) between 25 November and 3 January was 716 ± 58 (754 ± 59) kg m^{-2}~~, indicating an underestimation of mass loss but that the two computation methods are within error of each other~~. Mass loss at site B from mesh volume changes (hypsometric height changes) between 11 December and 3 January was 582 (562) ± 166 kg m^{-2}. Measurements at site A over the same period give mass loss of 573 (558) ± 95 kg m^{-2}, so again, measurements at both sites are within error of each other.

The morphometry of the sampled penitentes changed visibly over the measured intervals (Figures 3 and 4). The strong east-west ~~preferential orientation~~lineation and preferred north and south surface aspect predicted from theory developed early and was maintained throughout study period. ~~The expression of this alignment is more convoluted in the stages of development studied here than the parallel rows of penitentes used in model representations (Corripio and Purves, 2005; Lhermitte et al., 2014).~~ Over time ~~the~~ penitente troughs became fewer in number, but wider and deeper~~ inkeeping with the increasing surface relief evident in the manual measurements.~~. This ~~is reflected by increasing~~causes total surface area~~, with the penitente surfaces~~ to increase; at site A ~~providing~~the true surface is between 1.7 and 4.0 times the ~~surface area of the~~ horizontal equivalent area, ~~and at site B providing~~ between 2.1 and 3.7 times the horizontal surface area equivalent and at site B (Figure 4 a & b). Snowfall during the first measurement interval decreases the surface area at site A over that interval. ~~The surface~~Surface relief, expressed by the vertical range of the mesh, also increases through time, except when snowfall partially filled the developing penitentes~~,~~ ~~reducing~~ and reduces both the range of the surface and the general slope angle.~~ Nevertheless, the morphometric~~

~~properties of the meshes broadly meet the properties of simplified surfaces.~~ The largest part of the surface is facing southwards, and the predominant angle generally steepens over time, though again this trend is reversed by snowfall (Figure 4 c & d). From the onset of measurements the surface aspect distribution is strongly dominated by north and south facing components and this becomes more pronounced in the latter measurements and the preferred orientation rotates slightly over the course of the season (Figure 4 e & f).

~~3.4~~3.4 Manual measurements of reference cross-profile

The surface properties from manual measurements were computed on data sampled at 0.2 m over 5.0 m. Maximum relief of the sampled penitente profile, defined as the range of the distance from the horizontal reference to the surface, increased over time from 0.76, through 0.83 and 1.00 to 1.38 m on each measurement date. The standard deviation of the surface remained relatively unchanged with values of 0.24, 0.26, 0.28 and 0.32 m at each measurement date. Surface lowering rate calculated by differencing the mean surface height along the profile on each measurement data was 13, 57 and 61 mm d^{-1} over the three sampled intervals, giving a total mean surface lowering of 1.61 ± 0.14 m between 23 of November and 4 January. These manual measurements along the cross-profile compare well to the aerially-averaged lowering rates from the scanned surfaces, despite the fact that the manual measurements are made in only 2 dimensions, do not visually represent the complexity of the penitente surfaces, and individual points are sometimes out of the range of error of the Kinect (Figure 5). The computed mass loss over the same period is 688 ± 70 kg m^{-2}, which underestimates, but is within error of, the value for site A derived from volume changes.

To investigate the impact of sampling resolution, maximum elevation range, mean surface height compared to the horizontal reference and mean surface lowering were calculated from manual measurements at 0.1 (n = 52), 0.2 (n = 26), 0.4 (n = 14) and 1.0 m (n = 6) intervals on the last three measurement dates. The highest resolution sample was taken as a reference against which to evaluate coarser sampling. Surface relief differed from that measured at 0.1 m by maxima of 0.13, 0.29 and 0.41 m for 0.2, 0.4 and 1.0 m sampling intervals respectively. Mean measured surface height was within 0.03 m of the highest resolution measurements at 0.2 m and 0.4 m intervals, and within 0.12 m at 1.0 m resolution. Mean lowering rates at 0.1, 0.2 and 0.4 m sampling intervals were all within 3 mm d^{-1}. This increased to a maximum of 12 mm d^{-1} when the sampling resolution was decreased to 1.0 m. Decreasing the length of the sampled profile down to 2 m alters the mean lowering rate by less than 5 mm d~~ay~~$^{-1}$ at sampling resolutions of 0.1, 0.2 and 0.4 m.

Probing of the snow depth on 25 November indicated mean snow depth of 1.83 m (standard deviation 0.56 m). The underlying ice surface does not appear to be influencing the structure of the overlying snow penitentes (Figure 5). However, it is difficult to draw a firm conclusion based on these measurements, particularly as, while the surface of the penitentes was still snow on the 3 January, in several instances the surface had lowered below the level of the ice interface suggested by the initial probing.

3.5 Surface roughness assessments

Given that aerodynamic measurements to determine the most suitable representative height and zero displacement level for penitentes are thus far unavailable, the approach taken here was to do an exploratory study and compute geometric surface roughness values using various ways of expressing h and z_d. As a consequence the results are purely illustrative and while patterns can be drawn from them that have meaning for understanding the nature of the computation, the applicability of these values in turbulent exchange calculations remains to be established. The representative height, h, used in the calculations increases over time in all cases, and is bounded by the maximum case, taking h ~~to be the~~as range of the detrended surfaces ~~(maximum)~~, and the minimum case, taking h as twice the standard deviation of the detrended surface (Figure ~~5~~6). For clarity, the ~~other~~ two ~~case~~intermediate values are not included in ~~the plots shown here.~~Figure 6. Differences ~~within a single~~in h computed by the same method ~~between~~

~~the two sites~~ can reach as much as 0.2 m between the two sites, although the pattern of change over time is consistent.

The application of ~~Lettaus~~Lettau's (1969) formula is considered to be invalid if the ratio of the frontal area to the planar area of the obstacles exceeds 0.2 – 0.3, with 0.25 often being chosen as a single value. ~~In~~This ratio is greater than 0.2 for all ~~cases~~ of the penitente surfaces ~~this ratio exceeds 0.2~~, and ~~only 6% of cases computed at 10° intervals of bearing over all dates are below 0.3, and these are all early in the season, before~~after the 20th December is always greater than 0.3. Exceeding this threshold implies that the obstacles are so closely packed that 'skimming' airflow will occur. Ignoring this issue, calculated z_0 values increase with time and show a strong dependence on the impinging wind direction, with values peaking for wind directions perpendicular to the alignment of the penitentes (Figure ~~6~~7). Calculated z_0 ranges from 0.01 – 0.90 m, depending on the way in which the representative height is expressed, the ~~time of year~~date and the wind direction (Figure ~~7~~8). However, given the close spacing of the penitentes it ~~seems appropriate~~is likely more valid to ~~also~~ explore what the calculated z_0 would be ~~like~~ when ~~applying~~ a zero displacement height offset~~, although again~~ is applied. Again, in the absence of validation data ~~these numbers~~from independent measurements, calculated values can be only indicative of the pattern of roughness computed by these methods. Introducing the zero displacement height reduces the maximum calculated roughness by about half, and also reduces the variability between different representative heights (Figure ~~7~~8), as a smaller h value translates into a smaller z_d so that the calculation is performed on a larger portion of the mesh.

Surface roughness assessments on the basis of calculations following Munro's modification for single profile measurements were applied to cross profiles longer than 1.5 m yielding 20 (6) profiles orientated N-S and 33 (7) E-W at site A (B). Surface amplitude increases over time, and the amplitude of the N-S running cross profiles is generally larger than the E-W running cross profiles, as illustrated in the example of site B (Figure ~~8). The~~9). Table 3 shows the calculated roughness values at each survey date, revealing that while profile-computed roughness length increases monotonically over time at site B, ~~but shows a reduction~~it reduces over the first period at site A, associated with snowfall during this period. Both the range and relative increase in roughness over time is larger for the N-S running profiles. The computed roughness at both sites is 4.3 to 6.8 times larger for airflow impinging on the penitente field in an E-W direction than for airflow in the N-S direction. This is contrary to the results computed on the full 3D mesh surface, but is understandable because this formulation relies on the amplitude of the surface, which is generally larger in the N-S orientated cross profiles than the E-W running cross profiles.

4. Discussion

4.1 Penitente morphology

Although the natural penitentes sampled here are more convoluted than the parallel rows of penitentes used in model representations (Corripio and Purves, 2005; Lhermitte et al., 2014), the morphometric properties of the meshes broadly meet the properties of simplified surfaces. The penitente surface represents a much larger total surface area than the equivalent non-penitente surface and the control of solar radiation on penitente morphology means that the vast majority of the surface consistently dips steeply to the north and south at all stages of development. This means that the angle of incidence of direct solar radiation is reduced, decreasing both the intensity of the solar beam and the proportion of it that is absorbed. Although these effects are counteracted by multiple reflections of solar radiation within the penitente (Corripio and Purves, 2005; Lhermitte et al., 2014; Claudin et al., 2015) modeled mean net shortwave at sampled points in an example penitente field at the summer solstice at 33°S is about half of that of a level surface (Corripio and Purves, 2005). However, given the larger surface area of the penitente field compared to a flat surface, the total absorbed shortwave is a third higher in the modeled penitentes, broadly in line with the observed effect of penitentes on spatially-averaged albedo (Warren et al, 1998; Corripio and Purves, 2005; MacDonell et al., 2013; Cathles et al., 2014; Lhermitte et al., 2014). For idealized penitentes at 33°S during summer solstice, modeled increase in net shortwave radiation over penitentes is not compensated by modelled changes in net

longwave radiation, meaning that the excess energy receipts must be compensated by either turbulent energy fluxes or consumption of energy by melting (Corripio and Purves, 2005).

Unless a snowfall event occurs to partially fill the troughs, surface relief, slope angle, penitente spacing and total surface area all increase over time as the penitentes develop and deepen. Thus the impact of penitentes on surface properties will also change along with the morphological changes. At Tapado Glacier, penitentes are initially overhanging to the north, and the southfacing sides are convex compared to the northfacing overhanging faces. Over the season the penitentes become more upright as the noon solar angle gets higher. Idealized modelling based on measurements at Tapado Glacier, shows that concave and convex slopes, as well as penitente size have been shown to impact the apparent albedo as measured by ground and satellite sensors (Lhermitte, et el., 2014), and there may be some value in assessing the impact of these morphometry changes on albedo over time. In the context of the numerical theory of Claudin and others (2015), penitente spacing controls the atmospheric level at which water vapor content is representative of the bulk surface properties. Simultaneous field or laboratory measurements of penitente spacing evolution and vapor fluxes above the surface would be required to solidly confirm this, but the spacing from the field measurements provided here can be used as an indication of the level at which measurements would need to be made in order to capture the bulk surface fluxes rather than fluctuations governed by the small-scale surface terrain.

4.2~~Prevailing wind direction differs only slightly in each period with an increasing northwesterly component in the second two periods compared to the first. This may be related to the occurrence of snow during the first period, which can be expected to alter the thermally driven valley wind systems. Over the whole study period wind direction is predominantly from the south-westerly sector, but swings through southerly to easterly thereby encompassing both extreme wind angles used in the roughness calculations here (Figure 9). This indicates that the effective roughness can be expected to differ significantly depending on the wind direction.~~

~~**3.5 Manual measurements of reference cross-profile**~~

~~Using data sampled at 0.2 m over 5.0 m, the maximum relief of the sampled penitente profile, defined as the range of the maximum and minimum distance from the horizontal reference to the surface, increased through time, from 0.76, 0.83, 1.00 to 1.38 m on each measurement date. The standard deviation of the surface remained relatively unchanged over time with values of 0.24, 0.26, 0.28 and 0.32 m at each measurement date. The difference in the mean surface height measured at the ablation frame profile at site A indicates mean lowering rates of 13, 57 and 61 mm day^{-1} over the three sampled intervals resulting in a total mean surface lowering of 1.61 ± 0.14 m between 23 of November and 4 January. The manual measurements at the cross profile compare well to the aerially-averaged lowering rates from the scanned surfaces, despite the fact that the manual measurements are only made in 2 dimensions, do not visually represent the complexity of the penitente surfaces, and individual points are sometimes out of the range of error of the Kinect (Figure 10). The computed mass loss over the same period is 688 ± 70 kg m^{-2}, which underestimates the value for site A derived from volume changes but is within error, even accounting for the two extra days measurement interval.~~

~~Values of maximum elevation range and standard deviation along the profile, mean surface height compared to the horizontal reference and mean lowering were computed from the manual measurements for available data at 0.1 (n = 52), 0.2 (n = 26), 0.4 (n = 14) and 1.0 m (n = 6) intervals to investigate the impact of sampling resolution. The highest resolution sample was taken as a reference against which to evaluate the values from coarser resolution sampling. Calculated surface relief differed from that measured at the highest resolution by maxima of 0.13, 0.29 and 0.41 m for 0.2, 0.4 and 1.0 m sampling intervals respectively. Mean measured surface height was within 0.03 m of the highest resolution measurements at 0.2 m and 0.4 m intervals, and within 0.12 m at 1.0 m resolution. Mean lowering rates at 0.1, 0.2 and 0.4 m sampling intervals were all within 3 mm day^{-1} with the difference increasing to a maximum of 12 mm day^{-1} when the sampling resolution was decreased to 1.0 m. Decreasing the length of the~~

~~sampled profile down to 2 m alters the mean lowering rate by less than 5 mm day^{-1} at sampling resolutions of 0.1, 0.2 and 0.4 m.~~

~~Probing of the snowdepth on 25 November indicated a mean snow depth of 1.83 m (standard deviation 0.56 m). The underlying ice surface identified by the snow probing, does not appear to be influencing the structure of the snow penitentes developing in the current season. However, it is difficult to draw a firm conclusion based on measurements at only 0.2 m spacing, particularly as, while the surface of the penitentes was still snow on the 3 January, in several instances the surface had lowered below the level of the ice interface indicated by the initial probing.~~

~~4. Discussion~~

~~4.1~~ Methods of measuring change of rough glacier surface elements

The test site for scanning penitentes with a TLS was chosen as ~~it provided the most optimal viewing angles possible from scanning positions, as the penitentes lay in a river bed and~~ scanning positions could be established on the surrounding ~~river banks to look down into~~higher ground overlooking the penitente field~~.~~, thereby offering the best viewing angles possible. Nevertheless, the terrestrial laser scanning could only capture the ~~tips rather than the whole surface~~upper portions of the penitentes ~~and, as~~. As ablation is at its maximum in the troughs, TLS data is therefore not able to determine the true volume change ~~ongoing in~~of penitentes. The coverage would be increased if a higher viewing angle could be achieved, but the steep, dense nature of penitente fields makes it difficult to imagine where sufficient suitable locations can be found surrounding glaciers or snowfields with penitentes. In contrast, the mobile Kinect sensor can be moved across the complex relief of the penitente field to make a complete surface model. Although it is in principle possible to capture a large area with the ReconstructMe software used here, and it offers the advantage of providing real time feedback on the mesh coverage, it proved difficult to capture the study sites in a single scan given (i) the reduced signal range of the sensor over snow and ice (Mankoff ~~et al.,~~and Russo, 2013), and (ii) the difficulty of moving around the penitente field. As a result, partial scans were obtained, with the disadvantage that subsequently combining these introduces a substantial degree of additional error associated with alignment if the component scans were not of high quality at the margins, or did not overlap adjacent scan areas sufficiently. A combination of these two techniques might allow the extrapolation of small-scale geometry changes and volume loss determined from a Kinect surface scan to be extrapolated usefully to the glacier or snowfield scale using measurements made with a TLS.

