Abstract. Mountain permafrost and rock glaciers in the dry Andes are of growing interest due to the increase in human activities in this remote area. Empirical models of mountain permafrost distribution based on the spatial analysis of intact and relict rock glaciers and mean annual air temperature (MAAT) have been established as a tool for regional-scale assessments
10 of permafrost favorability across entire mountain ranges; however, this kind of model approach has never been applied for a large portion of the Andes. In the present study, this methodology is applied to map permafrost favorability throughout the semi-arid Andes of central Chile (29° S-32° S), excluding areas of exposed bedrock. After spatially modeling MAAT distribution from scarce temperature records (116 station-years) using a linear mixed-effects model (LMEM), a generalized additive model (GAM) was built to model the activity status of 3524 rock glaciers. A Permafrost Favorability Index (PFI) was
15 obtained by adjusting model predictions for conceptual differences between permafrost and rock glacier distribution. The results indicate that the model has an acceptable performance (median AUROC: 0.76). Conditions highly favorable to permafrost presence (PFI ≥ 0.75) are predicted for 1051 km² of mountain terrain, or 2.7 % of the total area of the watersheds studied. Favorable conditions are expected to occur in 2636 km², or 6.8% of the area. Especially in the Elqui and Huasco watersheds in the northern half of the study area, where a substantial surface portion (11.8 % each) was considered to be
20 favorable for permafrost presence, while predicted favorable areas in the southern Limarí and Choapa watersheds are mostly limited to specific sub-watersheds. In the future, local ground-truth observations will be required to confirm permafrost presence in favorable areas, and to monitor permafrost evolution under the influence of climate change.

1 Introduction

Mountain permafrost is widely recognized as a phenomenon that may influence slope stability (Kääb et al., 2005; Harris et
25 al., 2009) and hydrological systems (Bommer et al., 2010; Caine, 2010; Haeberli, 2013), and that poses a challenge to economic development in high mountains (Taillant, 2015). Its extent and characteristics and its response to climate change are of major concern, but the present knowledge is still very limited especially in remote environments such as the high Andes (Gruber, 2012). Some case of rock glacier destabilization have been observed in the Andes (Bodin et al, 2012), raising the question of sensitivity of ice rich permafrost to climate warming. In addition, the cryosphere of the Central Andes is a growing interest

zone due to the increase in human activities related to mining and border infrastructure, likewise, societal concern about possible environmental damages and new environmental acts (Brenning, 2008; Brenning and Azócar, 2010a).

Empirical models describing the distribution of mountain permafrost based on geomorphological permafrost indicators and topographic and climatic predictors are a simple yet effective approach toward a first assessment of its distribution at a regional

5   scale (Lewkowicz and Ednie, 2004; Janke et al., 2005; Boeckli et al., 2012a, 2012b ; Sattler et al., 2016). In the Andes, the boundaries of permafrost have been determined based on global climate models at coarse resolution scales (Gruber, 2012, Saito et al., 2015); however, regionally calibrated permafrost mapping based on geomorphological evidence has not been attempted previously in the Andes. The recent availability of accurate global Digital Elevation Models (DEMs), the compilation of new rock glacier inventories and the improved access to meteorological data, provide a unique opportunity to

10   model permafrost distribution at high resolution for a large portion of the Andes.

The goal of this research was therefore to create an index map of potential permafrost distribution in the semi-arid Chilean Andes between ~29° S and 32° S based on statistical modeling of topographic and climatic conditions and rock glacier activity status. For this purpose, a rock glacier inventory was compiled in order to obtain a variable indicating the presence and absence of permafrost conditions according to rock glacier activity status. As a prerequisite for permafrost modeling, we assessed the

15   regional-scale distribution of Mean Annual Air Temperature (MAAT), used as one of the predictors for the favorability for permafrost occurrence. A Generalized Additive Model (GAM) was then used to map a Permafrost Favorability Index (PFI) in debris surfaces within the study area.

2 Study area

The study area comprises a large portion of the semi-arid Chilean Andes, covering from north to south the upper sections of

20   the Huasco, Elqui, Limarí and Choapa river basins between ~28.5 S and 32.2° S. Regarding the altitudinal distribution of the studied watersheds, about 35 % of the terrain are located above 3000 m a.s.l., with the Huasco and Elqui basins bearing the highest altitudes. Their median elevation are 2995 and 2536 m a.s.l. , respectively, compared to median values of approximately 1300 m a.s.l. for the Limarí and Choapa basins (Fig. 1), limiting the presence of glaciers, snow and permafrost in the latter two basins.

25   Population is scarce, but lowland populations rely on water resources from the high-altitude headwater areas (Gascoin et al., 2011). Climatically, it is located in a transition zone between arid and semiarid climates where the presence of the South Pacific anticyclone inhibits precipitation, favoring clear skies and high solar radiation. Precipitation at high altitudes almost exclusively occurs as snow as it is concentrated between May and August, i.e. austral winter (Gascoin et al., 2011). Regarding the recent climatic trends in this part of the Andes, atmospheric warming reaches 0.2 to 0.4° C/decade (period 1979-2006;

30   Falvey & Garreaud, 2009), whereas precipitation exhibits no trend (~1986-2005; Favier et al., 2009); these trends are, however, subject to large uncertainties due to limited data availability.

