18 **Abstract**

19 Ice, Cloud, and land Elevation Satellite-2 (ICESat-2) is scheduled to launch in 2017 and
20 will carry the Advanced Topographic Laser Altimeter System (ATLAS), which is a
21 photon-counting laser altimeter and represents a new approach to satellite determination
22 of surface elevation. Given the new technology of ATLAS, an airborne instrument, the
23 Multiple Altimeter Beam Experimental Lidar (MABEL), was deployed in July 2014 to
24 Alaska to provide data needed for satellite-algorithm development, simulating key
25 elements of the photon-counting sampling strategy, and assessing elements of the
26 resulting data that may vary seasonally. Here, we compare MABEL lidar data to *in situ*
27 observations in Southeast Alaska to assess instrument performance in summer conditions

1 and in the presence of glacier surface melt ponds and a wet snowpack. Results indicate
2 that: 1) the ATLAS 90 m beam-spacing strategy will provide a robust assessment of
3 across-track slope that is consistent with shallow slopes ($<1^\circ$) of an ice-sheet interior over
4 50 to 150 m length scales; 2) the dense along-track sampling strategy of photon counting
5 systems provides crevasse detail; and 3) MABEL 532 nm wavelength light may be
6 sampling the surface and subsurface of shallow (approximately 2 m deep) supraglacial
7 melt ponds.

8

9 **1 Introduction**

10 Ice, Cloud, and land Elevation Satellite-2 (ICESat-2) is a NASA mission scheduled to
11 launch in 2017. ICESat-2 is a follow-on mission to ICESat (2003-2009) and will extend
12 the time series of elevation-change measurements aimed at estimating the contribution of
13 polar ice sheets to eustatic sea level rise. ICESat-2 will carry the Advanced Topographic
14 Laser Altimeter System (ATLAS), which uses a different surface detection strategy than
15 the instrument onboard ICESat. Specifically, ATLAS will be a 6-beam, photon-counting
16 laser altimeter. In a photon-counting system, single-photon sensitive detectors are used,
17 and the arrival time of any detected photon is recorded. ATLAS will use short (< 2 ns)
18 532 nm wavelength pulses, with a 10 kHz repetition rate, a ~ 14 m diameter footprint, and
19 a ~ 70 cm along-track sampling interval (Abdalati et al., 2010). An accurate assessment of
20 ice-sheet surface-elevation change based on altimetry is dependent upon knowledge of
21 local slope (Zwally et al., 2011). Therefore, the six ATLAS beams are arranged into three
22 sets of pairs. Spacing between the three pair sets is ~ 3 km to increase sampling density,
23 while spacing between each beam within a given pair will be ~ 90 m to make the critical
24 determination of local slope on each pass. Therefore, elevation change can be determined
25 from only two passes of a given area (Abdalati et al., 2010; Brunt et al., 2014).

26 Given this new approach to satellite surface elevation measurement, an airborne
27 instrument, the Multiple Altimeter Beam Experimental Lidar (MABEL), was developed
28 to: 1) enable the development of ICESat-2 geophysical algorithms prior to launch; 2)
29 enable ICESat-2 error analysis; and 3) provide ATLAS model validation. MABEL
30 (discussed in detail in McGill et al., 2013) is a multibeam, photon-counting lidar,

1 sampling at both 532 and 1064 nm wavelengths using short (~1.5 ns) laser pulses.
2 MABEL beams are arranged approximately linearly, perpendicular to the direction of
3 flight, with 1064 beams leading 523 beams by ~60 m. The system allows for beam-
4 geometry changes between flights with a maximum beam spread of ± 1 km from the 20
5 km nominal altitude of the NASA ER-2 aircraft. The laser pulse repetition rate is variable
6 (5 to 25 kHz) and was 5 kHz for the data presented here. At this nominal altitude and
7 repetition rate, and at an aircraft speed of ~ 200 m s⁻¹, MABEL samples a ~ 2 m footprint
8 every ~ 4 cm along-track.

9 Following engineering test flights in 2010 and 2011, MABEL was deployed to Greenland
10 (April 2012) and Alaska (July 2014) to collect data that included glacier targets. The
11 Greenland 2012 campaign was intended to sample winter-like conditions while the
12 Alaska 2014 campaign was timed to collect data during the summer melt season.

13 MABEL beam geometry, specifically the spacing between the individual beams, is
14 adjustable but has generally been configured to allow simulation of the planned beam
15 geometry of ATLAS. Previous results from the MABEL 2012 Greenland campaign
16 suggest that the ATLAS beam geometry is appropriate for the determination of slope on
17 ~ 90 m across-track length scales, a measurement that will be fundamental to
18 deconvolving the effects of local surface slope from the ice-sheet surface-elevation
19 change derived from ATLAS (Brunt et al., 2014).

