8 **Abstract**

9 A new methodology for retrieval of glacier and ice sheet elevations and elevation changes from  
10 CryoSat-2 data is presented. Surface elevations and elevation changes determined using this  
11 approach show significant improvements over ESA's publically available Cryosat-2 elevation  
12 product (L2 Baseline-B). The results are compared to near-coincident airborne laser altimetry  
13 from NASA's Operation IceBridge and seasonal height amplitudes from the Ice, Cloud, and  
14 Elevation Satellite (ICESat).

15 Applying this methodology to CryoSat-2 data collected in Interferometric Synthetic  
16 Aperture mode (SIN) over the high relief regions of the Greenland ice sheet we find an  
17 improvement in the root-mean-square-error (RMSE) of 27% and 40% compared to ESA's L2  
18 product in the derived elevation and elevation changes, respectively. In the interior part of the  
19 ice sheet, where CryoSat-2 operates in Low Resolution Mode (LRM), we find an improvement in  
20 the RMSE of 68% and 55% in the derived elevation and elevation changes, respectively. There  
21 is also an 86% improvement in the magnitude of the seasonal amplitudes when compared to  
22 amplitudes derived from ICESat data. These results indicate that the new methodology provides

23 improved tracking of the snow/ice surface with lower sensitivity to changes in near-surface  
24 dielectric properties.

25 To demonstrate the utility of the new processing methodology we produce elevations,  
26 elevation changes and total volume changes from Cryosat-2 data for the Greenland Ice Sheet  
27 during the period Jan-2011 to Jan-2015. We find that the Greenland Ice Sheet decreased in  
28 volume at rate of  $289 \pm 20 \text{ km}^3 \text{ a}^{-1}$ , with high inter-annual variability and spatial heterogeneity in  
29 rates of loss. This rate is  $65 \text{ km}^3 \text{ a}^{-1}$  more negative than rates determined from ESA's L2  
30 product, highlighting the importance of Cryosat-2 processing methodologies.

## 31 1 - Introduction

32 The European Space Agency (ESA) launched CryoSat-2 in April 2010 tasked with monitoring  
33 the changes of the Earth's land and sea ice. CryoSat-2 carries a new type of Doppler/delay  
34 radar altimeter (Raney, 1998) referred to as SIRAL (SAR Interferometric Radar Altimeter).  
35 SIRAL operates in two different modes over land ice. Over the interior part of the ice sheets it  
36 operates as a conventional pulse limited radar system, referred to as the "Low Resolution  
37 Mode" (LRM). In more complex high-sloping terrain the system uses a novel second antenna to  
38 operate in "Interferometric Synthetic Aperture Radar" (SIN) mode. This new feature allows the  
39 satellite to monitor changes in complex terrain including ice caps, glaciers and the high relief  
40 marginal areas of the ice sheets. Such areas are sensitive to changes in climate and contribute  
41 greatly to current rates of sea level rise (e.g., Gardner et al. (2013) and Shepherd et al. (2012)).

42 Ku-band radar altimeters are insensitive to cloud cover providing superior coverage to  
43 laser altimeters (e.g., ICESat) but experience significant amounts of volume scattering, which is  
44 controlled by the time-evolving dielectric properties of the near-surface snow, firn, and ice  
45 (Lacroix et al., 2008; Remy et al., 2012). These effects can have large implications for the  
46 determination of mass change over a wide range of both spatial and temporal scales. Changing  
47 snow conditions can introduce time-varying biases in the data that, in combination with the radar

48 signals interaction with the surface, introduce large elevation biases (0.5 - 1 m) (Nilsson et al.,  
49 2015a). This, combined with other factors such as processing methodology and surface  
50 topography, makes it difficult to measure small changes for much of the world's ice covered  
51 regions (Arthern et al., 2001; Gray et al., 2015; Nilsson et al., 2015b).

52 The mitigation of these effects in the processing of radar altimetry data is required for  
53 improved accuracy of derived temporal and spatial changes in surface elevation of glaciers and  
54 ice sheets. Several studies have proposed different approaches to assess these effects and  
55 improve the retrieval process of surface elevation and elevation changes from radar altimetry  
56 data. These include different approaches to waveform retracking (Davis, 1993, 1997; Gray et  
57 al., 2015; Helm et al., 2014) and empirical corrections to the estimated surface elevation  
58 changes (Davis and Ferguson, 2004; Flament and Rémy, 2012; Sørensen et al., 2015;  
59 Wingham et al., 2006b; Zwally et al., 2005, 2011). Relatively little work has been done to assess  
60 methods for improving elevation and elevation changes derived from ESA's CryoSat-2 data  
61 (Abulaitijiang et al., 2015; Gray et al., 2013, 2015; Helm et al., 2014).

62 Here we conduct a thorough analysis of CryoSat-2 SIN and LRM waveform retracking,  
63 filtering and processing methodologies to design an optimal processing methodology for  
64 CryoSat-2 elevation retrieval over both smooth and complex ice-covered terrain. We then  
65 analyze two different approaches to determining surface elevation and volume changes from  
66 the scattered CryoSat-2 elevation retrievals. The overarching goal of this work is to develop  
67 robust and accurate elevation retrieval algorithms that are less sensitive to changes in surface  
68 and sub-surface scattering properties.

