### 21 **1 Surface energy balance model**

22 Daily ablation from the basic model based on the PDD approach was calibrated with  
23 surface energy balance values computed for a horizontal surface using the [Favier \*et al.\*](#)

24 (2011) approach from March 14, 2002 to August 31, 2003 (Figure S1) and from January 1,  
25 2005 to November 30, 2005. The energy used for melting or stored in the top layers of the  
26 glacier was calculated as (fluxes toward the surface are positive) (Favier *et al.*, 2011; Azam  
27 *et al.*, 2014):

28

$$29 \quad S\downarrow + S\uparrow + L\downarrow - ((1 - \epsilon) L\downarrow + \epsilon \sigma T_s^4) + LE + H = Q_{\text{surface}} \quad (\text{in W m}^{-2}) \quad (3)$$

30

31 where  $S\downarrow$  is incoming shortwave radiation,  $S\uparrow$  is reflected short-wave radiation;  $L\downarrow$   
32 is incoming long-wave radiation and the term in brackets is outgoing longwave radiation  $L\uparrow$ ;  
33  $H$  and  $LE$  are respectively, turbulent sensible and latent heat fluxes, which were computed  
34 using the bulk method including stability corrections based on the bulk Richardson number.  
35 We used the surface roughness length given by Favier *et al.* (2004a) considering the equality  
36 of values for momentum, moisture, and temperature. Air temperature and humidity were  
37 measured using an artificially ventilated HMP45 Vaisala sensor and wind speed was  
38 measured using a Young 05103 anemometer (Table 1). The incoming radiative fluxes and  
39 the albedo were measured locally at 4,900 m a.s.l. on Antizana Glacier 15 with a CNR1  
40 Kipp & Zonen net radiometer.  $L\uparrow$  was deduced from the modeled surface temperature  $T_s$  and  
41 Stefan-Boltzmann's equation, where  $\epsilon = 0.99$  is surface emissivity, and  $\sigma = 5.67 \cdot 10^{-8} \text{ W m}^{-2}$   
42  $\text{K}^{-4}$  is the Stefan-Boltzmann constant. The heat flux supplied by precipitation was not taken  
43 into account because during precipitation the temperature is always close to 0 °C.

44

45  $Q_{\text{surface}}$  is the energy available at the surface. Part of the net shortwave radiation ( $S$ )  
46 is actually not available for warming/cooling processes at the surface or for melting, because

47 the shortwave flux partly penetrates the ice. Hence,  $Q_{\text{surface}}$  is separated into two terms:

48

$$49 \quad Q_{\text{surface}} = G_0 + (1 - a) S \quad (\text{in } \text{W m}^{-2}) \quad (4)$$

50

51 where  $G_0$  is energy excess or deficit at the surface. In this equation,  $a$  is the fractional  
52 amount of shortwave radiation that is absorbed in the top layer of the model (at the surface).

53 We assumed  $a = 0.8$  for ice and  $a = 0.9$  for snow (e.g., [Bintanja et al. 1997](#)). When the  
54 surface temperature is  $0^\circ\text{C}$ , the positive  $G_0$  values represent the energy available for melt.

55 Otherwise, this amount is used to cool/warm the frozen surface and underlying snow/ice.

56 For this task, heat conduction within the snow or ice was computed by solving the thermal  
57 diffusion equation according to an explicit scheme to a depth of 2 m, with a 5 cm grid

58 resolution and a 20 s time step.

59

60 Calculations were validated using the melting amounts measured by the melting  
61 boxes (Figure S2c). Our results were in better agreement with measured melting amounts  
62 than results from [Favier et al. \(2004\)](#), with a correlation coefficient of  $r = 0.91$  (instead of  
63  $0.86$ ). The regression line was also closer to the 1:1 line (slope of  $1.01$  instead of  $0.89$ ). The

64 model was also validated using mass balance measurements performed on ablation stakes.

65 Because the ablation zone presents a significant slope ( $28^\circ$ ) and aspect (NW) for this  
66 elevation range, the surface energy balance model was run with these settings from March

67 14, 2002 to August 31, 2003. The computed monthly mass balance values were highly  
68 consistent with the mass balance values measured on the stakes ( $r = 0.90$ ,  $n = 18$ ,  $p = 0.001$ ,

69  $E = 0.79$ , Figure S2).