20 Here, we compare *in situ* measurements with MABEL airborne lidar data on the Bagley
21 (16 July 2014; 60.5° N, 141.7° W) and Juneau (31 July 2014; 58.6° N, 134.2° W)
22 icefields in Southeast Alaska (Fig. 1). These comparisons are made with consideration for
23 the ATLAS planned beam geometry to investigate instrument performance in summer
24 conditions and in the presence of surface crevasses and melt ponds.

25

26 **2 Data and methods**

27 **2.1 MABEL data**

28 MABEL data (release 9) for the Alaska 2014 campaign (Fig. 1) are available from the
29 NASA ICESat-2 website (http://icesat.gsfc.nasa.gov/icesat2/data/mabel/mabel_docs).

1 Each data file contains 1 minute of data for every available beam (approximately two
2 beams per deployment were compromised due to instrumentation issues). The data files
3 contain photon arrival times resulting from reflected laser light (*i.e.*, signal photons),
4 solar background and backscatter in the atmosphere (*i.e.*, background photons) and, to a
5 lesser degree, detector noise (*i.e.*, noise photons). A histogram-based surface-finding
6 algorithm developed at NASA Goddard Space Flight Center was used to discriminate
7 signal photons from background and noise photons. Details of this surface-finding
8 algorithm are described in Brunt et al. (2014). The derived surface elevations are reported
9 relative to the WGS84 ellipsoid.

10 MABEL beams have non-uniform transmit energy. This is because all beams originate
11 from a single laser source, but once the source is split into the individual beams, each
12 beam follows a unique optical path through the instrument. The laser source is of 1064
13 nm wavelength; part of this source beam is divided into a series of 1064 nm beams while
14 the rest of the source beam is frequency-doubled and then divided into a series of 532 nm
15 beams (McGill et al., 2013). Owing to the frequency-doubling process and the non-
16 uniform optical paths through the instrument, the 1064 nm and 523 nm transmit-pulse
17 shapes are generally not the same. Although MABEL does not digitize transmit pulse
18 shapes, examining pulse shape differences over impenetrable targets (*e.g.*, airport
19 runways) can be considered a proxy when examining 1064 nm and 532 nm return pulse
20 characteristics. During the 2014 Alaska campaign, there were fifteen 532 nm beams and
21 six 1064 nm beams. Our analysis used relatively high-energy beams. For analysis
22 intended to mimic the 90 m spacing of the ATLAS beam geometry, two 1064 nm beams
23 were chosen based on their across-track ground separation and along-track signal-photon
24 density: beams 43 (center of the array) and 48 (~90 m to the left of the array center
25 across-track). For analysis intended to assess issues that might be wavelength-dependent,
26 beams 5 (532 nm) and 50 (1064 nm) were chosen because, in an along-track direction,
27 they were in line with one another at approximately 35 m to the left of the array center in
28 the across-track direction.

29 Each MABEL beam has a unique range bias. This is also the result of the unique optical
30 path that each beam follows through the instrument. Much of the analysis performed
31 here, such as evaluation of local surface slope, did not require absolute range accuracy.

1 Therefore, the individual beams were generally only calibrated to one another based on
2 data collected over the nearest flat surface (*e.g.*, open water). These calibrations were
3 made relative to the beam closest to the center of the array.

4

5 **2.2 MABEL camera imagery**

6 For the 2014 Alaska campaign, a camera was integrated with MABEL and was
7 successful for over 40% of the campaign's duration. The images were typically used to
8 visually confirm the type of surface being measured by MABEL (*e.g.*, ice, open water,
9 sea ice, or melt ponds) or to confirm the presence or absence of clouds. These images are
10 also available on the ICESat-2 website. The MABEL camera is a Sony Nex7, with a 55 to
11 220 mm, f/4.5-6.6 telephoto lens. It was mounted on the same optical bench as the
12 MABEL telescopes and shared the same portal in the aircraft. At a nominal aircraft
13 altitude of 20 km, each image covers an approximately 2.25 by 1.5 km area. At the same
14 altitude, MABEL beams for the Alaska campaign had a total swath width of
15 approximately 200 m, and thus were wholly contained within the camera images. The
16 images collected were not systematically georeferenced; however, they were time-
17 stamped based on MABEL instrument timing to provide a first-order assessment of the
18 surface that the lidar had surveyed.

19

20 **2.3 Landsat 8 and WorldView-2 imagery**

21 Data from the Landsat 8 Operational Land Imager (OLI) on the Bagley Icefield (Fig. 1b)
22 were used as an independent assessment of the depths of melt ponds surveyed by
23 MABEL. We applied spectrally based depth-retrieval models to Landsat 8 imagery
24 (Moussavi, 2015; Pope et al., 2015; Moussavi et al., 2014), which were calibrated based
25 on data from supraglacial lakes in Greenland. The models compare Landsat 8 spectral
26 reflectance over the lakes during pre-drainage with a post-drainage digital elevation
27 model (DEM), derived from WorldView-2 imagery acquired from the Polar Geospatial
28 Center at the University of Minnesota, using image-processing software (ERDAS). Given

1 the small size of the melt ponds on the Bagley Icefield, we used reflectance values
2 recorded in the panchromatic channel of OLI imagery.