69 The new processing scheme is applied to estimate elevation and volume changes of the  
70 Greenland Ice Sheet for the period January 2011 to January 2015, using two independent  
71 methods to characterize the robustness of the results due to methodology. The results are  
72 compared to change estimates obtained from the ESA L2 Baseline-B surface elevation product  
73 (Bouzniaq et al., 2014), high accuracy airborne data from NASA IceBridge airborne topographic

74 mapper and seasonal height amplitudes estimated from Ice, Cloud, and Elevation Satellite  
75 (ICESat) data.

## 76 2 - Surface elevations from CryoSat-2

### 77 2.1 - Low Resolution Mode (LRM)

78 The LRM mode is used over the interior parts of the ice sheet, which mostly consist of low  
79 sloping terrain. Here, SIRAL operates as a conventional pulse limited radar system with a  
80 transmission frequency of 13.6 GHz (Ku-band) and has Pulse-Limited Footprint (PLF) radius of  
81 approximately 1.5 km and a beam-limited footprint (BLF) radius of approximately 7.5 km over  
82 flat terrain (Bouzinac, 2014). The gentle terrain allows for accurate mapping of the surface  
83 elevation of the ice sheet down to decimeter-level (Brenner et al., 2007). Within the LRM  
84 waveform we define the location of the surface from the leading edge of the waveform, based  
85 on a fraction of the maximum amplitude of the received power. This approach is commonly  
86 referred to as a threshold retracker. Following Davis et al. (1997) we use 20% threshold to  
87 define the location of the surface. Davis et al. (1997) argued that a 20% threshold represents  
88 the best compromise between waveforms that are entirely dominated by either volume or  
89 surface scattering, making it suitable for obtaining estimates of surface elevation for most parts  
90 of the Greenland Ice Sheet.

91 The CryoSat-2 LRM radar waveforms suffer from measurement noise, in the form of  
92 speckle noise. Furthermore, over the steeper parts of the LRM-area the range gate tracking-  
93 loop can lose track of the surface, producing non-usable waveforms. To remove bad or loss of  
94 track waveforms the radar waveform (20 Hz) is first filtered using a zero-phase low pass filter to  
95 reduce speckle noise on a line-by-line basis. The signal-to-noise-ratio (SNR) of the waveform is  
96 then estimated and if the  $SNR < 0.5$  dB the waveform is rejected. The SNR threshold was

97 empirically chosen to obtain a good trade-off between the quality of the measurements and  
98 sampling.

99 Before the waveform can be retracked the first surface return (first major peak) is  
100 identified within the range gate window. A copy of the waveform is heavily smoothed to remove  
101 small-scale surface roughness signals, keeping the overall surface signal intact. The range gate  
102 index of the first peak from the copy is then used to extract the leading edge of the original low  
103 pass filtered waveform. Only leading edges with a peak index above 20 are used in the  
104 retracking, as peaks before or after that can indicate troublesome surface ranging. The  
105 extracted leading edge is then oversampled by a factor of 100 (c.f. (Gray et al., 2013; Helm et  
106 al., 2014), and the range  $R$  between the surface and satellite is determined based on the 20%  
107 threshold computed according to Davis et al. (1997). The range is then corrected for several  
108 atmospheric and geophysical effects relevant to land ice studies according to Bouzinac (2014).  
109 The surface elevation  $H$  of the topography, relative to the WGS84 ellipsoid, is estimated as  $H =$   
110  $A - R$ , where  $A$  is the altitude of the satellite.

111 The measured surface return over a sloping surface does not originate from the  
112 satellites nadir location, but from the "Point Of Closest Approach" (POCA) to the spacecraft  
113 (Brenner et al., 1983). These off-nadir returns can introduce a large range bias to the surface,  
114 depending on the magnitude of surface slope, ranging from 0-120 m (Brenner et al., 1983) as  
115 the measured surface height is mapped to an erroneous position (i.e. the nadir position). To  
116 mitigate the effect of this error we correct the measured range and location to the POCA point  
117 using an a-prior DEM, following the approach of Bamber (1994). In contrast to previous studies  
118 we account also for the local surface curvature, as Remy et al. (1989) showed that accounting  
119 for surface curvature in addition to surface slope significantly improve results. The surface  
120 slope, aspect and curvature are estimated from an a priori DEM. The GIMP elevation model  
121 (Howat et al., 2014) was used to derive surface parameters for the slope-induced error  
122 correction in the LRM mode. The DEM was resampled to 2 km resolution, using bilinear

123 interpolation, prior to parameter estimation, which provided the lowest root-mean-square-error  
124 and further corresponds to the pulse-limited footprint of the LRM mode.

## 125 2.2 - Interferometric Synthetic Aperture Radar Mode (SIN)

126 The SIN mode is used over the marginal areas of the ice sheets and other smaller glaciated  
127 areas. In these areas the SIRAL altimeter operates as a Doppler/Delay radar system (Raney,  
128 1998). The Doppler/Delay radar allows for higher along-track resolution compared to  
129 conventional altimetry, resulting in 350 m resolution in along track and 1500 m across track. In  
130 ordinary SAR operation only the amplitude of the radar echo is measured and the phase content  
131 is discarded or ignored. With the inclusion of a second antenna on CryoSat-2, interferometric  
132 SAR can also be performed. The difference in path length between the POCA and the individual  
133 antennas introduce a phase shift between the two retrieved signals that can be related to the  
134 angle of arrival (look angle). The look angle can in turn be used to resolve the across track  
135 (across antenna) location of the echo.