Despite not visually capturing the complex ~~surface properties~~morphology of the penitentes, manual measurements of surface height change in a penitente field along a profile cross-cutting the penitentes are robust for determining mean surface lowering rates, and show good agreement to the volume changes computed from differencing the digital surface models scanned in detail using a Kinect. Thus, the detailed surface geometry need not be known in order to reasonably calculate the total volume loss over time within penitente fields. Comparison of the manual sampling at different intervals ~~suggest~~suggests that five samples per meter is adequate to characterize surface change of penitentes~~.~~, but that data will be unreliable is the cross-profile is too short. Over the 39 days of the study, ~~the~~ mass loss calculated from 26 points spaced at 0.2 m intervals along a 5 m profile crosscutting the penitentes differed from that calculated from volume change computed on surface meshes consisting of over 1.3 million points and covering an area of 7 m^2 by only 28 kg m^{-2}. Although this difference was within the error of the two measurement types, the seasonal difference, assuming that this difference applies to a whole ablation season of 120 days would be 86 kg m^{-2}, and applied to the whole glacier (3.6 km^2) would amount to an underestimate of mass loss over an ablation season of 0.3 gigatonnes. As a side note, the probing of snowdepth carried out as part of this study highlights the difficulty in identifying the underlying ice surface, or summer ablation surface, ~~in this way~~ within a penitente field, suggesting that a single location must be sampled very densely to obtain a characteristic snowdepth ~~in~~by this ~~way~~method.

4.3 Surface roughness

~~**4.2 Penitente**~~The changing morphometry ~~**and change in time**~~

~~The manual measurements at 0.2 m intervals are adequate to determine the mean surface lowering within a penitente field, giving confidence to this type~~ of ~~simplified measurement on seasonal timescales. However, the interval measurements cannot capture the surface morphometry, or how it changes in time.~~

~~At all times the penitente surface represents a much larger total surface area than the equivalent non-penitente surface. Over time the surface relief, and slope angle, increases as~~ the penitentes ~~deepen, unless a snowfall event occurs to partially fill the troughs, which also reduced the mean surface slope. The control of solar radiation on penitente morphology means that the vast majority of the surface consistently dips steeply to the north and south at all stages of development. This means that the angle of incidence of direct solar radiation is reduced, decreasing both the intensity of the solar beam and the proportion of it that is absorbed. Although these effects are counteracted by multiple reflections of solar radiation within the penitente (Corripio and Purves, 2005; Lhermitte et al., 2014; Claudin et al., 2015) modeled mean net shortwave in an example penitente field at the summer solstice at 33°S is about half of that of a level surface (Corripio and Purves, 2005). However, given the larger surface area of the penitente field compared to a flat surface, the total absorbed shortwave is a third higher in the modeled penitentes. At Tapado Glacier, penitentes are initially overhanging to the north, and the southfacing sides are convex compared to the northfacing overhanging faces. Over the season the penitentes become more upright as the noon solar angle gets higher. Idealized modelling based on measurements at Tapado Glacier, shows that concave and convex slopes, as well as penitente size have been shown to impact the apparent albedo as measured by ground and satellite sensors (Lhermitte, et el., 2014), and there may be some value in assessing the impact of these morphometry changes on albedo over time. For the idealized penitente surface at 33°S during summer solstice case, modeled increase in net shortwave radiation over penitentes is not compensated by modelled changes in net longwave radiation, meaning that the excess energy receipts must be compensated by either turbulent energy fluxes or consumption of energy by melting (Corripio and Purves, 2005).~~

~~In the context of the numerical theory of Claudin and others (2015), progressive widening of the penitente spacing, as observed at both site A and B, is indicative of changes in the atmospheric level at which water vapor content is unaffected by the vapor flux from the penitente surface. Simultaneous field or laboratory measurements of penitente spacing evolution and vapor fluxes above the surface would be required to solidly confirm this, but the field measurements provided here can be used as an indication of the level to which vapor flux from the surface is influencing the boundary layer vapor content.~~

alters the geometrical surface roughness as they develop over the ablation season. Values calculated using~~**4.3 Surface roughness**~~

~~In this work~~ a single, simple, geometric relationship (Lettau 1969) ~~was~~were investigated because a profile-based version of this formulation has previously been tested against aerodynamic measurements over glacier surfaces (Munro, 1989, 1990; Brock et al., 2006). Certainly other relationships could be explored in the context of linearized glacier features, but given the wide spread of values produced in previous comparisons such an analysis might be of limited value in the absence of simultaneous aerodynamical investigations (Grimmond and Oke, 1999). Furthermore, the results of Grimmond and Oke (1999) indicate that for the cities sampled, the Lettau method gives z_0 values that are in the middle of the range of all the methods. The analysis of geometric computations of roughness properties in Grimmond and Oke (1999) highlight the importance of correctly determining z_d, and limited sensitivity analyses show the computed z_d and z_0 to be strongly dependent on the dimensions of the obstacles. Lettau's (1969) formula, which does not account for z_d, overestimates roughness for densely packed obstacles, but this ~~overestimation~~ does not compensate sufficiently to reproduce values of $z_d + z_0$ ~~produced~~ for densely packed obstacles from formulations that include z_d in the computation of z_0. ~~This means that~~Thus, Lettaus formula is

expected to estimate the zero velocity point of a logarithmic wind profile to be lower than formulations that include z_d in ~~their computation of z_0. In this work however we computed z_d in a separate preceding step to explore the impact of z_d on the computed~~the computation of z_0.

~~As penitentes fields present very densely packed roughness elements, the frontal area of the surface tends to be large compared to the ground area, and the limits of the~~ The ratio of frontal to planar area ~~found in this study~~ of the penitentes implies that skimming flow ~~is almost always occurring over penitente fields~~prevails, such that turbulent airflow in the overlying atmosphere does not penetrate ~~to the full depth of the~~ penitente ~~fields~~troughs. This is in agreement with the theory of formation and growth of penitentes, in which the development and preservation of a humid microclimate within the penitente ~~hollows~~troughs is required to facilitate differential ablation between the trough and tip of the penitente. ~~As~~Although the ~~spacing between the~~data here shows that penitentes ~~also increases over the ablation season the features~~ become less densely packed over time, ~~although the~~ skimming flow regime persists over the study period, and available data ~~are~~is insufficient to determine if ~~the spacing increases sufficiently by the~~ this holds true to the end of the ~~season to comply with the applicable limits of the roughness calculation used here~~ablation season.

Application of geometrical roughness equations is made more problematic in penitente fields as it is not clear how an appropriate representative obstacle height should be expressed, nor how to define the zero displacement level during ~~presumed~~ skimming flow. Roughness calculated using a range of possible representations of these properties point towards roughness values in the order of 0.01-0.10 m during the early part of the ablation season and 0.10-0.50 m after the end of December. These values are in line with the roughest values previously published for glacier ice (Smeets et al., 1999; Obleitner, 2000). The topographic analysis clearly shows that in the absence of intervening snowfall events, this roughness increase is related to the deepening of the penitentes over time and an increase of the surface amplitude. The ~~patterns~~pattern of the computed roughness properties is consistent between the two neighbouring sites, but individual values can differ, suggesting that ~~local~~ relief varies substantially over short distances and sampling a ~~larger~~large area ~~would be beneficial in order~~is necessary to capture mean properties.

The strong alignment of penitentes means that ~~roughness~~ calculated roughness is strongly dependent on ~~the~~wind direction. Roughness calculated from 3D surface meshes ~~is~~are higher for wind impinging in a north-south direction, as the large faces of the penitentes form the frontal area in this case. In contrast, ~~if~~ roughness ~~is computed~~calculated for individual profiles extracted from the mesh to mimic manual transect measurements in the field, ~~roughness~~ is between 3 and 6 times larger for air flow ~~along the penitente lineation (E-W) than it is across the lineation (N-S). While clearly highlighting that the surface roughness of the strongly aligned penitente fields is dependent on wind~~impinging in an east-west direction, ~~this contradiction poses~~than in a ~~conundrum as neither~~north-south direction. Neither approach has been ~~specifically~~ evaluated against independent surface roughness derived from atmospheric profile measurements over penitentes. Consequently, although surface roughness calculations on the basis of profile geometry have been evaluated against aerodynamic roughness over rough ice surfaces, the available data is insufficient to distinguish if maximum aerodynamic roughness is associated with wind flowing across or along the penitente lineation. Thus it is not clear which ~~pattern is more~~method captures the appropriate relationship between wind direction and surface roughness for calculating turbulent fluxes over penitentes. It principle it sounds reasonable to expect airflow across the penitente lineation to maximize turbulence as the penitentes present a large surface area to the wind, yet, if skimming flow is established, with the result that only the tips of the penitentes are determining the structure of the turbulence then roughness in this direction would be strongly reduced, and perhaps even be less than for air flow along the penitente lineation, for which the smaller frontal area reduces the likelihood of skimming flow. Further investigation of this in order to quantify the impact of penitentes on turbulent fluxes for various airflow patterns requires measurement of turbulent fluxes using eddy covariance or atmospheric profile methods, which would demonstrate the nature of the directional roughness and establish the impact of penitentes on turbulent energy fluxes for different wind directions. Such measurements would be best implemented in a manner which can sample all wind directions equally, and eddy covariance systems for which analysis is limited to a sector

of airflow centred around the prevailing airflow source, might not be able to capture the nature of the directional dependence correctly.

Prevailing wind direction differs only slightly in each period with an increasing northwesterly component in the second two periods compared to the first. This may be related to the occurrence of snow during the first period, which is expected to alter thermally-driven valley wind systems. Over the whole study period wind direction is predominantly from the south-easterly and north-westerly sectors, and swings through both extreme wind angles used in the roughness calculations here (Figure 10). This indicates that the effective roughness at this site can be expected to differ significantly over time depending on the wind direction.

In this study we did not explicitly compute the blending height as available formulae are dependent upon z_0 and z_d. Estimates of the blending height independently from z_0 and z_d have been suggested to be 2.5 - 4.5 times h, as twice the mean element spacing, or as combination of the height and spacing (see examples within Grimmond and Oke, 1999). Given that only atmospheric measurements above the blending height give representations of integrated surface fluxes and conditions, the first approach would imply that aerodynamical or flux measurements over penitentes would have to be carried out at ~~some~~considerable height above the surface to capture mean surface properties rather than the effects of individual roughness elements. The mathematical model of Claudin and others (2015) ~~indicates that the~~ gives a characteristic length scale for the level at which the vapour flux ~~does not~~ is constant in horizontal space~~, and therefore is the product of mean surface properties,~~ that is related to the spacing of the penitentes. ~~Taking~~Interpreting this ~~to be representative of~~level as the blending height ~~would imply~~implies that ~~a formulation for~~ the blending height might be ~~possible~~determined on the basis of spacing of penitentes alone, and that this in turn might contain useful data for understanding the structure and efficiency of turbulence above penitentes. ~~However, exploring~~Exploring these ideas requires information from detailed meteorological measurements as well as the geometrical information offered in this paper.

5. Conclusion

Surface scanning technology and software is an area of rapid development, and a number of potentially superior alternative set-ups and data capture sensors and software is now available. This study demonstrates that the Microsoft Kinect sensor can work successfully at close range over rough snow and ice surfaces under low light conditions, and generate useful data for assessing the geometry of complex terrain and surface roughness properties.

The data collected offers the first detailed study of how the geometry of penitentes ~~evolves~~evolve through time, highlighting the rate of change of surface properties over an ablation season that can serve as a guideline for parameterizing surface properties required for energy and mass balance modelling of penitente surfaces.

The ~~measurements~~results confirm that even relatively crude manual measurements of penitente surface lowering are adequate for quantifying the seasonal mass loss, which is good news for the validity of measurements of surface change on glaciers with penitentes. However, further measurements and/or modelling studies are required to determine if the mass loss from the expanded and convoluted surface of penitentes is enhanced or inhibited compared to mass loss in the absence of penitentes.