3 A second WorldView-2-derived DEM was used near the terminus of the Lower Taku
4 Glacier (Fig. 1c) to assess surface elevations derived from MABEL signal photons in
5 steep and crevassed terrain. The DEM, created by the Polar Geospatial Center at the
6 University of Minnesota, was extracted from high-resolution along-track stereo
7 WorldView-2 imagery processed with NASA's open source Ames Stereo Pipeline
8 software (Moratto et al., 2010).

9

10 **2.4 Juneau Icefield GPS data**

11 Previous studies (Brunt et al., 2013; Brunt et al., 2014) have demonstrated that MABEL
12 precisely characterizes the ice-sheet surface when comparing MABEL-derived slope on
13 90 m across-track length scales with those based on both Airborne Topographic Mapper
14 (ATM; Krabill et al., 2002) and Laser Vegetation Imaging Sensor (LVIS, more recently
15 referred to as Laser Vegetation Ice Sensor; Blair et al., 1999).

16 We designed a GPS survey on the Juneau Icefield (Fig. 1c) to determine the length-scale
17 at which a ground-based local slope assessment on a flat surface ($<1^\circ$ slope) begins to
18 differ significantly from that of the 90 m across-track slope assessment based on
19 MABEL. On 19 July 2014, we conducted differential GPS surveys of the nodes of a
20 series of concentric equilateral triangles. WGS84 ellipsoidal heights, in a Universal
21 Transverse Mercator map projection (UTM zone 8N), were determined for each node
22 using Trimble 5700 base and rover receivers, operating in real-time differential mode.
23 The base-station receiver was located at the Juneau Icefield Research Program (JIRP)
24 Camp 10, approximately 1 km from where the rover receivers were operated. Eight
25 triangles were surveyed with side lengths of 5, 10, 25, 50, 75, 90, 125, and 150 m (Fig. 2,
26 black points). We fit a surface to each of the eight triangles and then calculated the
27 surface slope in both the UTM easting and northing directions (surface gradients $\delta z/\delta x$
28 and $\delta z/\delta y$).

1 MABEL-based surface gradients $\delta z/\delta x$ and $\delta z/\delta y$ were generated from data from the 31
2 July 2014 flight and compared with the GPS-based surface gradients. We used beams 43
3 and 48 (1064 nm), which had relatively high along-track signal-photon density,
4 approximately 90 m ground spacing, and intersected the GPS survey array (Fig. 2, red
5 lines). The MABEL beams were cross-calibrated to remove the relative elevation bias
6 resulting from their different optical paths through the instrument. To accomplish this
7 calibration, we chose beam 43 as a reference beam, calculated the mean difference
8 between the signal photons of the reference beam and beam 48 over the nearest open
9 ocean, and removed that offset (0.2 m) from beam 48. We projected the geodetic
10 MABEL data to the gridded map projection of the GPS data (UTM zone 8N) to facilitate
11 direct comparisons and so that changes in elevation in both the easting and northing
12 directions (surface gradients $\delta z/\delta x$ and $\delta z/\delta y$) could be treated uniformly. We generated a
13 MABEL triangle, with nodes based on the intersections of the GPS survey and the
14 ground tracks of the MABEL beams (Fig. 2, blue solid points). We then fit a surface to
15 those points and calculated the associated MABEL surface gradient in both the easting
16 and northing directions ($\delta z/\delta x$ and $\delta z/\delta y$). Based on this surface, the local slope for the
17 survey area was 0.5° , or comparable to what we expect for an ice-sheet interior. Finally,
18 we generated a surface based on the three GPS survey sites that were closest to the nodes
19 that defined the MABEL surface (Fig. 2, blue open circles).

20 We compared the MABEL-derived slopes to the slopes from each of the concentric GPS
21 triangles and the slope based on the GPS survey sites that were closest to the nodes that
22 defined the MABEL surface. Specifically, we created a surface gradient comparison
23 (SGC) parameter for each of the GPS-derived triangles (i) by calculating the square root
24 of the sum of the squares (RSS) of the differences between the MABEL-derived and
25 GPS-derived slopes in both the easting and northing (x and y) directions:

$$26 \quad SGC_{(i)} = \sqrt{\left[(\delta z/\delta x)_{MABEL} - (\delta z/\delta x)_{GPS_{(i)}} \right]^2 + \left[(\delta z/\delta y)_{MABEL} - (\delta z/\delta y)_{GPS_{(i)}} \right]^2}, \quad (1)$$

27 where $\delta z/\delta x$ and $\delta z/\delta y$ are the surface gradients associated with both MABEL and each of
28 the GPS triangles (i), in the easting and northing directions.