136 Multi-look processing is applied to ESA's L1B waveform product (Bouzinac, 2014) to  
137 reduce the noise in the SIN waveform but it is still affected by speckle-noise, as is the case for  
138 the LRM waveforms. To mitigate this effect, and to help identify the leading edge of the first  
139 return, we apply speckle reduction filtering and leading edge extraction of the SIN waveforms in  
140 the same way as for the LRM processing with minor changes due to differences in range gate  
141 resolution. In this case, compared to the LRM retracking algorithm, only leading edges with a  
142 peak index in the range of 100-350 are used for retracking the radar waveform ( $P_w$ ).

143 The estimated coherence  $C$  of the multi-looked waveforms is then filtered in two stages;  
144 (i) all coherence measures larger than one is set to zeros (coherence values larger than one  
145 exists in the L1B product due to unknown reasons). (ii) The coherence array, as a function of  
146 range, is filtered using a 2D 5x5 Wiener filter to remove high frequency noise. The filtering of the

147 waveform and the coherence is applied to remove noise in the recreation of the interferogram,  
 148 discussed below.

149 The measured differential phase  $\phi$  of the return signal is affected by phase ambiguities;  
 150 a sudden shift of  $2\pi$  in the measured phase. To reduce phase noise and aid the phase, an  
 151 unwrapping of the radar interferogram  $I$  is performed according to Gray et al. (2013):

$$152 \quad I = P_w \cdot C \cdot e^{-i\phi} \quad (1)$$

153 The interferogram is then filtered using a wavelet-based de-noising technique, where the real  
 154 and imaginary parts of the interferogram are filtered separately. The unwrapping of the  
 155 interferogram allows for indirect filtering of the phase, without being affected by the phase-  
 156 ambiguities. Phase filtering is an important consideration as it has a direct affect on accuracy of  
 157 the position of the ground echo. We selected a bi-orthogonal as the mother wavelet to produce  
 158 the wavelet coefficients decomposed into three levels. Soft thresholding was applied to detail  
 159 coefficients, using a heuristic threshold rule to remove noise at every level. This was done on a  
 160 line-by-line basis. The final filtered differential phase was then recovered by:

$$161 \quad \phi_f = Re\{I_f\} + Im\{I_f\} \quad (2)$$

162 To resolve the phase ambiguities the filtered phase measurements require unwrapping. The  
 163 phase unwrapping is done on a line-by-line basis in two directions starting from the center of  
 164 gravity of the waveform (Wingham et al., 1986).

165 The return power distribution of a Doppler/Delay radar system shows an important  
 166 distinction from those from conventional pulse-limited radar systems. Here, the point  
 167 corresponding to the mean surface is not located at the half-power point on the leading edge,  
 168 but rather closer to the maximum (Wingham et al., 2006a). Therefore a new retracker has been  
 169 developed, closely related to the one used in Gray et al. (2013), to allow for adaptive retracking  
 170 of the upper parts of the leading edge of the SAR waveform. The algorithm follows the main  
 171 concept of the threshold retracker, developed by Davis (1997), but instead of a pre-defined

172 threshold it tracks the maximum gradient of the leading edge of the oversampled waveform. We  
173 refer to this approach as that “Leading-edge Maximum Gradient retracker” (LMG).

174 The surface returns are geolocated using the across track look-angle  $\theta$  estimated from  
175 the differential phase at the retracking point according to (Wingham et al., 2006a). This, in  
176 combination with the viewing geometry, is used to define the location of the surface return on  
177 the ground using basic across track interferometric principles. We correct  $\theta$  for the  
178 interferometer surface slope error by applying the look-angle scaling factor estimated in (Galini  
179 et al., 2013).

180 The along-track differential phase estimate, interpolated to the retracking point, is  
181 affected by phase ambiguities not corrected for during the phase unwrapping procedure. To  
182 reduce residual phase ambiguities an a priori DEM (GIMP) is used to extract the DEM surface,  
183 resampled to 500 m resolution (corresponding roughly to the along-track sampling), elevations  
184 at the nadir and echolocation using bilinear interpolation. Over a sloping surface the surface  
185 return should always come from a position upslope from the nadir point. Therefore the following  
186 relation must hold where ( $H_{echo} > H_{nadir}$ ) or for a more practical application ( $H_{echo} - H_{nadir} > \epsilon$ ,  
187 where  $\epsilon$  is the uncertainty of the DEM used. If this relation is violated  $2\pi$  is added or subtracted  
188 to the individual along-track phase estimate, depending on the sign.

189 A final step is applied to correct for any lingering phase ambiguities not corrected by the  
190 a priori DEM. This step uses the assumption that the along-track phase should follow a  
191 consistent pattern over most part of the satellite ground track. Hence, any large discrepancies  
192 from the overall pattern of the along-track phase would indicate an ambiguity. The ambiguity is  
193 detected by computing the residuals of the along-track phase by removing a smoothed version  
194 of the differential phase. If any of the residuals have a magnitude larger than  $\pi$  it is considered  
195 ambiguous and thus corrected by adding or subtracting  $2\pi$ .