Aerodynamical roughness properties and related metrics over very rough surfaces remain poorly quantified and both geometric and meteorological determinations of these values show a wide spread; consequently it remains unclear what the best methods to use are or what values modellers would be best to use (Grimmond and Oke, 1999). In this context ~~penitentes and~~ further study of ~~them~~penitentes offers a useful opportunity as (a) their morphometric evolution over time allows various geometries to be evaluated by ~~instrumenting and scanning~~monitoring a single site, and (b) they offer a bridge between wind tunnel and urban field experimentation of turbulence and roughness over extreme terrain. Although validity of surface roughness calculations based on surface geometry remains to be

established for penitentes, this study highlights that (i) skimming flow is expected to persist over penitentes field, but is more likely under wind directions perpendicular to the penitente alignment; (ii) z_d is certainly greater than zero, and while the depth of penetration of surface layer turbulence into a penitente field is not clearly established it is likely to evolve with the developing penitentes, and values of $z_d \sim 2/3h$ give results that are theoretically reasonable in the framework outlined by Grimmond and Oke (1999); (iii) the two methods of geometric computation of surface roughness applied here give conflicting results as to whether the effective surface roughness of penitentes is greater for airflow along or across the penitente lineation and (iv) more complete understanding of the impact of penitentes on the turbulent structure, its evolution in time, and its directional dependency, would require atmospheric measurements with no directional bias concurrent with measurements of penitentes morphology.

Potential future applications and analyses of the surfaces generated in this study include (i) using surface properties and roughness values as a guide for input into surface energy balance models; (ii) assessing the performance of models against the measured volume loss over time and (iii) evaluating how well simplified representations of penitente surfaces used in small scale radiation models and turbulence models capture the real-world complexity. Such studies would help establish the nature of the likely micro-climatic distribution of the surface energy balance within a real penitente field, and as a result the impact of penitentes on runoff and exchange of water vapour with the atmosphere.

Author contributions. L.N. designed the study. Fieldwork was carried out by L.N. and B.P. with M.P. providing the TLS. TLS and AWS equipment was provided by S.M. through collaboration with CEAZA. The data was analysed by L.N. and M.P. and L.N. ~~prepared~~led the preparation of the manuscript and figures.

Acknowledgements. Fieldwork for this study was funded by a National Geographic Waitt Grant. L.N. was supported by an Austrian Science Fund Elise Richter Grant (V309). M.~~-~~P. was supported within statutory activities No 3841/E-41/S/~~2015~~ 2016 of the Ministry of Science and Higher Education of Poland. International cooperation was supported by the Centre for Polar Studies from the funds of the Polish Leading National Research Centre (KNOW) in Earth Sciences (2014–18). Thanks are also due to Mathias Rotach for reading the paper prior to submission.

Table 3: Surface roughness (z0) computed according to Munro (1989) on detrended profiles longer than 1.5 m, extracted at 0.10 m intervals from the Kinect surface meshes at site A and B for E-W impinging wind and N-S impinging wind. The number of profiles used for each wind direction is given in parenthesis. The likely displacement of the zero velocity plane (d_top ± standard deviation), was computed as the mean of 2/3h for all profiles and expressed as a distance from the top of the penitentes. The range of the detrended 3D mesh (3D range) provides a reference for the penetration depth of turbulence.

Figure 1: Map of Tapado Glacier in the Elqui catchment of the Coquimbo Region of Chile, showing the location of the measured sites and insets of (a) the glacier site layout, showing the location of the horizontal reference (black line) and ~~;~~ (b) the test site, ~~highlighting~~ indicating the boulder ~~(*)~~ (red star) at which the Kinect scans were compared against TLS~~, and (c) an example photograph of glacier site B at the time of installation.~~.

Figure 2: (a) Oblique view of the TLS~~-~~derived DSM of the test site highlights the patchy coverage of the penitentes obtained by this method. (b) Absolute differences between DSMs of the sample boulder produced using TLS and Kinect.

Figure 3: Shaded DSM meshes of N-S orientated DSMs for the 1.5m x 1.5m ~~subsample at~~ glacier site B on (a) 12.12.2013 (b) 20.12.2013 and (c) 03.01.2013 obtained using the Kinect.

Figure 4: Summary of the DSM properties through time at site A (left) and B (right). (a,b) Surface height distribution as a percentage of total surface area, in local coordinates [m] relative to the position of the northern end of ablation frame~~ (a & b).~~ .Inset tables show weighted mean mesh elevation, range, surface area and surface area as a function of the horizontal area of the sampled site. (c,d) Distribution of surface angles as a percentage of total surface area~~ (c & d).~~ ,(e,f) Aspect distribution as a percentage of total surface area~~ (e & f).~~.

Figure 5: Comparison of surface height through time extracted from the Kinect scan and measured manually along the horizontal reference. Vertical error on the Kinect cross profiles is given by a linear interpolation of total positional error between the bounding stakes. Solid black triangles indicate locations where snowdepth exceeded the length of the 3 m probe.

Figure ~~5~~6: Representative surface heights computed on detrended surface meshes for site A (solid) and site B (open) over time where h1-h4 refer to representative surface heights computed as range (h1), twice the standard deviation (h2), area weighted mean height above the minimum (h3), and area weighted median above the minimum mesh height (h4).

Figure ~~6~~7: 3D z_0 computed for 10° aspect intervals for all detrended DSMs highlighting peak roughness occurs in N-S airflow. Maximum values take h to be the detrended mesh elevation range, and minimum values take h to be twice the standard deviation of the detrended mesh.

Figure ~~7~~8: Comparison of three-dimensional surface roughness through time, indicating the range of z_0 computed for all incident wind angles (at 10° intervals). Upper panels show the roughness with no zero level displacement and lower panels show values with a zero displacement offset d1 = h; d1 = 2/3h and d3 = 1/3h.As before, h1- h4 refer to representative surface heights computed as range, twice the standard deviation, area weighted mean height above the minimum, and area weighted median above the minimum mesh height respectively.

Figure ~~8~~9: Examples of (a) N-S, and (b) E-W orientated cross sections longer than 1.5 m, sampled at 0.1 m intervals ~~in local coordinates at site B~~ from which effective surface roughness properties were computed using the methods of Munro (1989, 1999).The local coordinates are relative to the NE corner marker of site A (Fig 1).

Figure ~~9~~10: Wind rose for the whole study period (26 Nov 2013 – 3 Jan 2014).

~~Figure 10: Comparison of surface height through time extracted from the Kinect scan and measured manually along the horizontal reference. Error ranges on the Kinect cross profiles are given by a linear interpolation of total positional error between the bounding stakes. Solid black triangles indicate locations where snowdepth exceeded the length of the 3 m probe.~~

B2: Detailed mesh-processing procedure used in this study.

- All processesing was carried out in Meshlab unsless otherwise stated
- Pairwise point alignment of the component surface meshes covering each study site
- Applied filter to remove mesh sections (vertices and faces) consisting of < XXX vertices
- Applied filter to remove unreferenced and duplicated vertices
- ICP alignment optimization of the mosaicked component surface meshes using the following parameters:
    - sample number of 1000 for each ICP iteration
    - minimal starting distance for chosen points of 10 mm at the first iteration reducing by 20% on each iteration
    - maximum of 50 iterations were performed
    - using rigid matching so that no stretching or warping of the mesh is permitted
    - export distributed alignment error
- Flattened mosaicked surface meshes into a single layer and remeshed using a Poisson filter with the following paramters:
    - Octreee depth (12)
    - Solver divide (7)
    - number of samples per node (1)
- Meshes were georeferenced with differential GPS measurements in Polywork
- Corner marker stakes, and parts of the mesh representing sensors installed within the sample site were manually removed from the georeferenced surface mesh and the mesh was cropped at the margins
- Triangle numbers were reduced by merging vertices closer than 2.5mm
- Resultant non-manifold features were removed
- Closed holes using a 20mm diameter filter. Inspected boundaries of resultant meshes to confirm that all remaining boundaries are on the edges of the sub-sampled area.
- Cropped horizontal areas to a consistent patch size: A 2 x 3.5m; B 1.5 x 1.5m
- Exported as .OBJ file from which the vertex coordinates and face indices and metadata were extracted for subsequent analysis in Matlab.

C: Comments and recommendations on the Kinect sampling strategy used in this study.

- Daylight swamps the signal of the Kinect. Over rock surfaces the Kinect worked perfectly as long as the surface was not in direct sunlight. Over snow and ice the effective range was reduced to about 1m and scanning could only be performed once the sun was below the horizon and was even better after darkness had fallen.
- This study used ReconstructMe as the capture software as it performs real time meashing so that the quality of the surface collected can be assessed at the time of capture. This is an advantage for:
  - observing if return signals had been obtained from the troughs of the penitentes as penetration into very narrow penitente troughs was only achieved over several passes and by re-orientating the sensor to be parallel with the trough.
- The disadvantages of ReconstructMe are that:
  - it does not save the raw depth data
  - it requires a computer with a powerful graphics processor as the real time processing is performed at the same 30Hz frequency as the depth-map frame production of the Kinect.
  - the powerful graphics processor tends to be power hungry
- Alternative systems for sampling Kinect data are numerous and growing, and the user must do some up to date research to discover the newest developments, but some existing options are to:
  - use the 'KinectFusion' algorithm (Izadi et al., 2011;Newcombe et al., 2011), implemented in the 'Kinfu' program (part of the Point Cloud Library (PCL); Rusu and Cousins, 2011), which allows one to move the Kinect and scan an area or object, automatically stitching together each frame into one large 3D model, while also capturing raw data.
  - for very large areas, the Kinfu implementation has been extended, named Kintinuous, and used to map paths more than 100m long (Whelan et al., 2012).
- When covering an area larger than $1m^2$ with a Kinect survey it would be advantageous to have a camera boom mounting for moving the Kinect smoothly over the glacier surface, as this would mean larger areas can be scanned in a single mesh. This would save significant work, and additional error involved in aligning and mosaicking the meshes.
- Ground control point markers which have fixed geometric surfaces with known alignment to x, y, z would have facilitated the alignment and mosaicking the component meshes of each scan. On the basis of this study a marker pole with cubes attached to it at fixed heights and known orientations would be ideal. As the surface lowers and more of the marker stake is revealed additional markers should be added at known distances below the previous marker cube.
- A higher number of ground control points to provide redundancy is advisable as in the case of poorly represented locations for georeferencing step, these could be excluded and the remaining points would still allow successful georeferencing.

3D surface properties of glacier penitentes over an ablation season, measured using a Microsoft Xbox Kinect.

Abstract. ~~Penitentes are a common feature of snow and ice surfaces in the semi-arid Andes where very low humidity, in conjunction with persistently cold temperatures and sustained high solar radiation favour their development during the ablation season. As penitentes occur in arid, low latitude basins where cryospheric water resources are relatively important to local water supply, and atmospheric water vapor is very low, there is potential value in understanding how penitentes might influence the runoff and atmospheric humidity.~~

~~The complex surface morphology of penitentes makes it difficult to measure the mass loss occurring within them because the (i) spatial distribution of surface lowering within a penitente field is very heterogeneous, and (ii) steep walls and sharp edges of the penitentes limit the line of sight view for surveying from fixed positions and (iii) penitentes themselves limit access for manual measurements.~~ In this study, ~~we solved these measurement problems by using a Microsoft Xbox Kinect sensor to generate~~the first small-scale digital surface models (DSMs) of ~~small sample areas of snow and ice~~natural penitentes on a glacier surface were produced using a Microsoft Xbox Kinect sensor on Tapado Glacier ~~in~~, Chile (30°08'S; 69°55'W~~) between November 2013 and January 2014.~~). The surfaces produced by the complete processing chain were within the error of standard terrestrial laser scanning techniques~~. However, in our study~~, but insufficient overlap between scanned sections that were mosaicked to cover the ~~studied sites~~ sampled areas can result in three-dimensional positional errors of up to 0.3 m.

~~Mean surface lowering of the scanned areas was comparable to that derived from point sampling of penitentes at a minimum density of 5 m^{-1} over a 5 m transverse profile. Over time the~~Between November 2013 and January 2014 penitentes become fewer, wider, deeper, and the distribution of surface slope angles becomes more skewed to steep faces. ~~These~~Although these morphological changes cannot be captured by ~~the interval sampling by~~ manual point measurements~~. ~~, mean surface lowering of the scanned areas was comparable to that derived from manual measurements of penitente surface height at a minimum density of 5 m^{-1} over a 5 m transverse profile. Roughness was computed on the 3D surfaces by applying two previously published geometrical formulae; one for a 3D surface and one for single profiles sampled from the surface. Morphometric analysis shows that skimming flow is persistent over penitentes, providing conditions conducive for the development of a distinct microclimate within the penitente troughs. For each method a range of ways of defining the representative roughness element height ~~required by these formulae~~ was used, and the calculations were done both with and without ~~using~~application of a zero displacement height offset to account for the likelihood of skimming air flow over the closely~~-~~-spaced penitentes. The computed roughness values are in the order of 0.01-0.10 m during the early part of the ablation season, increasing to 0.10-0.50 m after the end of December, in line with the roughest values previously published for glacier ice. Both the 3D surface and profile methods of computing roughness are strongly dependent on wind direction. However, the two methods contradict each other in that the maximum roughness computed for the 3D surface coincides with airflow across the penitente lineation while maximum roughness computed for sampled profiles coincides with airflow along the penitente lineation. These findings highlight the importance of determining directional roughness and wind

direction for strongly aligned surface features and also suggest more work is required to determine appropriate geometrical roughness formulae for linearized features.