29

1 **2.4 Lower Taku Glacier GPS data**

2 The WorldView-2 images used to construct the Lower Taku Glacier DEM were collected
3 on 6 June 2014, while the MABEL data were collected on 16 July 2014 and thus,
4 separated by 40 days. GPS data were collected at six sites on the Lower Taku Glacier
5 throughout the summer, using a Trimble NetR9 receiver and used to tie the MABEL
6 survey data to the WorldView-2 DEM. The data were processed kinematically using the
7 Plate Boundary Observatory station AB50, located at the Mendenhall Glacier Visitor
8 Center, approximately 20 km west of the survey area. Velocities based on the GPS data
9 were used to migrate the MABEL data to match the timing of the WorldView-2 image
10 acquisition.

11

12 **3 Results**

13 **3.1 MABEL signal-photon density**

14 For illustrative purposes, we produced histograms of the MABEL surface-return for the
15 beams used in our analyses (Fig. 3; beams 5, 43, 48, and 50) from 3000 m of along-track
16 data over a stretch of open ocean. We calibrated the beam elevations to one another to
17 remove the unique beam elevation biases, and then detrended the surface elevations
18 based on a linear fit to the signal photons to remove any elevation differences associated
19 with wind stress or ocean dynamic topography. We then produced histograms for the
20 entire 3000 m of open ocean surface-return data using a 1 cm vertical bin size. We
21 determined the full width at half maximum (FWHM) for each of the beams, which
22 ranged from 0.19 m in beam 5 (532 nm) to 0.31 m in beam 43 (1064 nm). From Fig. 3,
23 the relative differences in the signal strengths of the individual beams are evident in the
24 non-uniform amplitudes of the photon-count distribution.

25 The MABEL return signal often demonstrates a strong surface return and a second,
26 weaker return approximately 0.5 to 1.5 m below the surface. This is due to unintended
27 secondary pulses from the MABEL laser that occur under some operational conditions.
28 These instrumental issues are more noticeable in the 1064 nm beams, but are minimized
29 when the 1064 nm source is frequency-doubled to generate 532 nm beams. This second

1 pulse can affect statistics associated with MABEL results and was therefore generally
2 removed. This secondary pulse is evident in the open-ocean data example at
3 approximately 0.75 m below the main surface return (Fig. 3).

4 Given nearly uniform surface conditions, along-track signal-photon density for each
5 beam varied within and between flights based on parameters such as reflectivity, weather
6 conditions, time of day, and sun-incidence angle. The signal-photon densities on the
7 Juneau and Bagley icefields, for each beam considered here, are given in Table 1. These
8 densities are reported based on 70 cm along-track length scales for direct comparison
9 with previous results (Brunt et al., 2014), to mimic the ATLAS sampling interval (one
10 laser shot every 70 cm), and for direct comparison with ATLAS performance models.
11 MABEL along-track signal-photon densities for the July 2014 Alaska campaign were
12 lower than those reported during the April 2012 Greenland campaign by Brunt et al.
13 (2014); they reported 3.4 and 3.9 signal photons per 70 cm for beams 5 and 6 (532 nm),
14 respectively. Some of this variation may have been related to seasonal differences in
15 surface reflectivity between the two campaigns, which include parameters such as sun
16 angle, the freshness of the most recent snowfall, the dust content of the surface, the
17 presence (or absence) of surface melt and ponds, and the presence (or absence) of snow
18 bridges that cover crevasses. Some variation may also have been related to
19 instrumentation issues, such as cleanliness of the elements in the optics.

20 The MABEL signal-photon densities (Table 1) are less than that expected for ATLAS.
21 Under similar conditions as the 2014 MABEL summer campaign, based on performance
22 models, we expect the strong beams of ATLAS to record 8.5 signal photons every shot
23 (or 70 cm along track) over ice sheets and 2.0 signal photons every shot over the open
24 ocean (A. Martino, NASA GSFC, personal communication 2014). We note that for the
25 Alaskan icefields, the expected number of signal photons based on the performance
26 model is high, as the model uses an albedo of 0.9, which is more appropriate for ice with
27 fresh snow or the interior of Antarctica. Relative to the performance model, the MABEL
28 data used in this analysis suggest that the signal-photon densities were ~65% of the
29 expected ATLAS signal-photon densities over open ocean and ~44% of the expected
30 ATLAS signal-photon densities over summer ice sheets. For ICESat-2 development

1 purposes, efforts are underway to merge data from adjacent MABEL beams, which will
2 facilitate more direct MABEL to ATLAS comparisons.