Vegetation is nearly absent above 3500 m a.s.l. (Squeo et al., 1993). Glaciers are present where summit elevations are higher than the modern equilibrium line altitude (ELA) of glaciers, which is located at about 5000 m a.s.l. at ~30° S and which also depends on local climatic anomalies (Kull et al., 2002; Azócar and Brenning, 2010). Most of the surface ice bodies in the study region correspond to small glaciers or "glacierets" (< 0.1 km²), while only 2 % of the glaciers in the study region are greater

5 than 1 km², mostly in the Elqui watershed at and near Cerro Tapado and in the upper Huasco watershed (Nicholson et al., 2009; DGA, 2009; Rabatel et al, 2009). Active and inactive rock glaciers as ice-debris landforms in the study area are present above ~3500 m a.s.l. near the southern limit of the study region and above ~4200 m a.s.l. towards its northern limit (Brenning, 2005a; Azócar and Brenning, 2010; UGP-UC, 2010), and ground ice and current movement have been detected in various cases (UGP UC, 2010; Monnier, et al., 2011, 2013; Monnier and Kinnard, 2012, 2013; Janke et al., 2015). While this pattern

10 broadly follows the latitudinal trend of the 0°C isotherm altitude (ZIA) of present-day mean annual air temperature (MAAT), in the southern part of the study region rock glaciers also exist at positive regional-scale MAAT levels (Brenning, 2005b; Azócar and Brenning, 2010). Rock glacier presence is furthermore constrained by topographic suitability for rock glacier development, and the scarce availability of Quaternary glacial sediments may further limit their development in the southern Limarí and northern Choapa watersheds (Azócar and Brenning, 2010). Recent geophysical investigations on rock glaciers in

15 the semi-arid Andes revealed complex internal structures and landform evolution as well as highly variable ice contents while confirming the presence of ice-rich permafrost in intact rock glaciers and the general relationship between landform appearance and presence of ground ice in this region (Monnier and Kinnard, 2015a, 2015b; Janke et al., 2015).

3 Methods

In adopting the empirical, regional-scale approach to permafrost favorability modeling of Boeckli et al. (2012a), several pre-
20 processing steps were necessary to compile the necessary data. To create a geomorphological indicator variable representing likely permafrost presence and absence, rock glaciers were mapped and then classified according to their likely activity status. Predictor variables such as Potential Incoming Solar Radiation (PISR) and MAAT were furthermore calculated. A Linear Mixed-Effects Model (LMEM) was used to regionalize point measurements of MAAT at weather stations to the landscape scale using a DEM. Finally, the Generalized Additive Model (GAM) was chosen to create a Permafrost Favorability Index

25 (PFI) for the study area, extending the Generalized Linear Modeling approach chosen by Boeckli et al. (2012a; Fig. 2).

3.1 Rock glacier inventory

In order to create a variable indicative of permafrost conditions, intact and relict rock glaciers were inventoried. Compiling, editing and extending previous inventories for the Huasco, Elqui, Limarí and Choapa watersheds (UGP-UC, 2013; Azócar, 2013), a new inventory was prepared using Microsoft's Bing Maps imagery accessible through ArcGIS 10.1. Rock glaciers

30 were identified following the criteria of classification proposed previously (Barsch, 1996; Roer and Nyenhuis, 2007; Azócar, 2013), and intact and relict rock glaciers were mainly classified following geomorphological criteria (e.g., appearance of the

rock glacier front). Because of uncertainties in this classification, the 'intact' category was considered as a whole, including active and inactive landforms. Rock glaciers were digitized as points located at the rock glacier toe using an on-screen map scale of 1:7,000.

3.2 Regionalization of mean Annual air temperature (MAAT)

5 Since MAAT strongly varies latitudinally and altitudinally throughout the study region, a statistical model was used for the regionalization of this variable. Considering the small number of, and large distances between, weather stations, no attempt was made to spatially model the residuals. The heterogeneous temporal coverage of different weather stations made it necessary to choose a model that is able to account for year-to-year temperature variations instead of regionalizing observations of MAAT directly. We therefore chose a Linear Mixed-Effects Model (LMEM) in order to relate Annual Average Temperature
10 (AAT) data to latitude and altitude as so-called fixed-effects variables while accounting for year-to-year variability by including a random-effect term for the year of observation.

3.2.1 Response and predictor variables

The response variable AAT was calculated using data from eleven weather stations for a time period of between 1 and 30 years (1981-2010), depending on data availability. AAT was calculated as the average of monthly means. Only weather stations
15 located above 2000 m a.s.l. and at least 100 km inland from the coast were selected in order to reduce oceanic influence (Hiebl et al., 2009) and focus on mountain climate. Moreover, stations located slightly north and south of the study area were also included to better represent latitudinal changes. Based on these criteria, 116 stations-years from eleven weather stations were available (Table 1).

The predictors elevation (m) and northing (coordinate in m) were used, taking elevation data from the ASTER Global Digital
20 Elevation Model (GDEM) version 2 with a 30 m x 30 m resolution and a vertical precision around 15 m (Tachikawa et al., 2011). Easting was not considered due to the limited extent of the study area in west-east direction and possible confounding with the dominant altitudinal MAAT gradient.

3.2.2. Linear Mixed-Effects Model

LMEMs are appropriate models when data is organized in hierarchical levels and observations are therefore grouped (Pinheiro
25 and Bates, 2000). Unlike ordinary linear regression models, LMEMs are able to account for the dependency among observations that arises from grouping (Twisk, 2006). In a LMEM, the predictors can contain random and fixed effects. Random effects can be thought of as additional error terms or variation in coefficients that are tied to different grouping levels. In a climatic context, this may include a year's overall departure from long-term mean temperature, for example. Fixed effects are comparable to ordinary linear regression predictors whose coefficients do not vary by group.