70

## 71 2 Correlation analysis

72 The daily and monthly mean values of temperature and of energy fluxes of AWS<sub>GI</sub>,  
73 from March 14, 2002 to August 31, 2003 were used for the correlation analysis presented in  
74 Supplementary Section 1.1.1 and 1.1.2.

### 75 2.1 Correlation at a monthly time scale

76 We first calculated the correlations between incoming energy fluxes, precipitation,  
77 and temperature at a monthly time scale for the period March 2002 to August 2003 for  
78 which all surface energy fluxes were available (Table S1). Correlation coefficients were also  
79 computed with wind speed because this variable has a marked impact on ablation processes  
80 on Antizana Glacier 15. The cumulative half-hourly positive temperature values over one  
81 month are noted  $T^+$ .

82 At the AWS<sub>GI</sub> monthly mean temperature was usually poorly correlated with the  
83 incoming energy fluxes ( $S\downarrow$ ,  $L\downarrow$ ,  $LE$ ,  $H$ ). However, correlations with  $S\uparrow$  and  $L\uparrow$  were more  
84 significant than for incoming fluxes, which reflected the impact of low temperature on high  
85 albedo values and on reduced melting. Interestingly, wind velocity was also correlated with  
86 local incoming fluxes (Table S1), but, surprisingly, wind speed was not correlated with  
87 albedo, net radiation, or melting (Table S1). In fact, variations in incoming fluxes were not  
88 able to explain the variations in melting (Table S1). Melting was almost totally controlled by  
89 variations in albedo (Table S1, see also correlations between melting and  $S$  and the net  
90 radiation ( $R$ )). Significant correlations were found between precipitation and  $S$  and albedo,  
91 suggesting that precipitation is a key variable when modeling mass balances in Ecuador.

92 Finally, a significant correlation was found between  $T^+$  and melting. This link was

93 already suggested by results obtained by Francou *et al.* (2004) (between January 1995 and  
94 December 2002), who proposed that monthly temperature and solid precipitation had a first  
95 order control on albedo variations on Antizana Glacier 15 specific mass balance.

## 96 **2.2 Correlation at a daily time scale**

97 Over the 2002-2003 period, net shortwave radiation was by far the most important  
98 variable involved in melting processes ( $r = 0.88$ ,  $n = 530$ ,  $p = 0.001$ ) (Table S2, see also  
99 [Favier \*et al.\* \(2004a&b\)](#) for details). Thus, melting may only be quite accurately modeled  
100 with this variable. Reproducing albedo variations is thus crucial over Ecuadorian glaciers.  
101 Here we observed that daily albedo values were only significantly correlated with daily  
102 temperature (even if the correlation was rather poor i.e.  $r = -0.53$  with  $T$  or with cumulative  
103 half-hourly positive temperature over one day,  $T^+$ , at  $p = 0.001$ ), reflecting the important  
104 impact of the  $0\text{ }^{\circ}\text{C}$  level on the precipitation phase and explaining why melting is also  
105 significantly correlated with temperature ( $r = 0.62$ , with  $T$  and  $T^+$ ). Conversely, no  
106 correlations were found between melting and wind speed or precipitation (Table S2).  
107 Writing a model based on daily temperature variations thus appears to some extent justified  
108 here.

109 To go a step further in this analysis, we investigated whether the correlations  
110 between temperature and melting or incoming heat fluxes remained constant over the year,  
111 or depended on meteorological conditions closely related to wind speed.

112 We observed that the correlations between temperature,  $S\downarrow$ ,  $L\downarrow$ ,  $LE$  or  $H$  and melting  
113 were effectively influenced by strong winds. Indeed, when we divided the study period  
114 according to wind speed (i.e. windy Period 1 versus calm Period 2),  $S\downarrow$  and  $L\downarrow$  (which were  
115 together significantly correlated ( $r = -0.73$ ,  $n = 530$ ) due to the impact of clouds) were

116 significantly correlated with T and with melting in Period 2 (Table S2), and during days with  
117 low-speed winds that sometimes occurred during Period 1 (i.e., when the wind speed,  $\bar{u}$ , was  
118 less than  $4 \text{ m s}^{-1}$ ). Indeed, on calm days, the turbulent heat fluxes and the resulting air  
119 mixing were not strong enough to affect the relationship between enhanced  $S\downarrow$ , melting, and  
120 surface warming. However, this relationship collapsed with strong winds because turbulent  
121 heat fluxes played an increasing role in the surface heat budget that controlled the melting  
122 processes.