1. Introduction

Penitentes are spikes of snow or ice, ranging from a few centimetres up to several metres in height that can form during the ablation season on snowfields and glaciers~~ under the right conditions. The conditions required for penitentes to form~~. They are ~~dew point below 0°C, persistently low air temperatures and sustained strong solar insolation (Lliboutry, 1954). These conditions are frequently met at~~a common feature of high elevation, low-latitude glaciers and snowfields~~, such as in the subtropical Andes~~ (e.g. Hastenrath and Koci, 1981; Corripio and Purves, 2005; Winkler et al., 2009~~),~~) where ~~penitentes are widespread during the ablation~~very low humidity, persistently cold temperatures and sustained high solar radiation favour their development (Lliboutry, 1954). As cryospheric water resources are relatively important to local dry season~~.~~ water supply in arid mountain ranges (Kaser et al., 2010), there is potential value in understanding how penitentes might influence both runoff and atmospheric humidity.

~~Observations show that penitente~~Penitentes form linearized, inclined fins of snow or ice on the surface. Both the latitudinal range (within 55° of the equator on horizontal surfaces) and geometry ~~is~~ (aligned with the arc of the sun across the sky, and tilted toward the sun at local noon~~, highlighting the importance~~) of penitentes are governed by solar~~ radiation in penitente formation~~-to-surface geometry (Lliboutry, 1954; Hastenrath and Koci, 1981; Bergeron et al., 2006~~). Indeed, the alignment and restricted latitudinal range of penitentes (within 55° of the equator on horizontal surfaces) can be explained by solar-to-surface geometry alone (~~; Cathles et al., 2014). ~~The process~~During the initial stages of penitente ~~growth involves geometric focusing of incident solar radiation~~ development, ablation is thought to proceed by ~~surface~~sublimation alone driven by the low atmospheric humidity. Surface irregularities ~~that causes~~focus reflected solar radiation within depressions ~~to receive more radiation than surrounding peaks~~ (Amstutz, 1958; Corripio and Purves, 2005; Lhermitte et al., 2014; Claudin et al., 2015~~). Consequently,~~) such that the energy receipts, and consequently ablation, are ~~initially~~ enhanced in the hollow ~~due to multiple reflection of irradiance,~~ and the surface irregularity becomes amplified. ~~However for substantial penitente growth it is crucial that, at the tips of penitentes, ablation occurs by sublimation and the snow/ice temperature remains below the melting point, while in the troughs between penitentes, melting can occur once~~Subsequently, as the surface relief increases, a more humid microclimate is ~~established within the hollow~~thought to develop in the hollows between penitentes, supressing sublimation and allowing melting in the depressions. Meanwhile, the penitentes tips continue to ablate by sublimation alone (Lliboutry, 1954; Drewry, 1970; Claudin et al., 2015~~). Once the snow/ice in the hollows has reached the melting point, the spatial differentiation of ablation processes serves to further amplify the penitente relief as melting only~~) and, as melting requires approximately an eighth of the energy of sublimation to remove the same amount of ice, the spatial differentiation of ablation process between penitente trough and tip is very effective at amplifying the penitente surface relief.

The altered partitioning of ablation between sublimation and melting that occurs in penitente fields, as compared to surfaces without penitentes (e.g. Lliboutry, 1998; Winkler et al., 2009; Sinclair and MacDonell, 2015~~The impact of penitentes on the surface energy balance and ablation of snow and ice is of interest in arid mountains catchments, where penitentes are widespread and meltwater can be a substantial contribution to local hydrological resources (Kaser et al., 2010). Previous studies have shown that penitentes alter the surface energy balance of snow and ice surfaces by reducing~~), is expected to alter the rate of mass loss and meltwater production of snow and icefields during the ablation season, but this has not yet been fully quantified. Previous studies, based on modelling idealized penitente surfaces, have investigated the impact of penitentes on the shortwave radiative balance, and suggest that penitentes reduce effective albedo by up to 40% compared to flat surfaces (Warren et al, 1998; Corripio and Purves, 2005; MacDonell et al., 2013; Cathles et al., 2014; Lhermitte et al., 2014~~) as well~~). In addition to altering the ~~partitioning of ablation between sublimation and melting (e.g. Lliboutry, 1998; Winkler et al., 2009; Sinclair and~~

~~MacDonell, 2015~~~~). Thus, the presence of penitentes is expected to alter the rate of mass loss and meltwater production of snow and icefields during the ablation season, and, on the basis of the~~ radiative ~~balance it has been postulated that they will accelerate the snow and ice mass loss rates (Cathles et al., 2014). However~~properties of the surface, the development of penitentes ~~on the surface will~~ also ~~alter the roughness properties in both space and time, but this, as well as its impact on the resultant turbulent fluxes is not quantified. The wind direction-dependence of~~ manifestly alters the surface roughness properties, but neither the impact of penitentes on surface roughness, nor the associated impact on turbulent energy fluxes has been investigated. The roughness of snow and ice surfaces is particularly prone to varying in space and time (e.g. Smeets et al., ~~over linearized surface features has been previously observed in wind~~1999; Brock et al., 2006; Fassnacht et al., 2009b). Wind profile measurements over ~~snow~~linearized sastrugi~~, for which~~ surface features shows that the derived aerodynamic roughness length varied from 1~~-~~–70 mm over a 120° range of impinging wind direction (Jackson and ~~Carol~~Carroll, 1978). While penitentes are a relatively rare form of linearized surface feature~~ in many glacierized environments, in contrast,~~ linear crevasses are widespread, and~~ although the impact of wind direction on roughness and the resultant turbulent heat fluxes is generally not treated in glaciology,~~ penitentes offer a unique test bed for investigating the significance of linearized features on effective surface roughness for various wind directions.

~~In general, the physical roughness of snow and ice surfaces are particularly prone to varying in space and time (e.g. Smeets et al., 1999; Brock et al., 2006; Fassnacht et al., 2009), it is desirable to be able to replace relatively logistically and technologically challenging methods of determining roughness parameters from atmospheric profile or eddy covariance measurements, with methods based on more readily measurable surface terrain properties (e.g. Kondo and Yamazawa, 1986; Munro, 1989; Andreas, 2011), or properties such as radar backscatter that can be derived from spaceborne instruments (e.g. Blumberg and Greeley, 1993). The most comprehensive surface of methods to determine apparent aerodynamic properties from surface morphometry was carried out by Grimmond and Oke (1999) who tested several methods in urban environments, which are among the roughest surface conditions encountered in boundary layer atmospheric studies. The morphometric estimates of roughness properties were compared with those from aerodynamic methods from numerous field and laboratory studies. Many of the aerodynamic studies were found to be flawed, and the study demonstrates that, despite the considerable effort in obtaining such measurements, their reliability in complex and rough terrain is contested as the computations rely upon theory that is developed for flat homogenous terrain, and in general the aerodynamic results show a similar amount of spread as the various geometrical methods tested. Although, Grimmond and Oke (1999) consider that direct measurements of fluxes over complex terrain are most likely the 'best' way of determining surface properties, the difficulties of deploying the expensive and relatively delicate instruments over glacier surfaces makes a geometric determination even more appealing. However, in the case of penitentes, such studies are impeded by a scarcity of information on real penitente geometry.~~

Measurements of natural penitentes ~~(e.g.~~ required to examine their morphometry and roughness are rare (e.g. Naruse and Leiva, 1997~~) are rare as they are generally found in relatively inaccessible areas and the complex surface relief poses a considerable impediment to movement and measurement, for example preventing~~), and difficult to obtain because the complex, and partially overhanging, surface prevents the use of simplified automated tools such as photogrammetric determination of surface profile heights (e.g. Fassnacht et al., ~~2010~~2009a; Manninen et al., 2012~~). Furthermore, accurately measuring the convoluted penitente surface is in itself a significant challenge, as it includes overhanging surfaces, which is problem for immobile~~) or line-of-sight surveying ~~equipment. However,~~from fixed positions. Recent advances in close-range mobile depth-of-field sensors and efficient feature tacking software used in interactive computer gaming offer potentially useful tools that can be applied to ~~generate small-scale digital surface models to~~ resolve such problems in earth science (e.g. Mankoff ~~et al.,~~and Russo, 2013). In this study ~~sample plots of penitentes in snow on a glacier surface are scanned using~~ a Microsoft Xbox Kinect sensor is used as a close-range mobile distance ranger to produce a series of small-scale digital surface models (DSMs). ~~These surface models are used to perform (i)~~ The method of DSM generation is evaluated against standard terrestrial laser scanning, and the Kinect-derived DSMs of the penitentes are used to (i) perform the first detailed examination of the

~~geometry~~morphometry of natural penitentes ~~and how they change~~ over the course of ~~the core~~an ablation season; (ii) ~~an examination of the geometrical roughness properties of penitentes and (iii)~~ compare the volume ~~changes~~change computed from DSM differencing ~~the DSMs~~ with ~~the volume changes estimated from~~estimates based on manual measurements of surface lowering ~~within a penitente field. These measurements enable evaluation of how accurately simplified~~and (iii) examine the geometrical roughness properties of the sampled penitente surfaces ~~used in theoretical modelling represent the true surfaces found in nature, improved parameterization of surface roughness in energy balance models applied to glacier and snowfields with penitentes, and the performance of energy balance models over penitente surfaces to be evaluated against mas loss derived from the measured surface changes~~.

2. Methods

2.1 Description of fieldsite

Tapado Glacier (30°08'S; 69°55'W) lies in the upper Elqui Valley of the semi-arid Andes of the Coquimbo Region of Chile (Figure 1). ~~This~~The glacier is relatively ~~easily~~ accessible and ~~previous research indicates that the glacier surface develops~~is known to develop penitentes every summer (Sinclair and MacDonell, 2015). Two separate study areas were analysed. Firstly, a test site was established at a patch of snow penitentes within a dry stream bed at 4243 m a.s.l. in the glacier foreland (Figure ~~1b~~1). This site was used to (i) ~~trial~~test instrumental setups in order to optimize the field operation of the Kinect sensor, and (ii) compare the performance of the Kinect sensor against a Terrestrial Laser ~~Scanning~~Scanner (TLS~~) system.~~). This location was chosen due to the logistical difficulties of transporting the TLS to the glacier. Subsequently, two study plots were established at an elevation of 4774 m a.s.l. ~~within~~on the glacier ablation zone~~.~~ (Figure 1). These ~~surfaces at these~~ sites were ~~measured~~scanned repeatedly ~~using~~with the Xbox Kinect (see section 2.3) during the core ablation season between the end of November 2013 and the beginning of January 2014. ~~An automatic weather station on a free-standing tripod was installed beside the two plots to provide meteorological context for the measurements.~~

The location and layout of the two glacier sites is shown in Figure ~~1~~1a. Site A (5 m by 2 m) was measured four times, on 25 November, 11 December, 20 December and 3 January. Site B (2 m by 2 m~~, Figure 1c~~) was only measured on the last three dates ~~(Figure 1c).~~. The corners of the study sites were marked with 2 m lengths of plastic plumbing piping hammered vertically into the snow, or drilled into the ice~~.~~ (Figure 1c). In order to locate the study sites in space and to provide a common reference ~~frame~~ for each survey date, marker stake positions were measured using a Trimble 5700 differential GPS with Zephyr antenna on the 25th November, with a base station in the glacier foreland. On each visit to the glacier, when possible, the stakes were hammered further into the snow and the resultant lowering of the stake top was noted. The maximum standard deviations of the GPS stake positions were < 1.0 cm, 1.1 cm and 1.7 cm in easting, northing and elevation respectively, with combined XYZ standard deviation < 2.0 cm for all stakes (Supplement A). Error on the manual measurements of height offsets of the marker stakes on subsequent survey dates is conservatively estimated to be 2.0 cm. This results in total positional errors of the ground control points at each scan date of between 2.3 and 2.7 cm depending on the stake. Manual measurements of surface lowering were made along the eastern long side of site A. All surfaces heights were referenced to the elevation of the glacier surface at the upglacier end of this cross profile at the date of installation. An automatic weather station (AWS) on a free-standing tripod was installed beside the two glacier plots to provide meteorological context for the measurements (Figure 1).

2.2 Terrestrial laser scanning

~~Surface scans of snow penitentes at~~At the test site ~~were undertaken with both a terrestrial laser scanner (TLS) and the Kinect sensor in order to compare the~~ surface scans produced by the ~~well-established TLS method and the~~ relatively new Kinect sensor ~~application~~were compared with those produced by the well-established TLS method. The TLS system used was an Optech ILRIS-LR scanner, which is a long-range terrestrial laser scanner especially

suitable for surveying snow and ice surfaces ~~thanks to~~as it has a shorter wavelength laser beam (1064 nm) than other models. This equipment surveys surface topography based on time-of-flight measurement of a pulsed laser beam reflected to a given angle by a system of two rotating mirrors. It has a raw range accuracy of 4 mm at 100 m distance, raw angular accuracy of 80 µrad, beam diameter of 27 mm at 100 m distance and beam divergence of 250 µrad. The instrument was placed in five locations around the surveyed snow patch and boulder, overlooking it from different directions. Positions of the TLS were measured with ~~the~~ Trimble 5700 differential GPS with Zephyr ~~antenna~~antennae in static mode. Seventeen point clouds were obtained with nominal resolution of 0.11-0.75 cm. Resulting point clouds were corrected for atmospheric conditions (pressure, temperature and humidity) and trimmed with ILRIS Parser software, aligned with Polyworks IMAlign software into a common local coordinate system and georeferenced with differential GPS measurements using Polyworks IMInspect software. The alignment error of the point clouds as estimated by this software is 0.36-0.87 cm and comparison with ground control points gives an error of 5.65 cm. The TLS scan of the snow penitentes is presented as an example of the nature of the DSM that can be obtained within a penitente field using TLS (Figure 2). Unfortunately, the scans of snow penitentes could not be carried out with both the TLS and Kinect on the same day, so direct comparison of the TLS and Kinect scans is instead performed on a reference boulder ~~lying on the ground beside~~within the test site, whose surface is assumed unchanged between different scan dates. ~~The TLS scan of the snow penitentes is presented as an example of the nature of the DSM that can be obtained within a penitente field using a TLS (Figure 2).~~

2.3 Kinect ~~scans of~~ surface ~~change~~scanning

The Kinect sensor emits a repeated pattern of structured infra-red (IR) beams, and records the pattern distortion with an ~~onboard~~ IR camera. The depth~~-~~-of~~-~~-field calculation is performed via a proprietary algorithm and a distance map is the raw data output. Using the standard calibration the static raw depth field resolution of the Kinect is 1 mm and the ~~Kinect measured~~ distance ~~at the center of the field of view is within 1% of the real distance (Mankoff et al., 2013), implying an~~ error ~~of~~is < 1.0 cm at the distance range of the penitente scans~~.~~ (Mankoff and Russo, 2013).