## 196 3 - Surface elevation changes from CryoSat-2

## 197 3.1 – Surface fit method

198 The surface-fitting method is based on fitting a linear model to the elevations as a function of  
 199 time and space inside a search radius of 1 km (e.g., Howat et al., 2008; Moholdt et al., 2010;  
 200 Sørensen et al., 2011; Wouters et al., 2015). The linear model consists of a time-invariant  
 201 (static) bi-quadratic surface model to account for variable topography inside the search radius  
 202 and time-variant part used to extract the temporal change in elevation. The model consists of a  
 203 total of 7-parameter whereof six of the parameters (a-coefficients) describe the bi-quadratic  
 204 surface modeling function,  $dh/dt$  the linear elevation change rate,  $t$  time in decimal years,  $t_0$  the  
 205 mean time inside the footprint and  $\varepsilon$  the residuals from the linear regression.

$$206 \quad h(x, y, t) = a_0 + a_1x + a_2y + a_3xy + a_4x^2 + a_5y^2 + \frac{\partial h}{\partial t}(t - t_0) + \varepsilon \quad (3)$$

207 The algorithm estimates the elevation change at every echolocation (or grid-node if desired) in  
 208 the data set. In each solution the signal amplitude and phase are also estimated by fitting a  
 209 seasonal signal model to the surface-fit elevation residuals, according to:

$$210 \quad \Delta h(t) = s_0 \cos(\omega t) + s_1 \sin(\omega t) + \varepsilon \quad (4)$$

211 where  $\Delta h$  is the elevation residuals estimated from the plan-fit model,  $s_{0,1}$  are the model  
 212 coefficients and  $t$  the time. The amplitude  $A$  is then defined as  $A = \sqrt{s_0^2 + s_1^2}$  and the phase  $P$  as  
 213  $P = \tan^{-1}\left(\frac{s_1}{s_0}\right)$ .

214 To remove outliers an iterative  $3\sigma$ -filter is used in the full model solution, i.e. the  
 215 topography, trend and seasonal signal are removed, using a maximum of 5-iterations. For each  
 216 iteration residuals (full-model) with an absolute value larger than 10 m are removed, as  
 217 seasonal changes larger than 10 m are not expected (Moholdt et al., 2010; Qi and Braun,  
 218 2013). The data inside the 1 km cap is weighted according to their distance from the estimation  
 219 point according to:

220 
$$W = \frac{1}{\left(1 + \left[\frac{d}{\rho}\right]^2\right)} \quad (5)$$

221 where  $W$  is the estimated weight,  $d$  the distance and  $\rho$  the correlation or resolution parameter  
 222 set to 500 m. The weighting allows the solution to better reflect local signal dynamics at the  
 223 prediction point.

224

225 Local elevation time-series are further computed from the elevation residuals and  
 226 elevation trend from each solution, according to:

227 
$$h(x, y, t) = (t - t_0) \cdot \frac{\partial h}{\partial t} + \varepsilon \quad (6)$$

228 where  $t$  is the time epochs inside the search cap,  $t_0$  is the mean time of  $t$ ,  $dh/dt$  is the estimated  
 229 elevation change rate and  $\varepsilon$  is the elevation residual at each time epoch.

230 The elevation changes estimated from the surface-fitting method are then culled to  
 231 remove outliers before spatial gridding. Elevation changes with a regression error larger than 15  
 232 m a<sup>-1</sup> are removed. The resulting surface elevations are binned at 5-km resolution for outlier  
 233 editing purposes. For each cell the local spatial trend is modeled as a bilinear surface, and  
 234 removed. The residuals are then edited using an iterative  $3\sigma$  filter until the RMS converges to  
 235 2%.

### 236 3.2 – Crossover method

237 The crossover method is used to derive the surface elevations at the intersection point between  
 238 an ascending and descending satellite ground track separated in time (Brenner et al., 2007;  
 239 Khvorostovsky, 2012; Zwally et al., 1989). The surface elevations and times are then estimated  
 240 at the crossover location for each track by linear interpolation of the two closest data points for  
 241 each ascending and descending track. The crossover height difference is then estimated by  
 242 taking the height difference between the two tracks according to:

$$\Delta h = h_2 - h_1 + \varepsilon \quad (7)$$

244 were  $h_1$  and  $h_2$  are the surface heights at the crossover location at time epoch  $t_1$  and  $t_2$ ,  
 245 respectively, and  $E$  is the random measurement error, including orbital, range and retracking  
 246 errors.

247 This approach produces crossover height differences with scattered time-epochs  
 248 ranging from 0-4 years. CryoSat-2 has a 369-day repeat orbit configuration with a 30-day sub-  
 249 cycle meaning that each crossover location will be revisited every 369 days and surrounding  
 250 area every 30 days. This produces annual and sub-annual crossover difference around each  
 251 crossover location. This fact is used to produce elevation change rates by incorporating all  
 252 multi-temporal crossover difference within a neighborhood of 2.5-km around each crossover  
 253 location. The elevation change is then estimated using the same procedure described for the  
 254 surface-fit method, except that a bilinear model is used to remove any spatial trends in the  
 255 topography of the crossover elevations according to:

$$dh(x, y, t) = a_1x + a_2y + \frac{\partial h}{\partial t}(t - t_0) \quad (8)$$

257 where  $dh$  is the crossover height difference,  $t$  the time,  $t_0$  is the mean reference time inside the  
 258 footprint,  $a_1$  and  $a_2$  the across and along-track slope and  $dh/dt$  the elevation change rate. This  
 259 produces elevation changes comparable in time and in spatial coverage with the surface-fit  
 260 method. The same outlier editing schemes is applied to the crossover elevation change rates as  
 261 for the surface-fit method.

### 262 3.3 - Gridding of sparse elevation and elevation change data

263 The gridding is done in a polar-stereographic projection with a latitude of origin at 70°N, central  
 264 longitude of 45°W and origin at the North Pole. The projection is referenced against the WGS-  
 265 84 ellipsoid and the grid-resolution. The observations derived from the surface-fit and crossover  
 266 method are gridded at a resolution of 1x1-km, due to the high spatial sampling.