In this study, fixed and random effects were estimated by maximum likelihood (ML). AAT data was considered as being grouped by year (30 groups, one for each year). Thus, the following model specification of the statistical temperature distribution model $(Temp)$ for AAT at a weather station i in year j was used:

$$AAT_{ij} = b_{0j} + b_1 altitude_i + b_2 northing_i + \varepsilon_{ij} \tag{1}$$

$$b_{0j} = b_0 + u_{0j} \tag{2}$$

In this model $(Temp)$, AAT_{ij} is the AAT at a particular weather station i in a particular year j, b_0 represents the overall mean intercept of AAT, which may vary from year to year by a random amount u_{0j} whose variance is estimated during model fitting. ε_{ij} denotes the residual error for each weather station and year. Thus, the model error is split into two components, the residual variation between years (u_{0j}) and the residual variation among weather stations within a particular year (ε_{ij}).

In order to predict spatially varying MAAT based on $(Temp)$, year-to-year and station-specific residual variation were disregarded since their statistical expected value is zero, and therefore only the fixed-effects portion is used to predict the expected value of MAAT at any location x with known altitude and latitude within the study region:

$$MAAT(x) = b_0 + b_1 altitude(x) + b_2 northing(x) + \varepsilon_{ij}(x) \tag{3}$$

The overall fit of the LMEM was evaluated by examining the residual standard error (RSE) in °C. The LMEM implementation of the 'nlme' package in R was used (Pinheiro and Bates, 2000; R Core Team, 2012).

3.3 Statistical permafrost favorability model

3.3.1. Response and predictor variables

In order to create a response variable Y indicating likely permafrost presence/absence, intact rock glacier were used as indicators of permafrost presence ($Y = 1$), and relict rock glaciers as indicators of permafrost absence ($Y = 0$). MAAT predicted by the LMEM and DEM-derived PISR were used as predictor variables. Annual PISR was preferred over PISR for part of the year such as the snow-free period since detailed information on snow cover duration was not available and seasonal PISR values are highly correlated. Nevertheless, the statistical interaction (Hosmer and Lemeshow, 2000) of PISR and MAAT was included in the model; this interaction term is capable of representing temperature-dependent (altitudinal) variation in the influence of PISR on permafrost occurrence, thus capturing the effects of snow cover duration on absorbed solar radiation (Brenning and Azócar, 2010b).

The PISR, i.e. the annual sum of direct and diffuse incoming solar radiation, was calculated using SAGA GIS version 2.1.0 (Conrad et al., 2015) and ASTER GDEM data. PISR was calculated at ten-day intervals with a half-hour time resolution

between 4 a.m. and 10 p.m.; latitudinal effects were accounted for. To simulate the extremely clear and dry skies, a lumped atmospheric transmittance of 0.9 was used (Gates, 1980).

3.3.2. Generalized additive model

5   A GAM was utilized as the statistical model of permafrost favorability, and its spatial predictions are referred to as the Permafrost Favorability Index (PFI). This type of model has been applied in environmental sciences, including ecology (Guisan et al., 2002), forestry (Janet, 1998), periglacial geomorphology (Brenning and Azócar, 2010b) and landslide research (Goetz et al., 2011). A GAM can be described as a Generalized Linear Model (GLM) in which some or all of the linear predictors are specified in terms of smooth functions of predictors (Hastie and Tibshirani, 1990; Wood, 2006). Like the GLM, the GAM can be applied to model binary categorical response variables such as the presence ($Y = 1$) versus absence ($Y = 0$) of permafrost.

10   Specifically, the probability $p = P(Y = 1|MAAT, PISR)$ of permafrost occurrence given known values of the predictors MAAT and PISR can be modeled in a GAM with a logistic link function as:

$$ln\left\{\frac{p}{1-p}\right\} = \beta_0 + f_1(MAAT) + f_2(PISR) \tag{4}$$

where β_0 is the intercept and f_1 and f_2 are smoothing functions for the predictors $MAAT$ and $PISR$. The ratio $p / (1 - p)$ is referred to as the odds of permafrost occurrence, and its logarithm as the logit.

15   When an interaction term $MAAT$ and $PISR$ is included in the above equation, the model becomes:

$$ln\left\{\frac{p}{1-p}\right\} = \beta_0 + f(MAAT, PISR) \tag{5}$$

where f is a bivariate smoother. In this model, the relationship between PISR and the response may depend on MAAT, and conversely the relationship between MAAT and the response may vary with PISR.

The GAM has the advantage over the GLM that it increases model flexibility by fitting nonlinear smoother functions to the 20 predictors (Wood, 2006). In this study, the smooth terms were represented using a local regression or "loess" smoother with two degrees of freedom. In this method local linear regressions are fitted to subsets of data falling within a moving window in order to construct a function that describes a smoothly varying relationship between predictor and response. One of the advantages of this method is that assumptions about the form of the relationship are avoided, allowing the form to be discovered from the data.

25 3.3.3 Model Evaluation

The overall performance of the GAM was evaluated using the Area Under the Receiver Operating Characteristic (ROC) Curve (AUROC). In the present context the curve shows the probability of detecting observed permafrost occurrences (sensitivity) and absences (specificity) for the whole range of possible decision thresholds that could be used to dichotomize predicted odds into permafrost presence/absence (Hosmer and Lemeshow, 2000). The AUROC can range from 0.5 (no separation) to 1 30 (complete separation of presence and absence by the model).