For its original gaming usage, the Kinect is in a fixed position and proprietary software uses feature tracking to track the movements of players moving within the field of view of the Kinect. However, the inverse of this workflow can also be applied ~~wherein~~whereby the Kinect sensor is moved interactively around a static surface or 3D body, using the same feature tracking to compute the position of the sensor relative to the object and thereby allowing a point cloud reconstruction of the object ~~to be constructed.~~. In this work we apply the second work flow ~~sampling~~and sample Kinect data using the ReconstructMe™ 2.0 software package. In common with alternative reconstruction packages that are compatible with the Kinect, ReconstructMe™ performs bilateral filtering on the output depth map frame and converts the pixel version of each depth map frame to 3D coordinate maps of vertices and normals. An iterative closest point (ICP) alignment algorithm is then applied frame by frame at three scales to repeatedly rotate and translate the depth field to determine camera position and an aligned surface, giving weighted preference to portions of the surface that are perpendicular to the line of sight. ~~This~~The ReconstructMe™ software has the advantage of producing surface meshes in real-time, so that the operator can ~~visibly~~ check the scan quality and coverage at the time of capture, but the disadvantage that the raw point cloud is not saved and if the real-time tracking is lost a new scan ~~sample~~ must be started.

The Xbox Kinect was connected via a 5m powered USB extension cord to an MSI GE60 gaming laptop, powered using a 240V 600W inverter connected to the ~~12V~~ 160Ah 12V battery of the automatic weather station on the glacier. Scans were carried out by two people; one moving the Kinect across the penitente field and the other monitoring the quality of the surface being generated~~. The~~ on screen. In bright conditions, the return IR signal of the Kinect is swamped by natural radiation ~~in bright conditions, and this is especially true over bright, rough~~over snow and ice surfaces, which reflect ~~the~~a high proportion of incident shortwave radiation, and absorb or scatter much of the longwave radiation signal. ~~To solve this~~Therefore, scanning was carried out at twilight or just after nightfall. Sudden movements caused by the operator slipping or the snow compacting underfoot ~~can result~~resulted in the

ReconstructMe software losing its tracking of common reference points~~ used to generate the continuous surface mesh.~~. Consequently, each study site was scanned in small sections and three to thirteen ~~separate~~overlapping surface meshes were used to cover the area of each study site.

2.4 ~~Mesh processing~~

~~Freely available Meshlab software was used to initially align the~~ **Kinect surface** ~~meshes covering each study site using a pairwise alignment procedure.~~ **mesh processing**

The full mesh processing procedure using the freely available Meshlab software is presented in Supplement B, and briefly described here. Small surface components, unreferenced and duplicated vertices were removed from the meshes using inbuilt filters. ~~The Meshlab alignment~~The component meshes that cover each sampling date at a single site were aligned using an iterative closest point (ICP) algorithm ~~was applied to objectively optimize the alignment and compute~~which distributes the alignment error~~. This alignment procedure uses an ICP algorithm to iteratively align the component meshes and distribute the alignment errors~~ evenly across the resultant mosaicked surface mesh. Alignment solutions consistently had mean distributed error < 4 mm (Supplement B). The aligned meshes were flattened into a single layer, remeshed using a Poisson filter and ~~finally~~ resampled to reduce the point density by setting a minimum vertex spacing of 2.5mm.

The surface mesh for each scan date was georeferenced in Polyworks software using the known coordinates of the base of the marker stakes at the time of each scan because the upper portions of the symmetrical stakes are often poorly captured by the meshing software. The local elevation zero was set to be the north-east corner of site A. The mismatch evident in the georeferencing step (Table 1) is much larger than the mesh alignment error (Supplement B). ~~stakes are often poorly represented in the scans due to the fact that ReconstructMe™ does not handle symmetrical objects well. It proved difficult in some cases to locate the surfaces in space such that the locations of all marker stakes were consistent with the ground control points.~~ This is most likely an artifact of a combination of (i) reduced mesh quality at the margins of the component scans and (ii) insufficient overlap between some scan sections producing distortion within the mesh alignment. ~~The mismatch evident in the georeferencing step (Table 1) is much larger than the mesh alignment error (Supplement B).~~

To eliminate the marker stakes and any data gaps near the margins of the study areas, each surface mesh was sub-sampled within the staked area. The sub-sampled area for site A is a 2.0 by 3.5 m horizontal area (7.00 m^2), and site B is a 1.5 x 1.5 m horizontal area (2.25 m^2) shown in the examples in Figure 3. Mesh vertices and an index file of the vertices comprising each face were exported from Meshlab for subsequent analysis in Matlab software.

2.5 Calculations of surface geometrical properties

The geo2d and geo3d toolboxes (available from the Matlab File Exchange) were used ~~in Matlab™~~ to compute the ~~triangle~~face areas and normals of the mesh, from which ~~the~~ surface height distribution, aspect and dip of the sampled surface ~~can be determined~~were calculated, weighted by the ~~triangle~~ratio of each face area ~~as a function of~~to the total surface area of all faces. ~~Volume change between~~As the surfaces ~~was~~contain overhanging parts, DSM differencing cannot be performed by simple subtraction. Instead volumes for all surfaces were computed ~~by projecting each triangle area onto~~ relative to a baselevel horizontal reference~~ surface.~~. Volumes relative to this horizontal reference for upward-facing triangles were computed column-wise~~ from these projected areas~~, by projecting the area of each triangular face onto the reference surface and using the height coordinate of the triangle centroid as the height dimension for each column. These were summed and volumes for overhanging triangles, calculated in the same way~~ as the up-ward facing volumes,~~ were subtracted to derive ~~a~~the total volume between the reference surface and ~~the~~each scanned penitente surface. Successive volumes were subtracted to obtain the volume change over each measurement interval.

~~2.6~~2.6 Manual measurements of surface change

Traditional single-point stake measurements of glacier surface lowering are unreliable within the inhomogeneous surface of a penitente field. One alternative is to measure surface lowering at intervals along a profile perpendicular to the main axis of alignment of the penitentes. Such a reference was installed along the 5 m-long eastern margin of site A, between two longer corner stakes drilled 3 m into the ice using a Kovacs hand drill. The distance between a levelled string and the glacier surface was measured using a standard tape measure at 0.2 m intervals on 23 November. Subsequent measurements, on the 12 and 21 December and on 4 January, were made at 0.1 m intervals. All measurements were recorded to the nearest centimetre, and the error on each measurement is estimated to be 2.0 cm, which is assumed to capture the error associated with the horizontal position of the measurements along the reference frame and the vertical measurements of the distance to the surface beneath.

2.7 Calculations of geometric surface roughness

The aerodynamic roughness length (z_0) is the distance above the surface at which an extrapolation of a logarithmic windspeed profile under neutral conditions ~~would be extrapolated down through~~towards the surface ~~layer and~~would reach zero. Over taller roughness elements the level~~ of action~~ of momentum transfer between the airflow and the surface roughness elements is displaced upwards by a distance, termed the zero-plane displacement (z_d). Above particularly rough surfaces, a roughness sub-layer is formed in the lowest part of the surface layer within which surface roughness elements create a complex 3D flow that is almost chaotic. Where roughness elements are widely spaced, the separated flow over obstacles reattaches to the surface before the subsequent obstacle is reached. More closely packed roughness elements experience a wake interference regime, and in the most densely packed arrays of roughness elements skimming flow occurs (Grimmond and Oke, 1999). At the top of the roughness sublayer individual wakes caused by surface obstacles are smeared out and the flow is independent of horizontal position, and thus, observations at this level represent the integrated surface rather than individual surface obstacles. This level is known as the blending height (z_r). All these properties are dependent on the size and arrangement of surface roughness elements.

As it is logistically challenging to deploy instrumentation to determine roughness parameters from atmospheric profile or eddy covariance measurements on glacier surfaces, efforts have been made to instead use methods based on properties such as radar backscatter (e.g. Blumberg and Greeley, 1993) or more readily measurable surface terrain properties (e.g. Kondo and Yamazawa, 1986; Munro, 1989; Fassnacht et al., 2009a; Andreas, 2011). Grimmond and Oke (1999) tested several methods of determining apparent aerodynamic properties from surface morphometry in urban environments, which are among the roughest surface conditions encountered in the atmospheric boundary layer, and found that morphometric determinations of surface roughness do not clearly underperform in comparison with aerodynamic methods, suggesting that morphometric measurements of roughness are worth pursuing.

There are a number of formulations for deriving z_0 from geometrical measurements. For example, the simplest approach is to take the standard deviation of the surface elevations as a measure of roughness (Thomsen et al., 2015). In this work, the surface meshes were analysed for roughness on the basis of a widely-used relationship established by Lettau (1969), initially developed for isolated, regular obstacles distributed over a plane:

$$z_0 = 0.5\, h \left(\frac{s}{S}\right) \tag{1}$$

where h is the height of the obstacles, s is the upwind silhouette area of each obstacle and S is the specific area occupied by each roughness element obstacle, also referred to as its lot area. The roughness values computed using Equation 1 over 3D snow surfaces has been shown to vary widely depending on the methods of surface interpolation used (Fassnacht et al., 2014), due to the influence on interpolation method on the unit surface area occupied by each roughness element. However in this work the high resolution meshes used can be expected to adequately capture the

surface properties as no extrapolation or interpolation procedure is needed. Isolated roughness elements of regular geometry distributed over a horizontal plane are a poor analogy for the irregular surface topography of a penitente field, and the applicability of this formulation over penitentes has not been established. Nevertheless, we apply the analysis as an illustration of the nature of the results generated from such an approach over penitentes and hope that future aerodynamic roughness lengths obtained from micrometeorological measurements can be compared to these ~~geometrically~~ morphometrically-derived ones. Macdonald and others (1998) state that for irregular obstacles *h* can be replaced by average obstacle height, *s* with the sum of all the upwind silhouette areas, and *S* with the total area covered by the obstacles. While the upwind silhouette area, and indeed surface area in any direction, is relatively easily defined for each surface mesh area using trigonometry, it is difficult to define individual roughness elements and their representative heights, due to the lack of an apparent base level. Here we first detrend the surfaces to remove any general surface slope at the site, then compute the roughness for the detrended 3D meshes assuming that the roughness elements cover the whole surface area (i.e S = plot area), and for four possible representations of average obstacle height (h) as follows: (i) the maximum range of the detrended mesh; (ii) twice the standard deviation of the detrended surface mesh; (iii) mean mesh height above the mesh minimum; and (iv) median mesh height above the minimum.

These data are computed for illustrative purposes only as it is reported that Equation 1 fails when the roughness element density exceeds 20-30~~%,~~% (Macdonald et al., 1998), as is expected for penitente fields~~ (Macdonald et al., 1998).~~. High density roughness elements means that they interfere with the airflow around each other, and upwards displacement of the zero wind velocity level ~~is displaced upwards, and~~means that effective roughness is a result of the roughness elements above this zero velocity displacement plane~~. The~~, and the zero displacement height~~ in this sense~~, gives an indication of the penetration depth of effective turbulent mixing into the penitente field. Accordingly, we additionally present sample calculations of three-dimensional roughness on the detrended surface meshes using three possible realizations of z_d, as, like h, z_d is also unknown in the case of the penitente fields being sampled. In the first case, z_d is taken to be h, in the second 2/3 h, which is a widely used standard in forests and other complex terrain applications (~~Brutseart~~Brutsaert, 1975), and in the third 1/3 h~~ for comparison, both~~. Each z_d case is computed for the four realizations of h used as before. Equation 1, (for irregular obstacles) is then applied to the roughness elements remaining above the plane of the general surface slope offset by a distance z_d above the minimum height of the surface mesh. The representative height h for this portion of the mesh exceeding the plane is taken to be the mean area-weighted height of all triangles above this plane, s is the summed frontal area of all mesh triangles above z_d that face into the chosen wind direction and S is the total horizontal area of the surface components above z_d.

Munro (1989, 1990) modified the formula of Lettau (1969) to be applied to a single irregular surface cross-section of length X, sampled perpendicular to the wind direction. This modified formulation is easier to work with on a glacier where the roughness elements are irregular, closely spaced, and generally poor approximations of objects distributed over a plane. Instead of having to define an obstacle height above the plane, h is replaced with an effective height h^* expressed as twice the standard deviation from the standardized mean profile height; s is replaced with $h^*X/2f$, in which f is the number of profile sections that are above the mean elevation; and S is replaced with $(X/f)^2$. This approach approximates the surface elevation profile as rectangular elements of equal size, and has been shown to give results within 12% of the silhouette area determined by integrating between true topographic minima (Munro, 1989). Importantly, roughness values derived this way over snow, slush and ice surfaces show reasonable agreement with roughness values derived from wind profiles (Brock et al., 2006). To investigate the nature of the roughness computed this way for north-south and east-west impinging wind directions, cross profiles longer than 1.5 m at 0.~~1m~~1 m intervals orientated E-W and N-S were extracted from each scanned surface. Cross-sections were detrended to remove the influence of any general surface slope at the site, and roughness was computed on each of these cross-sectional profiles following the modifications of Munro~~ for each detrended surface profile~~. Mean profile roughness for these two wind directions are presented for each sampled surface.