3

4 **3.2 Elevation bias and uncertainty**

5 We compared MABEL elevations to those based on the Juneau Icefield GPS array,
6 interpolated to the MABEL/GPS points of intersection (Fig. 2, blue solid points). The
7 mean offset, or bias, for the three points of intersection was 3.2 ± 0.08 m. While this 3 m
8 instrument bias is larger than that of other airborne lidars, it is within the MABEL design
9 goals (algorithm development, error analysis, and ATLAS model validation), where
10 instrument precision is more critical to satellite algorithm development than absolute
11 accuracy. Thus, while other photon-counting systems are being used for change detection
12 (e.g., Young et al., 2015), in its current configuration, MABEL is not suitable for time-
13 series analysis of elevation change, either independently or when integrated with other
14 datasets.

15 We assessed the surface precision of MABEL data (*i.e.*, the spread of the MABEL data
16 point cloud about a known surface, or the standard deviation of the mean difference
17 between MABEL and a known surface elevation, Hodgson, and Bresnahan, 2004) over a
18 flat stretch of open ocean. For approximately 3000 m of along-track open water, the
19 surface-precision estimates for the strong 532 and 1064 nm beams, based on a standard
20 deviations of the mean differences from the flat surface, were ± 0.11 and ± 0.12 m,
21 respectively. Brunt et al. (2014) reported similar surface-precision values (± 0.14 m)
22 based on direct comparison of MABEL elevation data with high-resolution ground-based
23 GPS data (differentially post-processed with an RMS < 5 cm) over an airport departure
24 apron. Further, Brunt et al. (2013) reported that for all MABEL campaigns (2010 –
25 2014), when similar ground-based GPS data were available, MABEL surface precision
26 ranged between ± 0.11 and ± 0.24 m. During that time period, MABEL had been deployed
27 on two different types of aircraft and in a number of different optical configurations
28 (McGill et al., 2013).

29

1 **3.3 Local slope assessment for ice-sheet interiors**

2 Using Eq. (1), we compared the MABEL-derived surface-gradient comparison (SGC)
3 parameters to those based on the Juneau Icefield GPS array (Fig. 4). The MABEL-
4 derived SGC parameters were consistent with GPS-derived SGC parameters over length
5 scales ranging from 50 m (just over half of the ATLAS beam spacing) to 150 m (just
6 under twice the ATLAS beam spacing). The SGCs for 50 to 150 m spatial scales were
7 less than 0.2° .

8

9 **3.4 Surface characterization**

10 Analysis of data from individual beams over the Bagley Icefield indicated that MABEL
11 can capture surface detail of crevasse fields. Fig. 5a shows stitched MABEL images of
12 one set of crevasses on the Bagley Icefield; Fig. 5b shows MABEL signal and
13 background photons for a 500 m range that includes the glacier surface; and Fig. 5c
14 shows MABEL signal photons, indicating both the glacier surface and the bottoms of a
15 series of crevasses. The along-track slope of this crevasse field, between 140.60° and
16 140.56° W longitude in Fig. 5c, is 1° .

17 Similarly, analysis of the individual beams on a different stretch of the Bagley Icefield
18 indicated that MABEL can determine the location of melt ponds. Fig. 6a shows stitched
19 MABEL images from crevasse and melt-pond fields on the Bagley Icefield; Fig. 6b
20 shows MABEL signal and background photons for a 500 m range window that includes
21 the glacier surface; Fig. 6c shows both signal and background photon-count densities (per
22 125 shots, or ~ 2.5 m of along-track distance); and Fig. 6d shows MABEL signal photons,
23 indicating the location of a melt pond, which is approximately 70 m in along-track length.
24 The along-track slope of this crevasse field, between 141.90° and 141.86° W longitude in
25 Fig. 6d, is 2° . A histogram of the signal photons associated with the location of the melt
26 pond in the inset of Fig. 6d is provided in Fig. 7. This was generated to investigate how
27 the penetration of light into the melt pond, at 532 and 1064 nm wavelengths, would affect
28 the statistics of the return signal. The FWHM for the 532 and 1064 nm return signal were
29 0.26 and 0.34 m, respectively. We applied spectrally based depth-retrieval models to
30 Landsat 8 imagery (Moussavi, 2015; Pope et al., 2015; Moussavi et al., 2014) for an

1 independent assessment of the depth of the melt-pond on the Bagley Icefield in Fig. 6d.
2 This analysis indicated that melt ponds in this region were approximately 2 m deep.

3 Analysis of data from individual beams near the terminus of the Lower Taku Glacier
4 (Fig. 8) provided insight in to how MABEL will operate in regions of steeper slope. The
5 slope in this region is 4° and more consistent with slopes on an ice-sheet margin. A slope
6 of 4° is also the maximum angle used for ATLAS performance modeling over ice-sheet
7 margins (A. Martino, NASA GSFC, personal communication 2014). Fig. 8a shows
8 stitched MABEL camera images, which suggest a much rougher surface than that of the
9 low slope areas of interest on the Bagley Icefield examined in Fig. 6. Additionally, the
10 MABEL ice-surface signal near the terminus was slightly compromised due to
11 intermittent cloud cover, which attenuated the MABEL transmit laser pulses. Further,
12 when cloud cover allows for only intermittent surface determination, the surface-finding
13 algorithm used to discriminate signal photons from background and noise photons is
14 compromised.