The performance of the predictive model was evaluated using spatial cross-validation where testing and training data sets are spatially separated (Brenning, 2012). *k*-means clustering was used to partition the subsets randomly into *k*=10 equally-sized subsamples for *k*-fold spatial cross-validation. Cross-validation was repeated 100 times.

5 The model was implemented using R and its package 'gam' for generalized additive models (Hastie, 2013). Performance was assessed using the 'verification' package for ROC curves (Gilleland, 2012) and 'sperrorest' for spatial cross-validation (Brenning, 2012). PFI predictions were created using the 'RSAGA' package (Brenning, 2011).

3.3.4 Model adjustments

In order to distinguish between two surfaces with different thermal properties, bedrock and debris-covered areas were identified. This was necessary since the present model was based on rock glaciers as evidence of permafrost conditions in

10 areas with rock debris as the surface material. Therefore, the permafrost model cannot be extrapolated to non-debris surfaces such as steep bedrock slopes, which have different thermophysical properties and limited winter snow cover. A slope angle ≥ 35° in the ASTER GDEM was used to identify probable bedrock surfaces and to exclude these areas from the predictive modeling following Boeckli et al. (2012b). Although bedrock exposures may be found on gently inclined terrain, we disregarded these and tentatively classified slopes less steep than 35° as debris zones.

15 While rock glaciers are commonly used as indicators of permafrost conditions in mountain regions, they are also known to overestimate permafrost distribution in adjacent debris-covered areas for several reasons including (1) a cooling effect in coarse blocky material that is often present on the surface of rock glaciers, (2) the long-term creep of rock glaciers downslope into non-permafrost terrain, and (3) a delayed response of ice-rich permafrost to climatic forcings (Boeckli et al., 2012b). Boeckli et al. (2012b) suggest that the last two effects can be compensated by the use of a temperature offset term. However, the first

20 effect cannot be easily accounted for due to the lack of information about surface characteristics of rock glaciers. Nevertheless, qualitatively speaking, in our experience surface grain size of rock glaciers in the semi-arid Andes is not necessarily much different from surrounding areas, and the complexity of relationships between the structure of the surface layer and thermal characteristics makes it difficult to estimating the size of this potential bias (Brenning et al., 2012).

In this research, a temperature offset term was applied to estimate the above-mentioned effects (2) and (3). It was approximated

25 by the mean altitudinal extent of rock glaciers, which was derived from the mean slope angle and mean length of rock glaciers inventoried by Azócar (2013) and UGP UC (2010). The calculated mean altitudinal extent was 89 m, which corresponds to a temperature offset of -0.63 °C, using the lapse rate of -0.0071°C m^{-1} obtained in this work. This temperature offset was chosen and added to MAAT values (renamed as 'adjusted MAAT') prior to permafrost model fitting. In other words, the adjusted MAAT used for model fitting was made 0.63°C cooler, while using the warmer original MAAT for prediction; this effectively

30 shifts the high PFI values towards higher elevations.

4. Results

4.1 Rock glacier inventory

Information on 3575 rock glaciers was compiled based on existing inventories and the identification of additional rock glaciers in the study area. Of these, 1075 were classified as active, 493 as inactive, 343 as intact and 1664 as relict forms. Active rock

5 glaciers are present at altitudes above 3349 m a.s.l. in the study area. They are most abundant in the Elqui (*n*=463), Huasco (*n*=252) and Limarí (*n*=224) watersheds.

The majority of rock glaciers (~60-80 %) are located below the present ZIA obtained in this study from the LMEM of temperature, and 37 % of active, 21 % of inactive, 26 % intact and 15% of relict rock glaciers are located above the ZIA. However, these proportions vary considerably between watersheds. In the Huasco and Elqui watersheds, nearly 50% of all

10 active rock glaciers are located at negative MAAT compared to less than 20 % in the Limarí and Choapa watersheds in the southern part of the study area (Fig.3).

Of the 3575 rock glaciers in the inventory, 51 were removed from the data set due to their isolated or unusual location in order to prevent these from becoming influential points. Of the remaining 3524 rock glacier observations, 1909 were used as indicators of permafrost, and 1615 as indicators of the absence of permafrost. In general MAAT and PISR values at sites with

15 permafrost were lower than the sites without permafrost. Exploratory analysis showed a clear trend towards a greater presence of intact rock glaciers at lower MAAT and lower PISR.

4.2 Mean annual air temperature model

Model coefficients indicate an average lapse rate of -0.71 °C per 100 m while accounting for latitude and year-to-year variation (95 % confidence interval: -0.68 to -0.74 °C per 100 m; Table 2). With every 200 km of northward distance, the AAT increased

20 on average by 1.6 °C (95 % confidence interval: 1.4-1.8 °C). Therefore, there is a 4 °C MAAT difference between the northern and southern border of the study area at equal elevations. Based on the fitted model, regional-scale MAAT was predicted using the Eq.:

$$MAAT = -23.87 - 7.11 \times 10^{-3} altitude\ [m] + 8.06 \times 10^{-6} northing\ [m] \tag{6}$$

As a measure of precision of the AAT distribution model, the RSE was 0.44°C (95 % confidence interval: 0.26-0.76 °C) for

25 year-to-year variation and 0.93 °C (95 % c.i.: 0.8-1.08 °C) within years and between stations (Table 2). According to the model the ZIA was situated at ~4350 m a.s.l. in the northern (29°S) section and dropped southward to ~4000 m a.s.l. at 32 °S (Fig. 4).