123         These observations were confirmed by a detailed analysis of the relationships  
124 between cumulative half-hourly positive temperatures and the various energy balance fluxes  
125 on selected days when direct field melting measurements were available (Figure S3).  
126 Indeed, the cumulative hourly positive temperature values were significantly correlated (at  $p$   
127 = 0.001) only with incident shortwave radiation and with the net shortwave radiation during  
128 calm periods. When turbulent fluxes were strong due to strong winds, these correlations  
129 disappeared.

130         In conclusion, moderate but significant (at  $p=0.001$ ) correlations between air  
131 temperature,  $S$  and albedo, do exist and correlations between temperature and  $S\downarrow$  are  
132 significant but only during low-speed wind periods.

### 133 **2.3 Correlation between sublimation and wind speed**

134         Turbulent heat fluxes are difficult to estimate with temperature, but  $LE$  was  
135 significantly correlated with the daily wind speed ( $r = -0.79$ ,  $n = 530$ ,  $p = 0.001$ , see Table  
136 S2). This rather high correlation was already used by [Favier \*et al.\* \(2008\)](#) and [Soruco \*et al.\*](#)  
137 [\(2009\)](#) to assess sublimation on glaciers. The regression line between the daily wind speed  
138 and turbulent latent heat flux enables daily sublimation to be written as follows:

139

140 
$$\text{Sublimation} = LE*24*3600 / L_s = -5.73 u \quad (\text{in kg m}^{-2} \text{ or mm w.e.}) \quad (7)$$

141

142 where  $u$  is daily mean wind speed (in  $\text{m s}^{-1}$ ) and  $L_s$  is latent heat constant for  
143 sublimation ( $2.834 \cdot 10^6 \text{ J kg}^{-1}$ ). Application of this equation gives a cumulative sublimation  
144 of 446 mm w.e. in 2002-2003 (530 days), compared to 420 mm w.e. given by computing the  
145 full turbulent heat fluxes. In 2002-2003, this simple model for sublimation presented an  
146 efficiency of  $E = 0.58$  with sublimation values given by the bulk method. Equation (7) was  
147 validated using data from 2005. The correlation between estimated sublimation and the  
148 results of the computation of full turbulent heat fluxes was still significant ( $r = 0.78$ ,  $n =$   
149  $334$ ,  $p = 0.001$ ), and a similar cumulative sublimation amount was observed with the  
150 simplified method (250 mm w.e.) and with the bulk method (284 mm w.e.). Finally, the  
151 Nash test gave  $E=0.53$ , which is still acceptable given the simplicity of our relationship.

152

153 **Supplementary Tables**

154 Table S1: Correlation coefficients ( $r$ ) computed between monthly temperature, cumulative  
 155 half-hourly positive temperature ( $T^+$ ), precipitation, and the different incoming energy  
 156 fluxes measured at  $AWS_{GI}$  between April 2002 and August 2003. Correlation coefficients  
 157 that are significant at  $p=0.001$  level are in bold.

Table S2: Correlation coefficients ( $r$ ) computed between daily temperature, cumulative half-hourly positive temperature ( $T^+$ ), melting ( $\Delta Q$ ), wind speed ( $u$ ) and the different energy fluxes measured at AWS<sub>G1</sub> from March 14, 2002 to August 31, 2003 period (n = 530 days). The period with high speed winds (Period 1) and low speed winds (Period 2) (P1 and P2 in the Table) represent 240 and 290 days, respectively. Additional separation is done for Period 1 to keep observations with low speed winds (see data in brackets). Selected days were when the mean 7-day running mean of wind speed was less than 4 m s<sup>-1</sup> (51 days). Correlations in bold are significant at p = 0.001.