15 MABEL-derived surface elevations over the Lower Taku Glacier were compared to
16 elevations from the WorldView-2-derived DEM (Fig. 8b), which had 2 m horizontal-
17 resolution. Fig. 8c is one of the images used to create the DEM shown in Fig. 8d. GPS
18 data collected on the Lower Taku Glacier were used to determine an ice-flow velocity of
19 0.2 m day^{-1} at SDWN (Fig. 8c, 800 m from the center of the MABEL data line). Ice-flow
20 velocities for the two central GPS sites (Fig. 8c, C10 and SLFT, 1500 m from the center
21 of the MABEL data line) were 0.7 m day^{-1} , while velocities for the three northern GPS
22 sites (Fig. 8c, C20, SRIT, and SUP, 3000 m from the center of the MABEL data line)
23 were 1.0 m day^{-1} . The northing and easting components of the SDWN velocity were used
24 to migrate the MABEL data to match the timing of the WorldView-2 image acquisition.
25 An elevation was then extracted from the WorldView-2 DEM for each migrated MABEL
26 data point. The MABEL elevations, or the red points in Fig. 8b, were corrected for a
27 range bias and migrated based on the velocities of SDWN for direct comparison with the
28 elevation values extracted from the WorldView-2 DEM, or the black points in Fig. 8b.
29 While SDWN is not ideal for the entire MABEL data line, we chose this GPS site based
30 on proximity to the center of the data line and because the direction of flow in the
31 northing and easting directions matched the southern end of the MABEL data line.

1 MABEL elevations were 8 m lower than the values extracted from the WorldView-2
2 DEM. This bias is higher than other biases assessed during this campaign. We attribute
3 the difference to: 1) the difference between the DEM and true elevation, which can be on
4 the order of meters to 10 meters; 2) a standard MABEL range bias, which is
5 approximately 3 m; and 3) the amount of surface melting that occurred between June and
6 July, which is approximately 3 m.

7 Migration of the MABEL data to take into account ice flow had a very small effect on the
8 MABEL surface-elevation statistics, relative to the WorldView-2 DEM. This is probably
9 due to the orientation of the MABEL survey line, which was oblique to the ice-flow lines.
10 Further, we note that elevation uncertainty is a function of MABEL horizontal
11 uncertainty (2 m) and surface slope; therefore, steeper terrain leads to greater overall
12 elevation uncertainty (Brunt et al., 2014). While the MABEL surface precision (*i.e.*, the
13 standard deviation of the mean difference between the MABEL and DEM elevations) of
14 all of the Lower Taku Glacier data in Fig. 8b was slightly lower after the migration of the
15 data (from 2.6 m to 2.5 m, for beam 43), the surface precision was appreciably lower (1.8
16 m) when comparing only the southern part of the data line ($<58.43^\circ$ latitude), where the
17 data were more consistent with the ice-flow lines and were closer to the GPS site used in
18 this analysis (Fig. 8c, SDWN). Unfortunately, the southernmost section of the data line
19 was slightly compromised by intermittent cloud cover.

20

21 **3.5 Slope assessment for steeper glacial settings**

22 The high-resolution WorldView-2 DEM also provided a means of assessing MABEL-
23 derived across-track slopes in steeper glacial settings. Similar to the methods of Brunt et
24 al. (2014), we calculated a ~ 40 m across-track MABEL-derived slope and compared this
25 with a ~ 40 m across-track slope based on WorldView-2 DEM elevations. The MABEL-
26 derived across-track slope was calculated using beams 43 and 50, migrated to match the
27 timing of the WorldView-2 image acquisition and limited to continuous stretches of the
28 southern part of the data line. Along-track signal-photon density for beam 48 was
29 insufficient to allow for a 90 m across-track assessment. The MABEL data from each
30 beam were interpolated along track to a common time so that along-track elevations for

1 each beam could be used to calculate an across-track slope for each increment of along-
2 track time. A DEM-derived across-track slope was calculated based on elevations that
3 were extracted from the DEM at each migrated MABEL data point for beams 43 and 50.
4 Fig. 9a shows good agreement between the MABEL and DEM elevations associated with
5 beam 43. Similarly, Fig. 9b shows good agreement between MABEL-derived and DEM-
6 derived across-track slopes. The total along-track distance used in this analysis was ~300
7 m (see box in Fig. 8b). The mean residual between the MABEL-derived slope and the
8 DEM-derived slope was 0.25° .