4.3 Statistical permafrost favorability model

According to the model results, at a regional-mean PISR, locations with a MAAT of +1°C were associated with ~33 % lower

30 odds of permafrost occurrence compared to 0°C MAAT. At extremely sunny sites with PISR two standard deviations above

the regional average, by comparison, the same MAAT contrast was associated with a ~73 % decrease in the odds of permafrost occurrence.

Similarly, a large PISR had a greater estimated effect at higher MAAT levels than at lower MAAT. At -1 °C MAAT, a PISR value one standard deviation above the average PISR was associated with approximately 27 % lower odds of permafrost occurrence compared to average PISR, while the same PISR difference at +1 °C MAAT was associated with an estimated 57 % decrease in the odds of permafrost occurrence.

Based on spatial cross-validation estimation of the GAM's overall accuracy using a decision threshold of 0.5, 64 % of observations indicating permafrost conditions were correctly classified by the model (sensitivity: 58 %; specificity: 78 %). Spatially cross-validated AUROC confirmed this acceptable performance (median AUROC: 0.76), and the comparison with non-spatial cross-validation results (median AUROC: 0.75) suggests that the GAM generalized well from the training data.

4.3.1 Spatial distribution of PFI

Considering a PFI ≥ 0.5 and excluding steep bedrock and glacier surfaces, site conditions favorable for permafrost occurrence were inferred for ~6.8 % of the study area, or 2636 km². Considering only highly favorable conditions with a PFI ≥ 0.75, the potential permafrost area would be limited to 2.7 % of the area, or 1051 km² (Table 3). The largest potential permafrost areas were concentrated in the Huasco and Elqui watersheds where the PFI ≥ 0.5 covers more than 10 % of each watershed (1150 km² in the Huasco; 1104 km² in the Elqui). In the Limarí and Choapa watersheds, areas with PFI ≥ 0.5 represented less than 3 % of each watershed (Limarí: 217 km²; Choapa: 192 km²).

The spatial distribution of the predicted PFI in the study area is depicted in Fig. 5. In general, the potential permafrost areas tend to decrease southward. More favorable conditions were concentrated in the highest areas in the central part of the study area (e.g., Pascua-Lama area, Cerro El Toro 6168 m a.s.l., Las Tórtolas 6160 m a.s.l., Olivares 6216 a.s.l.). On the other hand, lower scores (< 0.5) were associated with lower hillslopes and valley bottoms.

5. Discussion

5.1 Rock Glacier Inventory

The rock glacier inventory prepared for this work expands our previous knowledge of rock glacier distribution in the semiarid Andes as it adds rock glaciers to previous compilations that were mostly based on lower-quality imagery or statistical sample surveys (Azócar and Brenning, 2010a; Nicholson et al., 2009; UGP-UC 2010).. In particular, in the Elqui, Limarí and Choapa watersheds, the present inventory increases the number of known active rock glaciers from 581 to 933 (increase 60%), inactive rock glaciers from 151 to 415 (increase 75%) and intact rock glaciers from 135 to 249 (increase 84%) within of these watersheds. Moreover, this work added relict rock glaciers (n = 1664), which were missing from previous inventories (Nicholson et al., 2009; UGP-UC, 2010) and which were mapped for the first time systematically throughout this study area.

This has been possible because in the current research, rock glaciers are recognized using images with better resolution than in previous studies, allowing the identification of small landforms (below 0.1 km²).

The considerable proportion of intact rock glaciers located at (present, regional-scale) MAAT above 0°C is confirmed by this study. It has previously been attributed to the delayed response of ice-rich permafrost to MAAT increases since the Little Ice

5   Age, rock glacier advance towards lower elevations, and the possible preservation of ice-rich mountain permafrost in favorable local topoclimatic conditions (Azócar and Brenning, 2010; Boeckli et al., 2012b). The interaction of permafrost with buried glacier ice from Holocene / Little Ice Age glacier advances may play an additional important role in the development of rock glaciers in these areas (Monnier and Kinnard, 2015a).

5.2. Temperature distribution model

10   The temperature distribution model indicated a present (1981-2010 mean) ZIA at ~4350 m a.s.l. at 29 °S, which drops southward to ~3900 m a.s.l. at 32°S. Although the result cannot be directly compared with other studies that may refer to different time periods or provide only general statements, our ZIA is somewhat higher than previously thought (Brenning, 2005a; ZIA ~4000 m at 29° S, ~3750 at 32° S). The environmental lapse rate obtained in this study (-0.71 °C per 100 m) is reasonably close to the average temperature decrease in the free atmosphere (~ -0.6 °C per 100 m; Barry, 1992).

15   The precision (RSE) of the MAAT distribution model of 0.8-1.08 °C (with 95 % confidence) highlights important uncertainties in this key predictor of permafrost favorability in this region. Nevertheless, this level of uncertainty is comparable to MAAT products used in permafrost distribution models for the European Alps (RSE <1°C in Hiebl et al., 2009) and at a global scale (RSE ≈ 1 °C in Gruber et al., 2012). Compared to other studies that had only very limited access to high-elevation weather data from the high Andes, our approach focused on incorporating all available high-elevation data into a locally calibrated

20   regionalization in order to avoid an over-reliance on assumed or extrapolated lapse rates. Still, the available temperature data over-represented non-permafrost altitudes, underlining the need for increased weather observation efforts at high elevations.