~~**2.7 Manual measurements of surface change**~~

~~Traditional stake measurements of glacier surface lowering made at a single point are unreliable within the inhomogeneous surface of a penitente field, as multiple measurements are required to characterize the complex surface. One alternative is to measure surface lowering at intervals along a profile perpendicular to the main axis of alignment of the penitentes. Such a reference was installed along the 5 m-long eastern margin of site A, between two longer corner stakes drilled 3 m into the ice using a Kovacs hand drill. The distance between a levelled string and the glacier surface was measured using a standard tape measure at 0.2 m intervals on 23 November. Subsequent measurements, on the 12 and 21 December and on 4 January, were made at 0.1 m intervals. All measurements were recorded to the nearest centimetre, and the error on each measurement is conservatively estimated to be 2.0 cm, which is assumed to capture the error associated with the horizontal position of the measurements along the reference frame and the vertical measurements of the distance to the surface beneath.~~

3. Results

3.1 Evaluation of the quality and suitability of penitente scans by TLS and Kinect

~~At the~~The test site~~, the~~ was well-developed snow penitentes ~~were well-developed and between~~ 0.5 ~~and~~- 1.0 m in height in a channel (Figure 1b). TLS scans ~~were made~~ of these penitentes ~~to illustrate the capabilities of this more conventional scanning system in capturing the penitente surfaces. TLS scans~~ were taken from five different vantage points ~~positioned~~ above the penitentes. The penitente surface produced by the TLS had surface slope ranging between -30 and 90 degrees, indicating that overhanging surfaces within the penitente field ~~are~~can be captured~~, however~~. However the limitations of this conventional fixed-point scanning system in capturing the penitente surfaces is illustrated by the fact that only 58% of the total surveyed horizontal area could be scanned, as the deepest parts of the troughs were obscured from the view ~~of TLS~~ by the surrounding penitentes (Figure 2a). By comparison, the hand-held, mobile nature of the Kinect means that ~~100% of~~ the whole surface of the penitente field can be captured as the field of view can be adjusted into almost limitless close-range positions~~. The long range of the TLS makes it easier to cover large areas in comparison to~~, although the close range Kinect sensor~~, but as only penitente tips are scanned the utility of this larger areal coverage~~ is ~~limited~~impractical to apply over large areas.

~~The Kinect scan~~For the direct comparison of the two methods on a reference boulder, the Kinect-derived surface, produced from three mosaicked meshes was aligned to ~~that~~the surface produced from the TLS point clouds. The TLS scan was incomplete, with parts of the top and overhanging surfaces of the boulder missing due to being obscured from the TLS survey positions, while the Kinect scan achieved complete coverage of the boulder. The difference between the two aligned meshes where overlapping data existed was always < 2 cm (Figure 2b), which is well within the error of the georeferenced TLS surface model. Larger differences in Figure 2b, up to 5 cm, occur only where there are holes in ~~one of~~ the surfaces being compared.

It is difficult to formally assess the total error of the surfaces produced by the Kinect scans because the ~~proprietary software, ReconstructMe™ and Poisson surface reconstruction in Meshlab, are all~~workflow involves several black box processing steps ~~in the workflow~~. The mean alignment errors of the mesh mosaicking step in Meshlab is < 0.4 cm and quantifiable errors associated with the GPS positions, subsequent measurement of the stake bottom positions relative to the GPS positions are all < 2.0 cm. However, ~~in this study~~ the three-dimensional georeferencing error in this study is large (Table 1) compared to the other sources and ~~can be~~is therefore taken as a reasonable value for the error of the total process chain. Errors given on the seasonal mass, volume and surface changes are based on summing the squares of the mean elevation difference between the marker stakes and ground control points (GPCs) at each site on the first and last survey dates.

3.2 Meteorological conditions

During the study period one significant snowfall event occurred on the 8th December 2013, when the sonic ranger recorded ~~an increase of~~ a surface height increase of 0.09 m over the course of the day~~, and temperature and incoming longwave radiation increase progressively~~ (Table 2). ~~The surface conditions of~~Surface albedo and ~~surface~~ temperature are derived from radiation measurements that ~~integrate the signal from a~~ sample an area beneath the instrument. Surface temperature was calculated from measured surface longwave emissions, assuming ~~a surface longwave~~ emissivity of 1. Over the study period, air temperature and atmospheric longwave receipts increase, while albedo decreases and derived surface temperature increases (Table 2). Thus, over the course of the study, ~~the~~ atmospheric energy supply increases and ~~the~~ surface properties become ~~gradually~~ more conducive to melting. ~~In the three measurement periods 22, 38 and 43% of hourly values of surface temperature exceed the melting point and the~~The warming atmosphere is clearly expressed in the positive degree days of the three periods which are 3.7, 2.2 and 31.5 over the 16, 9 and 14 day-long periods respectively. ~~The height change difference~~Hourly surface temperatures exceed the melting point in 22, 38 and 43% of cases in each period respectively. Daily surface lowering rates calculated between the hourly mean sensor-to-surface distance recorded by the AWS sonic ranger at midnight at the end of the survey days indicates lowering rates of 17, 37 and 56 mm d~~ay~~$^{-1}$ over the ~~same~~three measurement intervals, ~~indicating~~confirming that the increasing energy receipts translate into increasing rates of surface lowering at the AWS.

3.3 Areal scans of penitente surfaces

Surface lowering rates derived from the ~~computed~~calculated volume changes per unit area are 21, 41 and 70 mm d~~ay~~$^{-1}$ over each interval at site A, and 57 and 61 mm d~~ay~~$^{-1}$ over the last two intervals at site B. Surface lowering calculated as the difference between successive hypsometric mean mesh elevation for each site were within a few millimetres of the volume computations: 22, 38 and 69 mm d~~ay~~$^{-1}$ for the three measured intervals at site A, and 54 and 60 mm d~~ay~~$^{-1}$ for the last two intervals at site B. The total surface lowering over the whole available period computed by volume change (hypsometric mean height change) was 1.68 (1.77) ± 0.11 m at site A and 1.37 (1.32) ± 0.38 m at site B. Surface height changes recorded at site A over the same period as at site B were 1.35 (1.31) ± 0.21 m, indicating that the values were repeatable ~~across~~at both sites. The volume loss was converted to mass loss ~~on the basis of~~using the mean snow density of 426 kg m^{-3} (with an assumed error of ± 5%) measured in a 1.10 m snow pit excavated on 22 November 2013 beside the ~~weather station.~~AWS. Mass loss at site A computed from mesh volume ~~changes~~change (hypsometric height ~~changes~~change) between 25 November and 3 January was 716 ± 58 (754 ± 59) kg m^{-2}~~, indicating an underestimation of mass loss but that the two computation methods are within error of each other~~. Mass loss at site B from mesh volume changes (hypsometric height changes) between 11 December and 3 January was 582 (562) ± 166 kg m^{-2}. Measurements at site A over the same period give mass loss of 573 (558) ± 95 kg m^{-2}, so again, measurements at both sites are within error of each other.

The morphometry of the sampled penitentes changed visibly over the measured intervals (Figures 3 and 4). The strong east-west ~~preferential orientation~~lineation and preferred north and south surface aspect predicted from theory developed early and was maintained throughout study period. ~~The expression of this alignment is more convoluted in the stages of development studied here than the parallel rows of penitentes used in model representations (Corripio and Purves, 2005; Lhermitte et al., 2014).~~ Over time ~~the~~ penitente troughs became fewer in number, but wider and deeper~~ inkeeping with the increasing surface relief evident in the manual measurements.~~. This ~~is reflected by increasing~~causes total surface area~~, with the penitente surfaces~~ to increase; at site A ~~providing~~the true surface is between 1.7 and 4.0 times the ~~surface area of the~~ horizontal equivalent area, ~~and at site B providing~~ between 2.1 and 3.7 times the horizontal surface area equivalent and at site B (Figure 4 a & b). Snowfall during the first measurement interval decreases the surface area at site A over that interval. ~~The surface~~Surface relief, expressed by the vertical range of the mesh, also increases through time, except when snowfall partially filled the developing penitentes~~,~~ ~~reducing~~ and reduces both the range of the surface and the general slope angle.~~ Nevertheless, the morphometric~~

~~properties of the meshes broadly meet the properties of simplified surfaces.~~ The largest part of the surface is facing southwards, and the predominant angle generally steepens over time, though again this trend is reversed by snowfall (Figure 4 c & d). From the onset of measurements the surface aspect distribution is strongly dominated by north and south facing components and this becomes more pronounced in the latter measurements and the preferred orientation rotates slightly over the course of the season (Figure 4 e & f).

~~3.~~43.4 Manual measurements of reference cross-profile

The surface properties from manual measurements were computed on data sampled at 0.2 m over 5.0 m. Maximum relief of the sampled penitente profile, defined as the range of the distance from the horizontal reference to the surface, increased over time from 0.76, through 0.83 and 1.00 to 1.38 m on each measurement date. The standard deviation of the surface remained relatively unchanged with values of 0.24, 0.26, 0.28 and 0.32 m at each measurement date. Surface lowering rate calculated by differencing the mean surface height along the profile on each measurement data was 13, 57 and 61 mm d^{-1} over the three sampled intervals, giving a total mean surface lowering of 1.61 ± 0.14 m between 23 of November and 4 January. These manual measurements along the cross-profile compare well to the aerially-averaged lowering rates from the scanned surfaces, despite the fact that the manual measurements are made in only 2 dimensions, do not visually represent the complexity of the penitente surfaces, and individual points are sometimes out of the range of error of the Kinect (Figure 5). The computed mass loss over the same period is 688 ± 70 kg m^{-2}, which underestimates, but is within error of, the value for site A derived from volume changes.

To investigate the impact of sampling resolution, maximum elevation range, mean surface height compared to the horizontal reference and mean surface lowering were calculated from manual measurements at 0.1 (n = 52), 0.2 (n = 26), 0.4 (n = 14) and 1.0 m (n = 6) intervals on the last three measurement dates. The highest resolution sample was taken as a reference against which to evaluate coarser sampling. Surface relief differed from that measured at 0.1 m by maxima of 0.13, 0.29 and 0.41 m for 0.2, 0.4 and 1.0 m sampling intervals respectively. Mean measured surface height was within 0.03 m of the highest resolution measurements at 0.2 m and 0.4 m intervals, and within 0.12 m at 1.0 m resolution. Mean lowering rates at 0.1, 0.2 and 0.4 m sampling intervals were all within 3 mm d^{-1}. This increased to a maximum of 12 mm d^{-1} when the sampling resolution was decreased to 1.0 m. Decreasing the length of the sampled profile down to 2 m alters the mean lowering rate by less than 5 mm d~~ay~~$^{-1}$ at sampling resolutions of 0.1, 0.2 and 0.4 m.

Probing of the snow depth on 25 November indicated mean snow depth of 1.83 m (standard deviation 0.56 m). The underlying ice surface does not appear to be influencing the structure of the overlying snow penitentes (Figure 5). However, it is difficult to draw a firm conclusion based on these measurements, particularly as, while the surface of the penitentes was still snow on the 3 January, in several instances the surface had lowered below the level of the ice interface suggested by the initial probing.

3.5 Surface roughness assessments

Given that aerodynamic measurements to determine the most suitable representative height and zero displacement level for penitentes are thus far unavailable, the approach taken here was to do an exploratory study and compute geometric surface roughness values using various ways of expressing h and z_d. As a consequence the results are purely illustrative and while patterns can be drawn from them that have meaning for understanding the nature of the computation, the applicability of these values in turbulent exchange calculations remains to be established. The representative height, h, used in the calculations increases over time in all cases, and is bounded by the maximum case, taking h ~~to be the~~as range of the detrended surfaces~~ (maximum)~~, and the minimum case, taking h as twice the standard deviation of the detrended surface (Figure ~~5~~6). For clarity, the ~~other~~ two ~~case~~intermediate values are not included in ~~the plots shown here.~~Figure 6. Differences ~~within a single~~in h computed by the same method ~~between~~

~~the two sites~~ can reach as much as 0.2 m between the two sites, although the pattern of change over time is consistent.

The application of ~~Lettaus~~Lettau's (1969) formula is considered to be invalid if the ratio of the frontal area to the planar area of the obstacles exceeds 0.2 – 0.3, with 0.25 often being chosen as a single value. ~~In~~This ratio is greater than 0.2 for all ~~cases~~ of the penitente surfaces ~~this ratio exceeds 0.2~~, and ~~only 6% of cases computed at 10° intervals of bearing over all dates are below 0.3, and these are all early in the season, before~~after the 20th December is always greater than 0.3. Exceeding this threshold implies that the obstacles are so closely packed that 'skimming' airflow will occur. Ignoring this issue, calculated z_0 values increase with time and show a strong dependence on the impinging wind direction, with values peaking for wind directions perpendicular to the alignment of the penitentes (Figure ~~6~~7). Calculated z_0 ranges from 0.01 – 0.90 m, depending on the way in which the representative height is expressed, the ~~time of year~~date and the wind direction (Figure ~~7~~8). However, given the close spacing of the penitentes it ~~seems appropriate~~is likely more valid to ~~also~~ explore what the calculated z_0 would be ~~like~~ when ~~applying~~ a zero displacement height offset~~, although again~~ is applied. Again, in the absence of validation data ~~these numbers~~from independent measurements, calculated values can be only indicative of the pattern of roughness computed by these methods. Introducing the zero displacement height reduces the maximum calculated roughness by about half, and also reduces the variability between different representative heights (Figure ~~7~~8), as a smaller h value translates into a smaller z_d so that the calculation is performed on a larger portion of the mesh.