9

10 **4 Discussion**

11 The result of this analysis indicates that the MABEL-derived local slope assessment, on a
12 relatively flat glacial surface and on a 90 m across-track length scale, is consistent with *in*
13 *situ* slope assessments made at spatial scales ranging from 50 to 150 m. For a planar
14 surface, such as the interior of an ice sheet, where slope is less than 1° , we expect the
15 local slope measured by a GPS survey and MABEL to be similar, over a wide range of
16 spatial scales. Any small differences observed between the two survey techniques would
17 likely reflect 1) the non-planarity of the surface and/or 2) the sensitivity of the results to
18 small-scale slopes or roughness captured by one measurement technique and not the
19 other. With the good observed agreement between MABEL-derived and GPS-derived
20 slope assessments over 50 to 150 m length scales (Fig. 4), we feel confident that the
21 ATLAS 90 m beam-spacing strategy will provide a robust estimate of local slope for ice-
22 sheet interiors ($<1^\circ$) over a wide range (50 to 150 m) of spatial scales. This knowledge is
23 necessary for accurate assessments of ice-sheet surface-elevation change.

24 Figs. 5c and 6d suggest that the dense along-track sampling of MABEL is sufficient to
25 provide surface detail, including melt-pond information, from a single, static beam in
26 regions of low slope, consistent with that of an ice-sheet interior. Based on the continuous
27 nature of the surface return through the crevasse field, especially in the 1064 nm beam
28 (50) in Fig. 5c, we conclude that MABEL is generally retrieving a signal from the bottom
29 of the crevasses. Further, Fig. 8b indicates that MABEL continues to provide surface
30 detail in regions of steeper slope, including the retrieval of the steep slopes of the

1 crevasse walls (e.g., Figs 5c and 6d). As previously noted, MABEL data used in this
2 analysis had signal-photon densities are ~44% of the expected ATLAS signal-photon
3 densities over summer ice sheets (A. Martino, NASA GSFC, personal communication
4 2014). Therefore, we believe that the detail of ATLAS will be sufficient to determine
5 local surface characteristics, similar to those observed on the Lower Taku Glacier. Such
6 knowledge is critical to determining ice-sheet surface-elevation change, as features that
7 could compromise change calculations, such as deep crevasses, can move or advect with
8 ice-sheet flow.

9 The crevasse characterization associated with the Bagley Icefield is qualitatively
10 confirmed using the camera imagery (Fig. 5a). However, it should be noted that we have
11 no means of quantitatively assessing the accuracy of MABEL-derived crevasse depths.
12 Crevasses on an ice-sheet surface have an influence on solar radiation and albedo (Pfeffer
13 and Bretherton, 1987). This variation in reflectance is evident in Figs. 5b, 6b, and 6c,
14 where MABEL background photon counts, and the signal-to-noise ratios, change
15 significantly. Changes in MABEL background photon densities have also been used to
16 detect leads in sea ice (Kwok et al., 2014; Farrell et al., 2015). From Fig. 6c we note that
17 the overall background photon counts decrease significantly over the eastern region of
18 this plot, which is characterized by crevasses. However, this change is non-uniform.
19 Background photon counts drop steadily to nearly zero over the two melt ponds surveyed
20 along this transect.

21 The surface characterization of the Lower Taku Glacier is assessed using the camera
22 imagery, WorldView-2 imagery, and a DEM derived from the WorldView-2 imagery
23 (Fig. 8). Once the MABEL data have been migrated based on GPS ice-flow velocities,
24 the southern part of the MABEL-derived surface elevations are in good agreement with
25 the DEM data. However, the MABEL signal in this section is intermittent due to cloud
26 cover. In the northern part of the MABEL data line, while the migration failed to improve
27 surface-elevation statistics, a generally continuous signal is detected, including melt
28 ponds (Fig. 8b, inset). The slope comparison between MABEL-derived across-track slope
29 and DEM-derived across-track slope had a mean residual of 0.25° . This residual is larger
30 than that reported over the Greenland Ice Sheet ($<0.05^\circ$) by Brunt et al. (2014); we
31 attribute this difference to errors associated with the migration of the MABEL data, given

1 that the flight line was oblique to the local direction of ice flow. Since the GPS array on
2 the Lower Taku Glacier was not optimized to facilitate an across-track slope comparison
3 similar to the comparison made higher up on the Juneau Icefield (Figs. 2 and 4), we do
4 not expect good agreement between the two methods of estimating across-track slope.

5 Penetration of 532 nm wavelength light into the surface, be it a melt pond or snow, is an
6 ongoing area of research for ICESat-2 algorithm development. Based on the signal-
7 photon elevations in the inset in Fig. 6d, and the histogram of the signal photons in Fig. 7,
8 the total spread of the signal photons, at a wavelength of 532 nm, is approximately 1.5 to
9 2 m. Further, analysis of Landsat 8 and WorldView-2 imagery confirm that the melt
10 ponds in this region are approximately 2 m deep. These results suggest that the 532 nm
11 MABEL beam may be sampling the entire melt-pond water column. The 1064 nm
12 MABEL beam shows evidence of a secondary return 1.5 m below the main signal return,
13 due to unintended secondary pulses from the MABEL laser that occur under some
14 operational conditions.