5.3 Permafrost favorability model

Debris areas with a permafrost favorability score ≥ 0.5 in our study cover a spatial extension of 6.8 % (2636 km²) of the study area. Although the model includes the main factors that control the regional distribution of permafrost in the semi-arid Chilean

25   Andes, such as the temperature and the potential amount of solar radiation in relation to the altitude and latitude (Azócar and Brenning, 2010), the permafrost model does not account for the effect of specific local environmental factors in debris areas, such as spatially variable soil properties and the effects of long-lasting snow patches that can influence ground thermal regimes locally (Hoelzle et al., 2001; Apaloo et al., 2012). Therefore, all these local factors must be considered when interpreting PFI values (Boeckli et al., 2012b). In the Andes of Santiago directly south of the study region, for instance, 30 days of additional

30   snow cover in spring/summer were associated with 0.1-0.6 °C lower mean ground surface temperatures (MAGST), while openwork boulder surfaces were about 0.6-0.8 °C cooler than finer debris (Apaloo et al., 2012).

In summary, our model suggests that in areas with PFI ≥ 0.75, permafrost will occur in almost all environmental conditions; in contrast, in areas where PFI ranges between 0.5 and 0.75, permafrost will be present only in the favorable cold zones described before. In areas with PFI < 0.5, permafrost may be present in exceptional local environmental circumstances.

Comparisons of modeled permafrost distribution with independent ground-truth observations is naturally difficult due to the

5   bias toward permafrost presence sites and sampling design (Boeckli et al., 2012b). Such comparisons were therefore not performed in this study. Direct permafrost observations outside of rock glaciers are still scarce in the semi-arid Andes and mostly limited to unpublished data from a mining context. Additional systematic ground-truthing is therefore required for a quantitative assessment of permafrost extent and to reduce model uncertainties (Lewkowicz and Ednie, 2004). Model-model comparisons are therefore currently the only means for assessing uncertainties in permafrost distribution.

The permafrost zonation index (PZI) of Gruber (2012) is an independent global-scale empirical modeling effort at a 1 km x 1 km resolution based on downscaled reanalysis data and within-pixel relief. For comparison, PFI was resampled to PZI resolution (1 km) by averaging all PFI pixels that fall within a given PZI pixel (Azócar, 2013). While we do not suggest that equivalent PZI and PFI values should be interpreted the same way, it should be pointed out that potential permafrost areas with

15   a PZI ≥ 0.75 are substantially smaller (209 km², including exposed bedrock areas) than the areas with PFI ≥ 0.75 predicted by our approach (1051 km²), even though the latter only considers debris surfaces. Even PZI ≥ 0.50 covers only 653 km². Since vast areas with active rock glaciers present PZI values below 0.50, we conclude that the PZI is a very conservative measure of permafrost favorability in this region. However, more research is needed to confirm the appropriateness of the bias adjustment used in this and earlier rock glacier based studies (Boeckli et al., 2012) and thus the adequate calibration of such models.

20   Overall, compared to previous empirically based studies (Lewkowicz and Ednie, 2004; Janke et al., 2005; Boeckli et al, 2012a,b; Sattler et al., 2016), the permafrost modelling approach used in this work integrates the regionalization of MAAT distribution from scarce data with more flexible, nonlinear models of potential permafrost distribution in comparison with previous research approaches.

In this study, the discrimination of rock glacier classes based on PFI values results in an AUROC of 0.76 which is similar to

25   the AUROC value obtained in recent permafrost modeling studies in the Alps (Boeckli et al., 2012b). Other studies have reached AUROC values ≥ 0.9 (Deluigi and Lambiel, 2012; Sattler et al., 2016), which means nearly perfect separation. However, in logistic regression such high AUROC values may result in numerical difficulties in the estimation of logistic regression coefficients (Homer and Lemeshow, 2000), and in the case of Sattler et al. (2016) the high value may be explained by the omission of inactive rock glaciers as a permafrost landform located in topographic conditions between active and relict

30   ones.

5.4 Permafrost distribution and effects of climate change

According to the PFI model, mountain permafrost in the semi-arid Chilean Andes between 29° and 32° S is widespread above ~4500 m a.s.l. and more scattered between ~3900 and 4500 m a.s.l. Permafrost areas near the lower limit of permafrost

distribution can be more sensitive to degradation processes due to the possible effects of climate change (Haeberli et al., 1993) considering also its location at or near the present ZIA. A rise in air temperature can potentially lead to permafrost thaw and long-term degradation of ice-rich frozen ground (e.g., intact rock glaciers) as well as the acceleration and sudden collapse of rock glaciers (Schoeneich et al., 2015). In addition, this warming could lead to geotechnical problems related to high-altitude

5   road or infrastructure (Brenning & Azócar, 2010a; Bommer et al., 2010). Moreover, an increase in debris flow and rockfall activity would be expected and has been reported elsewhere (Haeberli et al., 1993; Gruber and Haeberli, 2007). In this context, PFI maps can serve as a first resource to assess permafrost conditions and uncertainties in mountain research and practical applications such as infrastructure planning (Boeckli et al., 2012b).

6. Conclusion

10   The statistical permafrost distribution model proposed here provided more detailed, locally adjusted insights into mountain permafrost distribution in the semi-arid Chilean Andes compared to previous coarser-resolution results from a global permafrost distribution model such as PZI (Gruber, 2012). General climatic and topographic patterns proved to be useful for mapping broad permafrost distribution patterns while local environmental factors (such as substrate properties or snow cover duration) which are not included in the model, could determine permafrost presence locally.

15   Data from rock glacier inventories combined with topographic and topoclimatic attributes were used to model the probability of permafrost occurrences in the semi-arid Chilean Andes. The GAM is particularly suitable for modeling these relationships due to its ability to incorporate nonlinear relationships between predictor and response variables.