267 The method of Least Squares Collocation (LSC), described in Herzfeld (1992) is used to  
 268 grid the observations onto a regular grid. LSC is similar to Kriging and allows for optimal  
 269 interpolation and merging of data with different accuracies, using their inherent covariance  
 270 structure. The LSC-algorithm uses the 25 closest data points in 8-quadrants surrounding the  
 271 prediction point to reduce spatial biasing. The prediction equation consists of two terms where  
 272 the first term is the actual prediction term and the second term accounts for the non-stationary  
 273 part of the data, as described by:

$$\hat{s} = C_{sz}(C_{zz} + N)^{-1}z + \left(1 - \sum (C_{sz}(C_{zz} + N)^{-1})\right)m(z) \quad (9)$$

274 where  $C_{sz}$  is the cross-covariance,  $C_{zz}$  is the auto-covariance,  $N$  the diagonal noise-matrix  
 275 consisting of the a priori RMS-error and  $m(z)$  is the median value of the observations inside the  
 276 search neighborhood.

277 The covariance of the data inside the local neighborhood is modeled as a function of  
 278 distance away from the prediction point using a third-order Gauss-Markov model described  
 279 below.

$$C(r) = C_0 \left(1 + \frac{r}{\alpha} - \frac{r^2}{2\alpha^2}\right) e^{\left(-\frac{r}{\alpha}\right)} \quad (10)$$

281 where  $r$  is the separation distance,  $C_0$  the local data variance and  $\alpha$  is a scaling factor estimated  
 282 from the correlation length.

283 LSC interpolation provides a RMS-error for each prediction point estimated from the  
 284 modeled covariance of the data according to:

$$C_s = C_0 - C_{sz}(C_{zz} + N)^{-1}C_{sz}^T \quad (11)$$

285 where the RMSE of the prediction equals to  $\sigma_s = (C_s)^{1/2}$  and where  $C_{sz}^T$  is the transposed cross-  
 286 covariance matrix.

287 The elevation changes estimated from the surface-fit and crossover methods are  
 288 interpolated to a regular grid using their a priori error estimated from the LSC scheme. To avoid  
 289 unrealistically small errors, common in the regression errors estimated over flat terrain, a

290 minimum error threshold is applied. Error values smaller than a specific threshold are set to the  
291 threshold value. The threshold value is representative of the overall precision of the elevation  
292 changes over flat terrain and is set to  $0.2 \text{ m a}^{-1}$ . The data are then gridded using a 75 km  
293 correlation length determined from the comparison of CryoSat-2 elevation to airborne  
294 measurements (Section 5).

295 The LSC algorithm is also used to generate a DEM based on the surface elevations  
296 generated from the surface-fitting algorithm. The surface elevations generated from the surface-  
297 fit were used as input to the gridding-algorithm. The use of surface elevations from the surface-  
298 fit provides several advantages compared to the raw observations as they: provide an almost  
299 equal number of observations as the raw data, have been screened for gross outliers, have  
300 been low-pass filtered using the 1-km search radius, and are all reference to roughly the same  
301 time epoch. Further the RMSE error generated from the surface-fit estimated surface height can  
302 be used as an a priori error for the LSC gridding procedure.

303 The DEM is generated using the same approach as for the surface elevation changes,  
304 as described previously in the section. Before the gridding procedure is applied elevations  $H < 0$   
305 and  $H > 3350 \text{ m}$  are removed from the data set. Further, elevations with a standard error larger  
306 than 30 m are also removed. The elevations are binned spatially into a resolution of 1000 m and  
307 inside each cell the local surface trend is removed by fitting of a planar surface, and an iterative  
308  $3\sigma$  filter is applied to the residuals to remove outliers.

#### 309 4 - Surface elevations and elevation changes from ICESat

310 To assess basin-scale patterns of elevation change we compare elevation changes from  
311 CryoSat-2 data to elevation changes derived from Ice, Cloud, and Elevation Satellite (ICESat)  
312 data. Here we use release 33 (GLA06) data collected over the 2003-2009 period. The ICESat  
313 surface heights were used to generate surface elevation changes and seasonal parameters

314 according to method M3 in Sørensen et al. (2011). The derived elevation changes were  
315 corrected for the G-C offset (Borsa et al., 2014). Valid elevation retrievals were selected  
316 according to Nilsson et al. (2015b). The ICESat elevation, seasonal amplitude and phase, are  
317 then used for comparison with CryoSat-2 and to build continuous time series using the surface  
318 fit method described in Section 3.1. For the purpose of this study no correction for the inter-  
319 campaign bias was applied, as this is still an active area of investigation.

## 320 5 -Validation

321 Elevation and elevation change results were generated for the entire Greenland Ice Sheet using  
322 CryoSat-2 data collected between Jan-2011 and Jan-2015 using the methodology presented in  
323 (Sections 2-3) (JPL product) and by applying the methods of (Section 3) to ESA's CryoSat-2 L2  
324 elevation products (ESA product). Surface elevations and elevation changes were validated  
325 against airborne data sets obtained from NASA's Operation Ice-Bridge Airborne Topographic  
326 Mapper (ATM), obtained from the "National Snow & Ice Data Center" (NSIDC) in the form of the  
327 ILATM2 product. The generated elevation product has a resolution of 80 m, with a 40 m spacing  
328 along-track. This mission produces both elevation and elevation changes with reported vertical  
329 accuracy of ~10 cm and temporal accuracy in the cm-level (Krabill et al., 2002).