Surface roughness assessments on the basis of calculations following Munro's modification for single profile measurements were applied to cross profiles longer than 1.5 m yielding 20 (6) profiles orientated N-S and 33 (7) E-W at site A (B). Surface amplitude increases over time, and the amplitude of the N-S running cross profiles is generally larger than the E-W running cross profiles, as illustrated in the example of site B (Figure ~~8). The~~9). Table 3 shows the calculated roughness values at each survey date, revealing that while profile-computed roughness length increases monotonically over time at site B, ~~but shows a reduction~~it reduces over the first period at site A, associated with snowfall during this period. Both the range and relative increase in roughness over time is larger for the N-S running profiles. The computed roughness at both sites is 4.3 to 6.8 times larger for airflow impinging on the penitente field in an E-W direction than for airflow in the N-S direction. This is contrary to the results computed on the full 3D mesh surface, but is understandable because this formulation relies on the amplitude of the surface, which is generally larger in the N-S orientated cross profiles than the E-W running cross profiles.

4. Discussion

4.1 Penitente morphology

Although the natural penitentes sampled here are more convoluted than the parallel rows of penitentes used in model representations (Corripio and Purves, 2005; Lhermitte et al., 2014), the morphometric properties of the meshes broadly meet the properties of simplified surfaces. The penitente surface represents a much larger total surface area than the equivalent non-penitente surface and the control of solar radiation on penitente morphology means that the vast majority of the surface consistently dips steeply to the north and south at all stages of development. This means that the angle of incidence of direct solar radiation is reduced, decreasing both the intensity of the solar beam and the proportion of it that is absorbed. Although these effects are counteracted by multiple reflections of solar radiation within the penitente (Corripio and Purves, 2005; Lhermitte et al., 2014; Claudin et al., 2015) modeled mean net shortwave at sampled points in an example penitente field at the summer solstice at 33°S is about half of that of a level surface (Corripio and Purves, 2005). However, given the larger surface area of the penitente field compared to a flat surface, the total absorbed shortwave is a third higher in the modeled penitentes, broadly in line with the observed effect of penitentes on spatially-averaged albedo (Warren et al, 1998; Corripio and Purves, 2005; MacDonell et al., 2013; Cathles et al., 2014; Lhermitte et al., 2014). For idealized penitentes at 33°S during summer solstice, modeled increase in net shortwave radiation over penitentes is not compensated by modelled changes in net

longwave radiation, meaning that the excess energy receipts must be compensated by either turbulent energy fluxes or consumption of energy by melting (Corripio and Purves, 2005).

Unless a snowfall event occurs to partially fill the troughs, surface relief, slope angle, penitente spacing and total surface area all increase over time as the penitentes develop and deepen. Thus the impact of penitentes on surface properties will also change along with the morphological changes. At Tapado Glacier, penitentes are initially overhanging to the north, and the southfacing sides are convex compared to the northfacing overhanging faces. Over the season the penitentes become more upright as the noon solar angle gets higher. Idealized modelling based on measurements at Tapado Glacier, shows that concave and convex slopes, as well as penitente size have been shown to impact the apparent albedo as measured by ground and satellite sensors (Lhermitte, et el., 2014), and there may be some value in assessing the impact of these morphometry changes on albedo over time. In the context of the numerical theory of Claudin and others (2015), penitente spacing controls the atmospheric level at which water vapor content is representative of the bulk surface properties. Simultaneous field or laboratory measurements of penitente spacing evolution and vapor fluxes above the surface would be required to solidly confirm this, but the spacing from the field measurements provided here can be used as an indication of the level at which measurements would need to be made in order to capture the bulk surface fluxes rather than fluctuations governed by the small-scale surface terrain.

4.2~~Prevailing wind direction differs only slightly in each period with an increasing northwesterly component in the second two periods compared to the first. This may be related to the occurrence of snow during the first period, which can be expected to alter the thermally driven valley wind systems. Over the whole study period wind direction is predominantly from the south-westerly sector, but swings through southerly to easterly thereby encompassing both extreme wind angles used in the roughness calculations here (Figure 9). This indicates that the effective roughness can be expected to differ significantly depending on the wind direction.~~

~~**3.5 Manual measurements of reference cross-profile**~~

~~Using data sampled at 0.2 m over 5.0 m, the maximum relief of the sampled penitente profile, defined as the range of the maximum and minimum distance from the horizontal reference to the surface, increased through time, from 0.76, 0.83, 1.00 to 1.38 m on each measurement date. The standard deviation of the surface remained relatively unchanged over time with values of 0.24, 0.26, 0.28 and 0.32 m at each measurement date. The difference in the mean surface height measured at the ablation frame profile at site A indicates mean lowering rates of 13, 57 and 61 mm day^{-1} over the three sampled intervals resulting in a total mean surface lowering of 1.61 ± 0.14 m between 23 of November and 4 January. The manual measurements at the cross profile compare well to the aerially-averaged lowering rates from the scanned surfaces, despite the fact that the manual measurements are only made in 2 dimensions, do not visually represent the complexity of the penitente surfaces, and individual points are sometimes out of the range of error of the Kinect (Figure 10). The computed mass loss over the same period is 688 ± 70 kg m^{-2}, which underestimates the value for site A derived from volume changes but is within error, even accounting for the two extra days measurement interval.~~

~~Values of maximum elevation range and standard deviation along the profile, mean surface height compared to the horizontal reference and mean lowering were computed from the manual measurements for available data at 0.1 (n = 52), 0.2 (n = 26), 0.4 (n = 14) and 1.0 m (n = 6) intervals to investigate the impact of sampling resolution. The highest resolution sample was taken as a reference against which to evaluate the values from coarser resolution sampling. Calculated surface relief differed from that measured at the highest resolution by maxima of 0.13, 0.29 and 0.41 m for 0.2, 0.4 and 1.0 m sampling intervals respectively. Mean measured surface height was within 0.03 m of the highest resolution measurements at 0.2 m and 0.4 m intervals, and within 0.12 m at 1.0 m resolution. Mean lowering rates at 0.1, 0.2 and 0.4 m sampling intervals were all within 3 mm day^{-1} with the difference increasing to a maximum of 12 mm day^{-1} when the sampling resolution was decreased to 1.0 m. Decreasing the length of the~~

~~sampled profile down to 2 m alters the mean lowering rate by less than 5 mm day^{-1} at sampling resolutions of 0.1, 0.2 and 0.4 m.~~

~~Probing of the snowdepth on 25 November indicated a mean snow depth of 1.83 m (standard deviation 0.56 m). The underlying ice surface identified by the snow probing, does not appear to be influencing the structure of the snow penitentes developing in the current season. However, it is difficult to draw a firm conclusion based on measurements at only 0.2 m spacing, particularly as, while the surface of the penitentes was still snow on the 3 January, in several instances the surface had lowered below the level of the ice interface indicated by the initial probing.~~

~~4. Discussion~~

~~4.1~~ Methods of measuring change of rough glacier surface elements

The test site for scanning penitentes with a TLS was chosen as ~~it provided the most optimal viewing angles possible from scanning positions, as the penitentes lay in a river bed and~~ scanning positions could be established on the surrounding ~~river banks to look down into~~higher ground overlooking the penitente field~~.~~, thereby offering the best viewing angles possible. Nevertheless, the terrestrial laser scanning could only capture the ~~tips rather than the whole surface~~upper portions of the penitentes ~~and, as~~. As ablation is at its maximum in the troughs, TLS data is therefore not able to determine the true volume change ~~ongoing in~~of penitentes. The coverage would be increased if a higher viewing angle could be achieved, but the steep, dense nature of penitente fields makes it difficult to imagine where sufficient suitable locations can be found surrounding glaciers or snowfields with penitentes. In contrast, the mobile Kinect sensor can be moved across the complex relief of the penitente field to make a complete surface model. Although it is in principle possible to capture a large area with the ReconstructMe software used here, and it offers the advantage of providing real time feedback on the mesh coverage, it proved difficult to capture the study sites in a single scan given (i) the reduced signal range of the sensor over snow and ice (Mankoff ~~et al.,~~and Russo, 2013), and (ii) the difficulty of moving around the penitente field. As a result, partial scans were obtained, with the disadvantage that subsequently combining these introduces a substantial degree of additional error associated with alignment if the component scans were not of high quality at the margins, or did not overlap adjacent scan areas sufficiently. A combination of these two techniques might allow the extrapolation of small-scale geometry changes and volume loss determined from a Kinect surface scan to be extrapolated usefully to the glacier or snowfield scale using measurements made with a TLS.

Despite not visually capturing the complex ~~surface properties~~morphology of the penitentes, manual measurements of surface height change in a penitente field along a profile cross-cutting the penitentes are robust for determining mean surface lowering rates, and show good agreement to the volume changes computed from differencing the digital surface models scanned in detail using a Kinect. Thus, the detailed surface geometry need not be known in order to reasonably calculate the total volume loss over time within penitente fields. Comparison of the manual sampling at different intervals ~~suggest~~suggests that five samples per meter is adequate to characterize surface change of penitentes~~.~~, but that data will be unreliable is the cross-profile is too short. Over the 39 days of the study, ~~the~~ mass loss calculated from 26 points spaced at 0.2 m intervals along a 5 m profile crosscutting the penitentes differed from that calculated from volume change computed on surface meshes consisting of over 1.3 million points and covering an area of 7 m^2 by only 28 kg m^{-2}. Although this difference was within the error of the two measurement types, the seasonal difference, assuming that this difference applies to a whole ablation season of 120 days would be 86 kg m^{-2}, and applied to the whole glacier (3.6 km^2) would amount to an underestimate of mass loss over an ablation season of 0.3 gigatonnes. As a side note, the probing of snowdepth carried out as part of this study highlights the difficulty in identifying the underlying ice surface, or summer ablation surface, ~~in this way~~ within a penitente field, suggesting that a single location must be sampled very densely to obtain a characteristic snowdepth ~~in~~by this ~~way~~method.

4.3 Surface roughness

~~4.2 Penitente~~The changing morphometry **~~and change in time~~**

~~The manual measurements at 0.2 m intervals are adequate to determine the mean surface lowering within a penitente field, giving confidence to this type~~ of ~~simplified measurement on seasonal timescales. However, the interval measurements cannot capture the surface morphometry, or how it changes in time.~~

~~At all times the penitente surface represents a much larger total surface area than the equivalent non-penitente surface. Over time the surface relief, and slope angle, increases as~~ the penitentes ~~deepen, unless a snowfall event occurs to partially fill the troughs, which also reduced the mean surface slope. The control of solar radiation on penitente morphology means that the vast majority of the surface consistently dips steeply to the north and south at all stages of development. This means that the angle of incidence of direct solar radiation is reduced, decreasing both the intensity of the solar beam and the proportion of it that is absorbed. Although these effects are counteracted by multiple reflections of solar radiation within the penitente (Corripio and Purves, 2005; Lhermitte et al., 2014; Claudin et al., 2015) modeled mean net shortwave in an example penitente field at the summer solstice at 33°S is about half of that of a level surface (Corripio and Purves, 2005). However, given the larger surface area of the penitente field compared to a flat surface, the total absorbed shortwave is a third higher in the modeled penitentes. At Tapado Glacier, penitentes are initially overhanging to the north, and the southfacing sides are convex compared to the northfacing overhanging faces. Over the season the penitentes become more upright as the noon solar angle gets higher. Idealized modelling based on measurements at Tapado Glacier, shows that concave and convex slopes, as well as penitente size have been shown to impact the apparent albedo as measured by ground and satellite sensors (Lhermitte, et el., 2014), and there may be some value in assessing the impact of these morphometry changes on albedo over time. For the idealized penitente surface at 33°S during summer solstice case, modeled increase in net shortwave radiation over penitentes is not compensated by modelled changes in net longwave radiation, meaning that the excess energy receipts must be compensated by either turbulent energy fluxes or consumption of energy by melting (Corripio and Purves, 2005).~~

~~In the context of the numerical theory of Claudin and others (2015), progressive widening of the penitente spacing, as observed at both site A and B, is indicative of changes in the atmospheric level at which water vapor content is unaffected by the vapor flux from the penitente surface. Simultaneous field or laboratory measurements of penitente spacing evolution and vapor fluxes above the surface would be required to solidly confirm this, but the field measurements provided here can be used as an indication of the level to which vapor flux from the surface is influencing the boundary layer vapor content.~~

alters the geometrical surface roughness as they develop over the ablation season. Values calculated using**~~4.3 Surface roughness~~**

~~In this work~~ a single, simple, geometric relationship (Lettau 1969) ~~was~~were investigated because a profile-based version of this formulation has previously been tested against aerodynamic measurements over glacier surfaces (Munro, 1989, 1990; Brock et al., 2006). Certainly other relationships could be explored in the context of linearized glacier features, but given the wide spread of values produced in previous comparisons such an analysis might be of limited value in the absence of simultaneous aerodynamical investigations (Grimmond and Oke, 1999). Furthermore, the results of Grimmond and Oke (1999) indicate that for the cities sampled, the Lettau method gives z_0 values that are in the middle of the range of all the methods. The analysis of geometric computations of roughness properties in Grimmond and Oke (1999) highlight the importance of correctly determining z_d, and limited sensitivity analyses show the computed z_d and z_0 to be strongly dependent on the dimensions of the obstacles. Lettau's (1969) formula, which does not account for z_d, overestimates roughness for densely packed obstacles, but this ~~overestimation~~ does not compensate sufficiently to reproduce values of $z_d + z_0$ ~~produced~~ for densely packed obstacles from formulations that include z_d in the computation of z_0. ~~This means that~~Thus, Lettaus formula is

expected to estimate the zero velocity point of a logarithmic wind profile to be lower than formulations that include z_d in ~~their computation of z_0. In this work however we computed z_d in a separate preceding step to explore the impact of z_d on the computed~~the computation of z_0.