Using rock glaciers as indicators of permafrost conditions in areas with debris as surface material, the result of the permafrost model cannot be extended to other types of surface covers. Therefore, future studies should address this limitation in order to

20   determine potential permafrost areas in steep bedrock. Furthermore, the effect of a delayed response of rock glaciers with high ice content to climate forcings should be considered in future analyses along with systematic direct ground-truthing of permafrost occurrence outside of rock glaciers.

On the other hand, the results of the MAAT model show that LMEMs can be appropriate to determine temperature distribution with scarce and heterogeneous temperature records from weather stations. Moreover, the results of the MAAT model can

25   provide valuable data to study other climatically-driven Earth surface features such glacier and vegetation patterns.

7. Data availability

The PFI and MAAT prediction maps are available for downloading and visualizing at www.andespermafrost.com Moreover, the rock glaciers inventory is accessible for downloading. Alternative, the data can be downloaded through Pangaea server: https://doi.pangaea.de/10.1594/PANGAEA.859332

Acknowledgements

We thank the Dirección General de Aguas (DGA) of Chile for providing rock glacier inventories and weather data and for funding the compilation of rock glacier inventories by the authors in an earlier project. We acknowledge funding received from CONICYT Becas Chile, University of Waterloo and NSERC through scholarships awarded to G. Azócar and a Discovery

5   Grant awarded to A. Brenning.

[1]Areal extent of watersheds including low elevation areas: Huasco 9766 km², Elqui 9407 km², Limarí 11683 km², Choapa

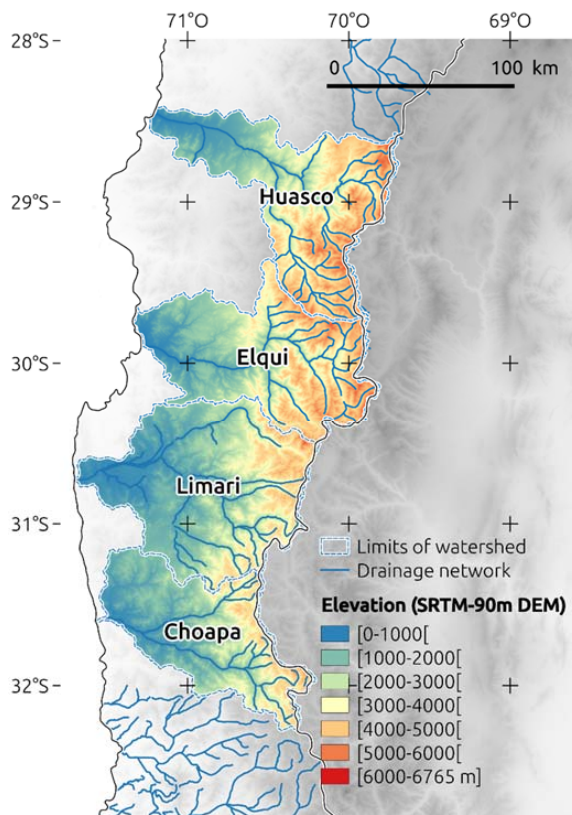
5   7795 km².


Figure 1: Altitudinal and hydrographic characteristics of the study area.
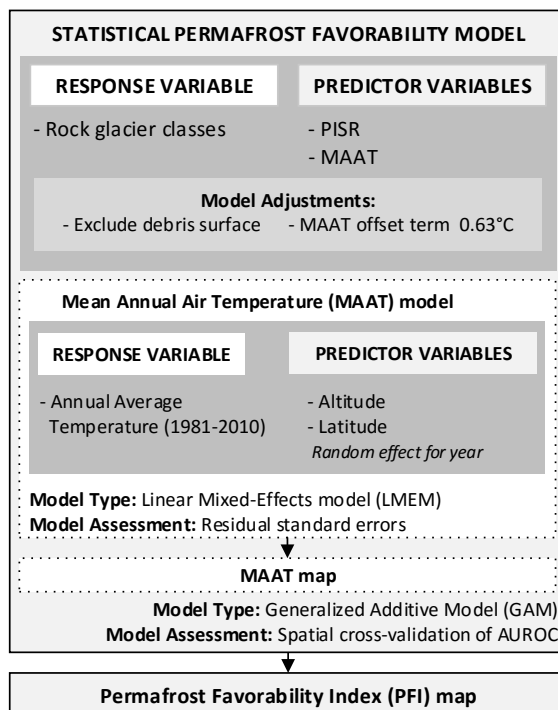