330 The derived surface elevations from CryoSat-2 are differenced against ATM surface  
331 elevations within 50 m of each ATM locations. One month of CryoSat-2 data consistent in time  
332 with the ATM elevations are used for the validation to avoid biases due to temporal sampling  
333 and to obtain sufficient sample size. A total of four years of campaign data are used for the  
334 validation of the surface elevations (2011-2014). The residuals are edited using an iterative  $3\sigma$   
335 filter to remove outliers. The accuracy and precision is estimated as the mean and standard  
336 deviation of the differences, respectively. The residual distribution is further binned according to  
337 surface slope estimated from the GIMP DEM (Howat et al., 2014) resampled to 500 m. The  
338 sensitivity to surface slope (slope error) can be identified in the standard deviation of the binned

339 residuals and can be used to judge the quality of the produced surface elevation and elevation  
340 changes, while the binned-average for the elevations can be used to determine radar-signal  
341 penetration depth.

342         Surface elevation change rates estimated from three different time-periods (2012-2014,  
343 2011-2013 and 2011-2014) of overlapping ATM observations (Krabill, 2014) are used to validate  
344 the surface elevation changes estimated from the CryoSat-2 data. The same validation  
345 methodology applied to surface elevations is applied to surface elevation changes, with a few  
346 minor modifications. First the search radius is increased to 175 m to make it conform to the ATM  
347 elevation change resolution of 250 m, as this search radius encloses the entire ATM grid cell.  
348 Secondly the estimated mean and standard deviation are multiplied with the individual time-  
349 intervals of the validation data sets to make the errors comparable, as they differ in time span.

350         For the surface-fit and crossover methods, near-coincident elevation change rates were  
351 compared with ATM rates (e.g., April-2011 to April-2014). This provided three validation data  
352 sets for the surface-fit method, due to its high spatial coverage. However, only the 2011-2014-  
353 validation data set could be used for the crossover method, due to the lower spatial sampling of  
354 the crossovers.

355         The overall accuracy and precision for both the surface elevation and elevations  
356 changes are then estimated by taking the weighted mean, using the number of observations as  
357 weights, for each data set giving an average error for each measurement mode, as seen in  
358 Table-2. The weighted average errors for each mode and method have been summarized in  
359 Table-1 and Table-2 for both the ESA's and our solutions, where the values for the individual  
360 campaigns can be found in the Supplementary material.

361         The estimated surface elevation changes from the two independent methods were  
362 validated separately using near-coincident ATM data. The statistics of the elevation change  
363 validation have been summarized in Table-2 for each method independently for the two modes  
364 of instrument operation. We find the lowest RMSE errors for the surface-fit method, followed by

365 the crossover method. This differs from the findings of Moholdt et al. (2010) who found lower  
366 intrinsic errors for the crossover method, compared to the surface-fit method when applied to  
367 ICESat data. The larger search radius used for our application of the crossover method most  
368 likely explains the difference in findings between the two studies. Further, we find that the  
369 surface-fit method provides the largest reduction in RMSE for the JPL product, corresponding to  
370 40% and 55% for the SIN and LRM-mode, respectively.

371         The correlation length used to derive the number of un-correlated grid-cells, which is  
372 used to estimate the standard error, was determined from a semi-variogram analysis of the  
373 elevation change residuals from CryoSat-2 minus ATM using the data from the surface-fit  
374 method. The comparison was done for each mode separately for all the individual campaigns  
375 and multiplied with the their individual time span. The semi-variogram was then computed from  
376 all the time-invariant residuals, to maximize the spatial coverage, for each mode. Analysis of the  
377 semi-variogram showed approximate correlation lengths of 100 and 75 km for the SIN and  
378 LRM-mode respectively. These correlation lengths are inside the range of the ones found by  
379 Sørensen et al. (2011) for their analysis of ICESat data, which was found to be between 50-150  
380 km.

381         The main goal of this study is not to derive or compare different types of DEM's.  
382 However, to gain insight into the overall quality of our CryoSat-2 derived DEM (referred to as  
383 JPL) we compare it to three other DEM's derived from other data sets. Firstly, we compare it to  
384 a DEM derived from ESA CryoSat-2 L2 data (referred to as ESA) gridded in the same manner  
385 as our DEM (Section 3.3). Secondly we compare it to a DEM from Helm et al. (2014), also  
386 based on CryoSat-2 data from 2011-2014 (referred to as AWI). Thirdly, we compare to a DEM  
387 from Howat et al. (2014) (which was used to derive topographical parameters and corrections  
388 for the JPL CryoSat-2 data), based on photogrammetry and altimetry data from the mid 1990's  
389 to 2010 (depending on data source) co-registered to ICESat elevation data from 2003-2009  
390 (referred to as GIMP).

391           These data sets were then compared to IceBridge ATM elevations, spanning the four  
392 different campaigns previously used for validation of the CryoSat-2 elevations. The DEM  
393 elevation was estimated at each ATM location, using bilinear interpolation, and the elevation  
394 difference computed as (DEM-ATM). No attempt was made to account for differences in DEM  
395 and ATM epochs. The estimation of the errors of the DEM was determined in the same way as  
396 for the individual CryoSat-2 surface heights. The results of the comparison have been  
397 summarized in Table-3, as the weighted average of the different campaigns. The values from  
398 each individual campaign can be found in the supplementary material.