15 Based on the surface characterization results of MABEL data from the Juneau and
16 Bagley icefields, and the dense, six-beam sampling strategy of ATLAS, we feel confident
17 that ICESat-2 will contribute significantly to glacier studies at local and regional scales
18 and in polar and mid-latitudes. While previous studies using satellite laser altimetry have
19 investigated the vertical dimension of rifts in the ice sheet (*e.g.*, Fricker et al., 2005),
20 those studies have been limited to major ice-shelf rift systems, as opposed to smaller-
21 scale crevasses. The 70 cm along-track sampling density of each individual ATLAS
22 beam is well suited for similar vertical dimension studies, but at finer length-scales, such
23 as those associated with alpine glacier crevasse fields.

24

25 **5 Conclusions**

26 Knowledge of local slope and local surface character are required to accurately determine
27 ice-sheet surface-elevation change. ATLAS beam geometry includes pairs of beams
28 separated at 90 m across track to enable the determination of local slope in one pass and,
29 therefore, to enable the determination of ice-sheet surface-elevation change in just two
30 passes. Based on the analysis of MABEL and ground-based GPS data, and the resultant

1 surface gradient comparison (SGC), we conclude that the ATLAS 90 m beam-spacing
2 strategy will provide a robust assessment of local slope that is consistent with the slope of
3 an ice-sheet interior ($<1^\circ$) on 50 to 150 m length scales. The density of along-track
4 photon-counting lidar data is sufficient to characterize the ice-sheet surface in detail,
5 including small-scale features such as crevasses and melt ponds. This information is also
6 required for accurate determination of ice-sheet surface-elevation change.

7 The MABEL 2014 Alaska campaign was timed to collect data during the summer melt
8 season to specifically investigate how 532 nm wavelength laser light interacts with a
9 melting snow surface. Results from MABEL, and confirmed through analysis of Landsat
10 8 imagery, suggest that 532 nm wavelength light is likely reflecting from the surface and
11 subsurface of the 2 m deep supraglacial melt ponds on the Bagley Icefield. This is an
12 ongoing area of research for ATLAS and ICESat-2 algorithm development.

14 **Acknowledgements**

15 Funding for this project was through the NASA ICESat-2 Project Science Office.
16 Funding for J.M. Amundson was provided by NSF-PLR 1303895. We acknowledge the
17 considerable efforts of the Project, Science, and Instrument teams of NASA's ICESat-2
18 and MABEL missions. We thank: Eugenia De Marco (ASRC Aerospace Corp.,
19 NASA/GSFC) and Dan Reed (Sigma Space Corp., NASA/GSFC) for MABEL
20 instrument support; Scott Luthcke (NASA/GSFC), David Hancock (NASA/WFF), and
21 Jeff Lee (NASA/WFF) for MABEL data calibration; Scott McGee and Ya' Shonti
22 Bridgers (JIRP) for GPS field data collection and data processing support; and
23 NASA/AFRC (specifically ER-2 pilots Tim Williams and Denis Steele) for Alaska
24 airborne support. WorldView imagery was provided by the Polar Geospatial Center at the
25 University of Minnesota, which is supported by NSF-PLR 1043681. GPS receivers for
26 the survey of the terminus of the Lower Taku Glacier were provided by UNAVCO. GPS
27 receivers for the JIRP survey were provided by Werner Stempfhuber of the Beuth
28 Hochschule for Technik University of Applied Sciences.

2

3 **Figure 2.** GPS survey on the Juneau Icefield. Ground tracks for MABEL beams 43 and
4 48, from the 31 July 2014 flight, are indicated (red lines). GPS survey points of the nodes
5 of concentric, equilateral triangles, with side lengths of 5, 10, 25, 50, 75, 90, 125, and 150
6 m, are indicated (black points). Also indicated are the intersections of the MABEL flight
7 lines with the GPS survey grid (blue solid points), which were used to calculate MABEL
8 surface gradients ($\partial z/\partial x$ and $\partial z/\partial y$). The GPS sites that are the closest to the MABEL
9 gradient points are also indicated (blue open circles). The overall slope, based on the
10 MABEL elevations at the points of intersections with the GPS survey grid (blue solid
11 points), is approximately 0.5° .

3 **Figure 3.** Histograms of the signal return for the MABEL beams used in this analysis (5,
4 43, 48, and 50). Plotted are ocean surface-return photon counts (per 1 cm vertical bins)
5 over a 3 km along-track distance against elevation (m). The elevations are calibrated to
6 one another and detrended. The full width at half maximum (FWHM) for each histogram
7 are indicated in the legend. The secondary return 0.75 m below the main signal return,
8 which is more evident in the 1064 nm beams, is due to unintended secondary pulses from
9 the MABEL laser that occur under some operational conditions; this was removed for
10 FWHM analysis.

11