Figure 2: General methodological framework of permafrost favorability and MAAT models.
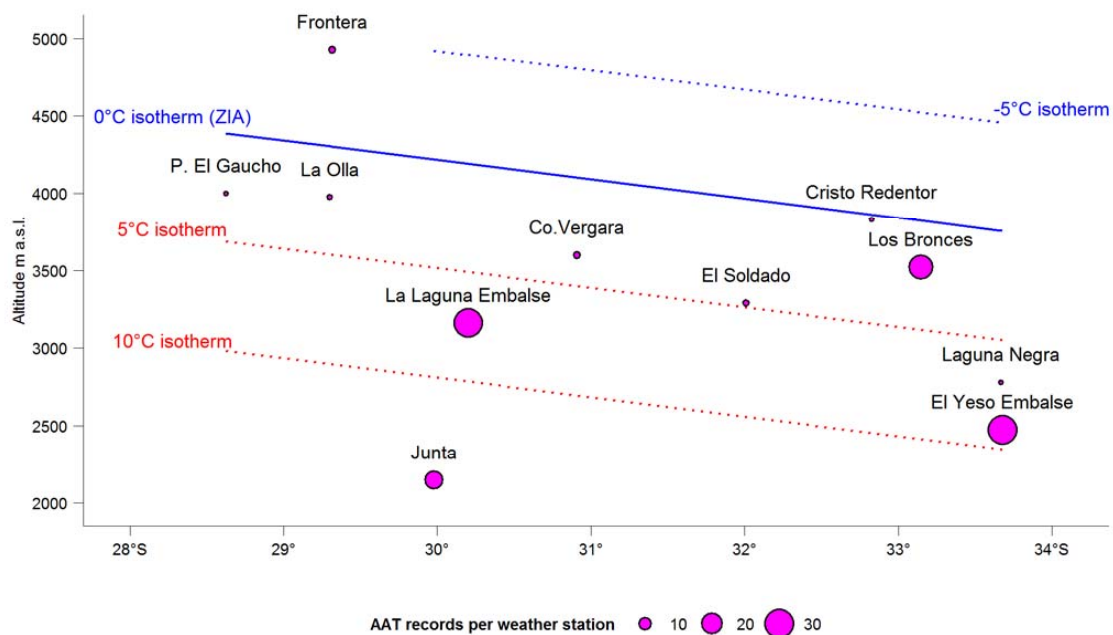
Figure 3: Proportion of active (1), inactive (2), intact (3) and relict (4) rock glaciers located below (+MAAT) and above (-MAAT) the 0°C MAAT isotherm altitude (ZIA) within each watershed.


Figure 4: Altitudinal and latitudinal distribution of modeled AAT (lines) and AAT records per weather station.
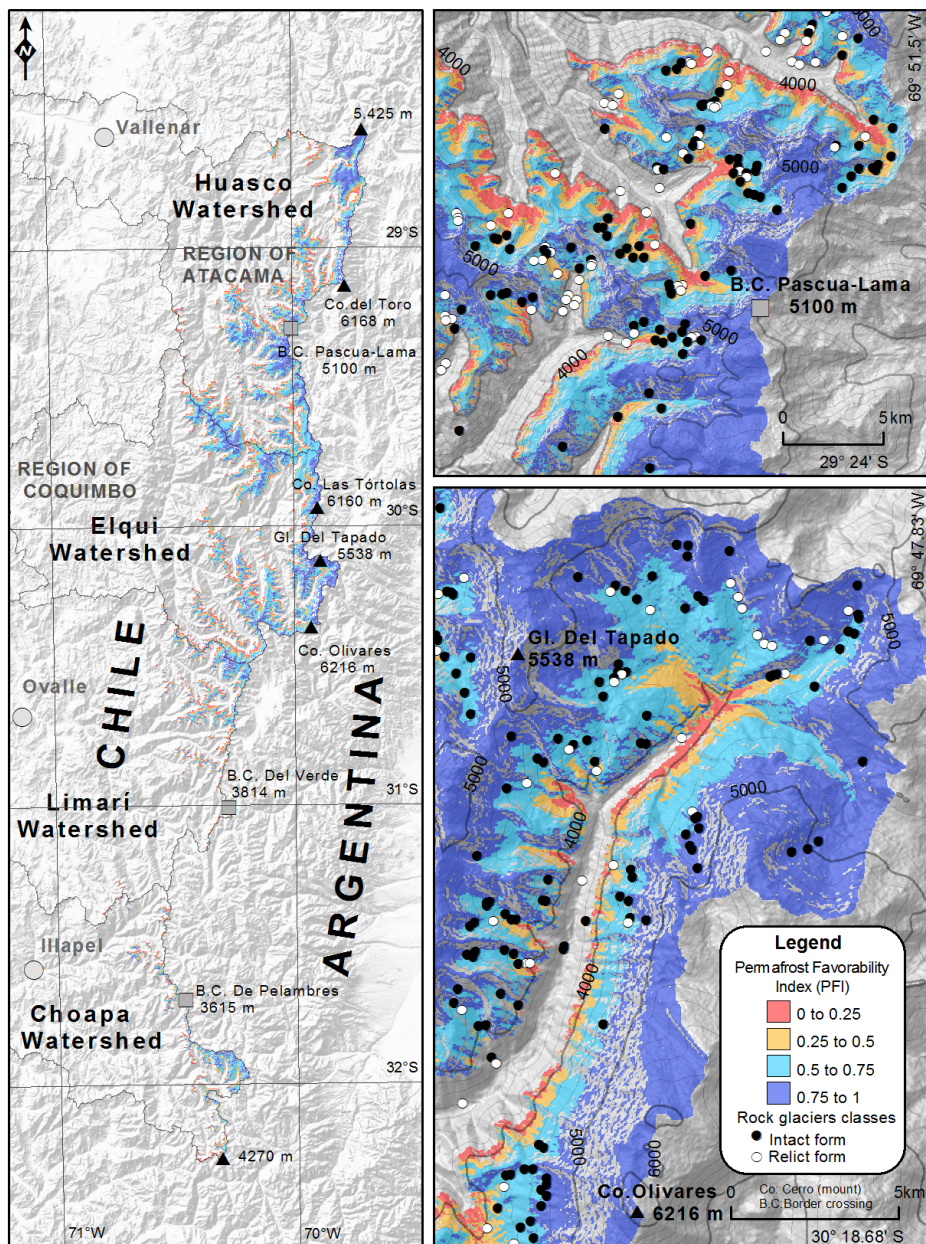

Figure 5: Permafrost favorability index (PFI) map of the semi-arid Chilean Andes based on the permafrost distribution model for debris areas.