## Supplementary Figures

Figure S1: Comparison between cumulative melting rates from Favier et al., (2004) and melting rates computed using Favier et al. (2011) full surface energy balance computation. The correlation coefficient is between daily melting rates of both methods.

Figure S2: Comparison between measured (circles) and modeled (black lines) surface mass balance and using the full surface energy balance approach in Favier et al. (2011) (values expressed in m of ice). Results are for 4,900 m a.s.l from March 14, 2002 to August 31, 2003. The gray line represents the level of snow assuming a density of  $200 \text{ kg m}^{-3}$ .

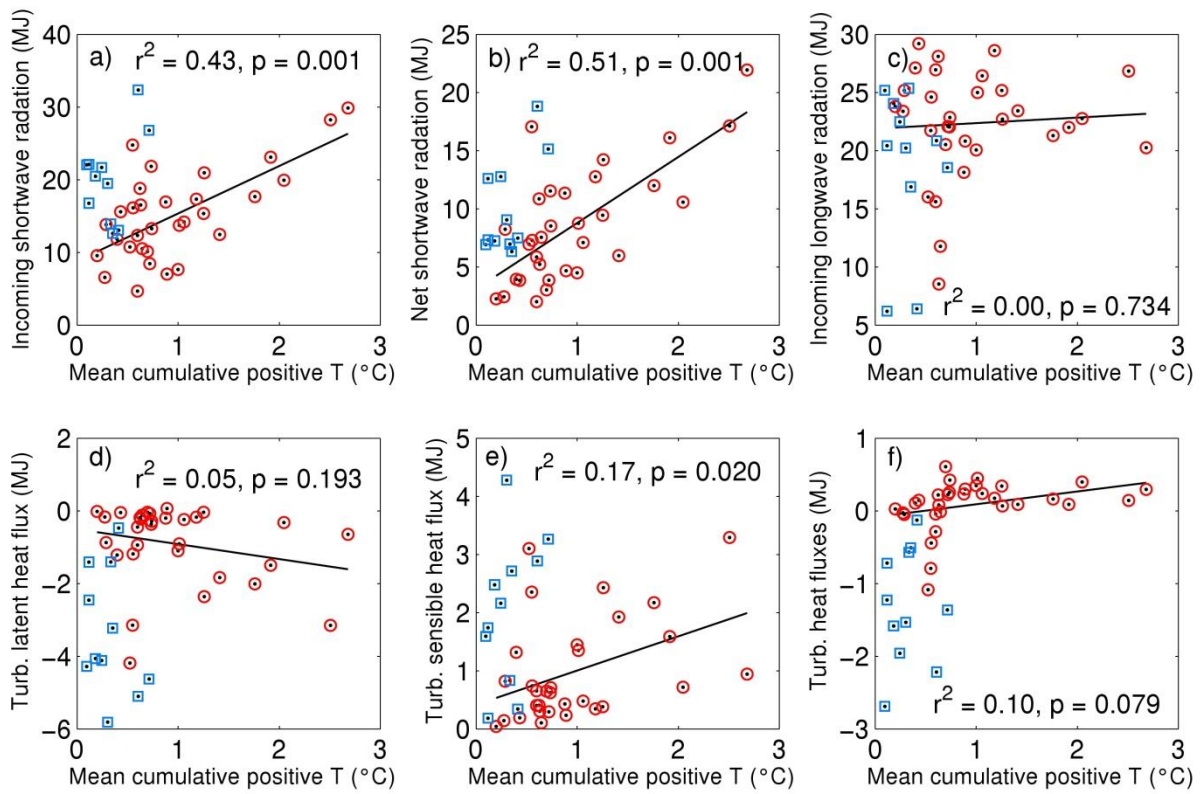

Figure S3: Comparison between the mean cumulative half-hourly positive temperature values in the melting box experiments and a) incoming shortwave radiation, b) net shortwave radiation, c) incoming longwave radiation, d) turbulent latent heat flux, e) turbulent sensible heat flux, and f) turbulent heat fluxes (LE+H). Blue squares refer to Period 1 (windy period) and red circles refer to Period 2. The determination lines and coefficients correspond to data for Period 2 only.