~~As penitentes fields present very densely packed roughness elements, the frontal area of the surface tends to be large compared to the ground area, and the limits of the~~ The ratio of frontal to planar area ~~found in this study~~ of the penitentes implies that skimming flow ~~is almost always occurring over penitente fields~~prevails, such that turbulent airflow in the overlying atmosphere does not penetrate ~~to the full depth of the~~ penitente ~~fields~~troughs. This is in agreement with the theory of formation and growth of penitentes, in which the development and preservation of a humid microclimate within the penitente ~~hollows~~troughs is required to facilitate differential ablation between the trough and tip of the penitente. ~~As~~Although the ~~spacing between the~~data here shows that penitentes ~~also increases over the ablation season the features~~ become less densely packed over time, ~~although the~~ skimming flow regime persists over the study period, and available data ~~are~~is insufficient to determine if ~~the spacing increases sufficiently by the~~ this holds true to the end of the ~~season to comply with the applicable limits of the roughness calculation used here~~ablation season.

Application of geometrical roughness equations is made more problematic in penitente fields as it is not clear how an appropriate representative obstacle height should be expressed, nor how to define the zero displacement level during ~~presumed~~ skimming flow. Roughness calculated using a range of possible representations of these properties point towards roughness values in the order of 0.01-0.10 m during the early part of the ablation season and 0.10-0.50 m after the end of December. These values are in line with the roughest values previously published for glacier ice (Smeets et al., 1999; Obleitner, 2000). The topographic analysis clearly shows that in the absence of intervening snowfall events, this roughness increase is related to the deepening of the penitentes over time and an increase of the surface amplitude. The ~~patterns~~pattern of the computed roughness properties is consistent between the two neighbouring sites, but individual values can differ, suggesting that ~~local~~ relief varies substantially over short distances and sampling a ~~larger~~large area ~~would be beneficial in order~~is necessary to capture mean properties.

The strong alignment of penitentes means that ~~roughness~~ calculated roughness is strongly dependent on ~~the~~wind direction. Roughness calculated from 3D surface meshes ~~is~~are higher for wind impinging in a north-south direction, as the large faces of the penitentes form the frontal area in this case. In contrast, ~~if~~ roughness ~~is computed~~calculated for individual profiles extracted from the mesh to mimic manual transect measurements in the field, ~~roughness~~ is between 3 and 6 times larger for air flow ~~along the penitente lineation (E-W) than it is across the lineation (N-S). While clearly highlighting that the surface roughness of the strongly aligned penitente fields is dependent on wind~~impinging in an east-west direction, ~~this contradiction poses~~than in a ~~conundrum as neither~~north-south direction. Neither approach has been ~~specifically~~ evaluated against independent surface roughness derived from atmospheric profile measurements over penitentes. Consequently, although surface roughness calculations on the basis of profile geometry have been evaluated against aerodynamic roughness over rough ice surfaces, the available data is insufficient to distinguish if maximum aerodynamic roughness is associated with wind flowing across or along the penitente lineation. Thus it is not clear which ~~pattern is more~~method captures the appropriate relationship between wind direction and surface roughness for calculating turbulent fluxes over penitentes. It principle it sounds reasonable to expect airflow across the penitente lineation to maximize turbulence as the penitentes present a large surface area to the wind, yet, if skimming flow is established, with the result that only the tips of the penitentes are determining the structure of the turbulence then roughness in this direction would be strongly reduced, and perhaps even be less than for air flow along the penitente lineation, for which the smaller frontal area reduces the likelihood of skimming flow. Further investigation of this in order to quantify the impact of penitentes on turbulent fluxes for various airflow patterns requires measurement of turbulent fluxes using eddy covariance or atmospheric profile methods, which would demonstrate the nature of the directional roughness and establish the impact of penitentes on turbulent energy fluxes for different wind directions. Such measurements would be best implemented in a manner which can sample all wind directions equally, and eddy covariance systems for which analysis is limited to a sector

of airflow centred around the prevailing airflow source, might not be able to capture the nature of the directional dependence correctly.

Prevailing wind direction differs only slightly in each period with an increasing northwesterly component in the second two periods compared to the first. This may be related to the occurrence of snow during the first period, which is expected to alter thermally-driven valley wind systems. Over the whole study period wind direction is predominantly from the south-easterly and north-westerly sectors, and swings through both extreme wind angles used in the roughness calculations here (Figure 10). This indicates that the effective roughness at this site can be expected to differ significantly over time depending on the wind direction.

In this study we did not explicitly compute the blending height as available formulae are dependent upon z_0 and z_d. Estimates of the blending height independently from z_0 and z_d have been suggested to be 2.5 - 4.5 times h, as twice the mean element spacing, or as combination of the height and spacing (see examples within Grimmond and Oke, 1999). Given that only atmospheric measurements above the blending height give representations of integrated surface fluxes and conditions, the first approach would imply that aerodynamical or flux measurements over penitentes would have to be carried out at ~~some~~considerable height above the surface to capture mean surface properties rather than the effects of individual roughness elements. The mathematical model of Claudin and others (2015) ~~indicates that the~~ gives a characteristic length scale for the level at which the vapour flux ~~does not~~ is constant in horizontal space~~, and therefore is the product of mean surface properties,~~ that is related to the spacing of the penitentes. ~~Taking~~Interpreting this ~~to be representative of~~level as the blending height ~~would imply~~implies that ~~a formulation for~~ the blending height might be ~~possible~~determined on the basis of spacing of penitentes alone, and that this in turn might contain useful data for understanding the structure and efficiency of turbulence above penitentes. ~~However, exploring~~Exploring these ideas requires information from detailed meteorological measurements as well as the geometrical information offered in this paper.

5. Conclusion

Surface scanning technology and software is an area of rapid development, and a number of potentially superior alternative set-ups and data capture sensors and software is now available. This study demonstrates that the Microsoft Kinect sensor can work successfully at close range over rough snow and ice surfaces under low light conditions, and generate useful data for assessing the geometry of complex terrain and surface roughness properties.

The data collected offers the first detailed study of how the geometry of penitentes ~~evolves~~evolve through time, highlighting the rate of change of surface properties over an ablation season that can serve as a guideline for parameterizing surface properties required for energy and mass balance modelling of penitente surfaces.

The ~~measurements~~results confirm that even relatively crude manual measurements of penitente surface lowering are adequate for quantifying the seasonal mass loss, which is good news for the validity of measurements of surface change on glaciers with penitentes. However, further measurements and/or modelling studies are required to determine if the mass loss from the expanded and convoluted surface of penitentes is enhanced or inhibited compared to mass loss in the absence of penitentes.

Aerodynamical roughness properties and related metrics over very rough surfaces remain poorly quantified and both geometric and meteorological determinations of these values show a wide spread; consequently it remains unclear what the best methods to use are or what values modellers would be best to use (Grimmond and Oke, 1999). In this context ~~penitentes and~~ further study of ~~them~~penitentes offers a useful opportunity as (a) their morphometric evolution over time allows various geometries to be evaluated by ~~instrumenting and scanning~~monitoring a single site, and (b) they offer a bridge between wind tunnel and urban field experimentation of turbulence and roughness over extreme terrain. Although validity of surface roughness calculations based on surface geometry remains to be

established for penitentes, this study highlights that (i) skimming flow is expected to persist over penitentes field, but is more likely under wind directions perpendicular to the penitente alignment; (ii) z_d is certainly greater than zero, and while the depth of penetration of surface layer turbulence into a penitente field is not clearly established it is likely to evolve with the developing penitentes, and values of $z_d \sim 2/3h$ give results that are theoretically reasonable in the framework outlined by Grimmond and Oke (1999); (iii) the two methods of geometric computation of surface roughness applied here give conflicting results as to whether the effective surface roughness of penitentes is greater for airflow along or across the penitente lineation and (iv) more complete understanding of the impact of penitentes on the turbulent structure, its evolution in time, and its directional dependency, would require atmospheric measurements with no directional bias concurrent with measurements of penitentes morphology.

Potential future applications and analyses of the surfaces generated in this study include (i) using surface properties and roughness values as a guide for input into surface energy balance models; (ii) assessing the performance of models against the measured volume loss over time and (iii) evaluating how well simplified representations of penitente surfaces used in small scale radiation models and turbulence models capture the real-world complexity. Such studies would help establish the nature of the likely micro-climatic distribution of the surface energy balance within a real penitente field, and as a result the impact of penitentes on runoff and exchange of water vapour with the atmosphere.

Author contributions. L.N. designed the study. Fieldwork was carried out by L.N. and B.P. with M.P. providing the TLS. TLS and AWS equipment was provided by S.M. through collaboration with CEAZA. The data was analysed by L.N. and M.P. and L.N. ~~prepared~~led the preparation of the manuscript and figures.

Acknowledgements. Fieldwork for this study was funded by a National Geographic Waitt Grant. L.N. was supported by an Austrian Science Fund Elise Richter Grant (V309). M.~~-~~P. was supported within statutory activities No 3841/E-41/S/~~2015~~ 2016 of the Ministry of Science and Higher Education of Poland. International cooperation was supported by the Centre for Polar Studies from the funds of the Polish Leading National Research Centre (KNOW) in Earth Sciences (2014–18). Thanks are also due to Mathias Rotach for reading the paper prior to submission.

B2: Detailed mesh-processing procedure used in this study.

- All processesing was carried out in Meshlab unsless otherwise stated
- Pairwise point alignment of the component surface meshes covering each study site
- Applied filter to remove mesh sections (vertices and faces) consisting of < XXX vertices
- Applied filter to remove unreferenced and duplicated vertices
- ICP alignment optimization of the mosaicked component surface meshes using the following parameters:
    - sample number of 1000 for each ICP iteration
    - minimal starting distance for chosen points of 10 mm at the first iteration reducing by 20% on each iteration
    - maximum of 50 iterations were performed
    - using rigid matching so that no stretching or warping of the mesh is permitted
    - export distributed alignment error
- Flattened mosaicked surface meshes into a single layer and remeshed using a Poisson filter with the following paramters:
    - Octreee depth (12)
    - Solver divide (7)
    - number of samples per node (1)
- Meshes were georeferenced with differential GPS measurements in Polywork
- Corner marker stakes, and parts of the mesh representing sensors installed within the sample site were manually removed from the georeferenced surface mesh and the mesh was cropped at the margins
- Triangle numbers were reduced by merging vertices closer than 2.5mm
- Resultant non-manifold features were removed
- Closed holes using a 20mm diameter filter. Inspected boundaries of resultant meshes to confirm that all remaining boundaries are on the edges of the sub-sampled area.
- Cropped horizontal areas to a consistent patch size: A 2 x 3.5m; B 1.5 x 1.5m
- Exported as .OBJ file from which the vertex coordinates and face indices and metadata were extracted for subsequent analysis in Matlab.

C: Comments and recommendations on the Kinect sampling strategy used in this study.

- Daylight swamps the signal of the Kinect. Over rock surfaces the Kinect worked perfectly as long as the surface was not in direct sunlight. Over snow and ice the effective range was reduced to about 1m and scanning could only be performed once the sun was below the horizon and was even better after darkness had fallen.
- This study used ReconstructMe as the capture software as it performs real time meashing so that the quality of the surface collected can be assessed at the time of capture. This is an advantage for:
  - observing if return signals had been obtained from the troughs of the penitentes as penetration into very narrow penitente troughs was only achieved over several passes and by re-orientating the sensor to be parallel with the trough.
- The disadvantages of ReconstructMe are that:
  - it does not save the raw depth data
  - it requires a computer with a powerful graphics processor as the real time processing is performed at the same 30Hz frequency as the depth-map frame production of the Kinect.
  - the powerful graphics processor tends to be power hungry
- Alternative systems for sampling Kinect data are numerous and growing, and the user must do some up to date research to discover the newest developments, but some existing options are to:
  - use the 'KinectFusion' algorithm (Izadi et al., 2011;Newcombe et al., 2011), implemented in the 'Kinfu' program (part of the Point Cloud Library (PCL); Rusu and Cousins, 2011), which allows one to move the Kinect and scan an area or object, automatically stitching together each frame into one large 3D model, while also capturing raw data.
  - for very large areas, the Kinfu implementation has been extended, named Kintinuous, and used to map paths more than 100m long (Whelan et al., 2012).
- When covering an area larger than $1m^2$ with a Kinect survey it would be advantageous to have a camera boom mounting for moving the Kinect smoothly over the glacier surface, as this would mean larger areas can be scanned in a single mesh. This would save significant work, and additional error involved in aligning and mosaicking the meshes.
- Ground control point markers which have fixed geometric surfaces with known alignment to x, y, z would have facilitated the alignment and mosaicking the component meshes of each scan. On the basis of this study a marker pole with cubes attached to it at fixed heights and known orientations would be ideal. As the surface lowers and more of the marker stake is revealed additional markers should be added at known distances below the previous marker cube.
- A higher number of ground control points to provide redundancy is advisable as in the case of poorly represented locations for georeferencing step, these could be excluded and the remaining points would still allow successful georeferencing.