399           Analyzing the overall RMSE we find that the AWI produces the lowest RMSE, followed  
400 by JPL, ESA and GIMP, due to AWI's lower standard deviation. However, the best accuracy is  
401 obtained by the JPL DEM, which shows the lowest elevation bias of all DEM's. The ESA derived  
402 DEM shows a slightly better standard deviation than the JPL DEM, which can be explained by  
403 higher data density in the marginal areas for the ESA data. The difference in density is due to  
404 the SNR rejection criterion applied in our elevation processing. The lower standard deviation in  
405 the AWI product is mostly likely due the use of lower resolution topography in many of the high  
406 relief areas in the 1 km elevation model, producing a smoother estimate of the surface. The  
407 GIMP data set showed higher degrees of impulse noise than the other products, explaining the  
408 higher observed standard deviation. This impulse noise is attributed to that local elevation  
409 change rate, which was not accounted for in the creation of the DEM (Howat et al., 2014).  
410 Overall we find that the JPL DEM provides a suitable compromise between resolving of local  
411 detail and the minimization of bias. Further, modification to the SNR filtering criteria will likely  
412 lead to additional improvements in the DEM.

413           To determine the effect of retracking on the accuracy and precision of the measured  
414 surface heights from CryoSat-2 several tests was performed over different parts of Greenland  
415 for both modes. Following the approach of Davis (1997) the accuracy (mean) and precision  
416 (standard deviation) was computed as a function of leading edge threshold (in percent). This

417 computation was performed using a standard leading-edge threshold retracker, referred from  
418 now on as LTH, for both the LRM and SIN mode independently. The validation was performed  
419 in the same manner as described in Section 5, where ATM elevations from 2013 was used as  
420 the surface reference.

421 For the LRM mode data from April 2013 from the northern parts of Greenland, spanning  
422 the region 75-81°N and 54-44°W around the North Greenland Eemian Ice Drilling camp  
423 (NEEM), was used to calculate height residuals for the different thresholds. This produced  
424 approximately 1000 comparison locations, which was used to calculate statistics. The same  
425 procedure was performed over Jakobshavn Isbræ, using the same time span, to calculate  
426 statistics for the SIN-mode providing roughly 2500 comparison locations.

427 The results of this analysis, summarized in Figure-2, show that for the LRM-mode the  
428 precision (as a function of threshold) follows the same behavior as observed by Davis (1997),  
429 with a decrease of precision following increasing retracking threshold. However, the most  
430 notable finding was the observed inverse relationship in precision for the SIN-mode compared  
431 to LRM. For LTH-algorithm, in the SIN-mode, we observe a clear increase in precision as the  
432 retracking threshold increases, seen in Figure-2, stabilizing around 30-40%.

433 Analyzing the accuracy derived from the different thresholds a clear difference in apparent  
434 penetration depth of the radar signal can be observed for the two modes. For the SIN-mode,  
435 below 40%, a positive bias is observed indicating that retracker produces elevations larger than  
436 the corresponding airborne measured heights. For thresholds larger than 40% surface  
437 penetration of the signal is observed which are in general closer to the surface compared to the  
438 LRM-mode. We attribute this to differences in the near-surface density structure covered by the  
439 two modes.

440 In general we conclude that for the LRM-mode applying low retracking thresholds (0-  
441 30%) reduces the magnitude of the apparent surface penetration bias and provides higher  
442 precision compared to higher thresholds. Therefore, a threshold of ~20% of the leading edge is

443 suggested for retracking surface elevations for the LRM-mode, which was also previously  
444 suggested by Davis (1997) and Helm et al. (2014). However, for the SIN mode a threshold  
445 below 40% is not recommended, as this produces a clear positive elevation bias and poor  
446 precision, as seen in Figure-2. Analyzing the difference between the LTH and the adaptive LMG  
447 algorithm, used in the SIN-mode, we find that the LMG algorithm produces superior results in  
448 precision compared to the standard LTH-algorithm. Comparing the adaptive solution from LMG  
449 to the optimum threshold found by the LTH-algorithm, we find a comparable magnitude of the  
450 elevation bias and a 32% improvement in precision, with an overall 27% reduction in RMSE,  
451 using the LMG-retracker. From this comparison between the two-retracker algorithms we  
452 recommend the use of the adaptive threshold approach (LMG), as it produces an elevation  
453 repeatability that exceeds that of the standard threshold retracker (LTH) and provides a low  
454 penetration bias.

455         A case study was also performed to determine the different processing steps effects on  
456 the quality of the retrieved elevations. For this purpose the Barnes ice cap, on Baffin Island in  
457 the Canadian Arctic, was chosen due to its small size, excellent validation coverage and due to  
458 that it consist mostly of super-imposed ice (reducing radar signal penetration). The ice cap saw  
459 a major IceBridge ATM campaign in 2011 providing a large number of flight tracks (spanning in  
460 both North-South and East-West directions) suitable for validating CryoSat-2 data. The result of  
461 this case study, which is detailed in supplementary material (i.e. Table-S1) shows that the  
462 filtering of the differential phase has the highest impact on the overall accuracy of the  
463 observation, reducing the RMSE by 12%, followed by the ambiguity correction. This shows the  
464 importance of these steps, as they can have important implications for the overall quality of the  
465 retrieved elevations. This is especially true in high relief areas where small changes in the look  
466 angle, or an introduced phase ambiguity, can produce large elevation errors ranging from 0-100  
467 m in elevation (Brenner et al., 1983).

468

## 469 6 - Error analysis

470 To compute volume change errors for the two methods we divide the error budget into two main  
 471 components (1) the observational standard error ( $\epsilon_{obs}$ ) and the interpolation standard error ( $\epsilon_{int}$ ).  
 472 The observational error budget is estimated using the root-mean-square error (RMSE) of the  
 473 difference between CryoSat-2 and airborne elevation change differences, as described in  
 474 Section 5. The RMSE is estimated separately from the two different modes, with the total  
 475 volume change error ( $\epsilon_{vol}$ ) being computed as the RSS of the standard elevation change error of  
 476 the two modes and their corresponding area, according to:

$$477 \quad \epsilon_{vol} = \sqrt{(\epsilon_{lrm} A_{lrm})^2 + (\epsilon_{sin} A_{sin})^2} \quad (12)$$

478 were  $A_{lrm}$  and  $A_{sin}$  are the areas covered by each mode. The  $\epsilon_{lrm}$  and  $\epsilon_{sin}$  are the standard  
 479 elevation change errors of the LRM and SIN computed from the airborne validation data sets.

480 The observational elevation change error is estimated from the residual elevation  
 481 change differences in Table-2 for the two methods. The RMSE from the LRM/SIN errors are  
 482 computed using Gaussian error propagation producing an observational elevation change error  
 483 ( $\sigma_{obs}$ ). For the surface-fit and the crossover method the interpolation error is estimated as the  
 484 RMS of the LSC uncertainty grid, defined as ( $\sigma_{int}$ ). The final elevation change error is then  
 485 estimated by combing the two error sources using RSS according to:

$$486 \quad \epsilon_{mode} = \epsilon_{dh/dt} = \sqrt{(\epsilon_{obs})^2 + (\epsilon_{int})^2} = \sqrt{\left(\frac{\sigma_{obs}}{\sqrt{N}}\right)^2 + \left(\frac{\sigma_{int}}{\sqrt{N}}\right)^2} \quad (13)$$

487 Here,  $N$  is the number of uncorrelated grid-cells estimated from empirical semi-variogram  
 488 analysis of the CryoSat-2 and airborne elevation change differences, and estimated according  
 489 to:

$$N = \frac{A_{mode}}{\rho_{mode}^2} \quad (14)$$

490 were  $A_{mode}$  is the total area of the Greenland Ice sheet ( $\sim 1.7 \times 10^6 \text{ km}^2$ ) and the correlation length  
 491  $\rho_{mode}$  of 75 and 100 km for the LRM and SIN mode respectively.

## 492 7 – Results

## 493 7.1 – Surface elevations compared to ATM

494 The measured surface elevations from the two CryoSat-2 products (JPL vs. ESA)  
495 showed large differences in both accuracy and precision of the elevation measurements, as  
496 seen in Table-1. The average accuracy and precision for the LRM-mode from the two products  
497 showed values of  $0.00 \pm 0.43$  m and  $-1.06 \pm 0.89$  m for the JPL and ESA products respectively.  
498 This corresponds to an average reduction in RMSE of 68% for the JPL product compared to the  
499 ESA LRM L2 data. Further, our product shows a lower residual slope error (seen in Figure-1c  
500 below  $\sim 0.5^\circ$ ) indicating a lower sensitivity to the degradation of performance as the surface  
501 slope increases.

502 Surface elevations generated from the SIN-mode showed the same type of improvement  
503 as for the LRM-mode. Here, an average accuracy and precision was found to be  $-0.52 \pm 0.58$  m  
504 and  $-0.90 \pm 1.05$  m for the JPL and ESA SIN elevation products respectively. This further  
505 corresponds to a reduction in the average RMSE of 27% for the JPL product compared to the  
506 ESA product. For the SIN-mode the JPL processing produces a slightly lower residual slope  
507 error, compared to the ESA processor (seen in Figure-1c above  $\sim 0.5^\circ$ )

508 Larger improvements can be observed if separating the RMSE into its mean and  
509 standard deviation, corresponding to the accuracy and precision of the measurements. Using  
510 these definitions the analysis found that there is a 45% and 52% increase in precision for the  
511 SIN and LRM mode respectively, compared to the ESA L2 product, and a 42% and 99%  
512 improvement in accuracy for the respective modes.

513 The implementation of the LMG SIN retracking algorithm was found to reduce noise in  
514 the retrieved surface elevations compared to conventional threshold retracking. Though roughly  
515 comparable in accuracy, the LMG shows overall higher precision over all comparable leading

516 edge thresholds. The adaptive nature of the algorithm provides improved estimates of surface  
517 elevation and a good trade-off between accuracy and precision.

518 The 20% threshold retracker implemented in the LRM-mode was also found to provide  
519 improved estimates of surface elevation (both in accuracy and precision) compared to the  
520 model-based ESA-L2 retracker. Further, it also showed lower sensitivity to the 2012 melt event,  
521 due to the lower threshold used on the leading edge of the waveform.

## 522 7.2 – Surface elevation changes compared to ATM

523 The estimated surface elevation changes generated from the surface-fit method also  
524 showed improvement in the estimated accuracy and precision, as seen in Table-2. Here, an  
525 overall improvement in RMSE of 55% and 40% in the LRM and SIN mode, respectively, was  
526 found when comparing against ESA L2 generated elevation changes from the same method.  
527 The average accuracy and precision, compared to ATM generated elevation changes, was  
528 found to be  $0.11 \pm 0.67$  m (LRM) and  $0.30 \pm 0.58$  m (SIN) for the JPL derived changes. This  
529 compared to  $0.25 \pm 1.51$  m (LRM) and  $0.34 \pm 1.06$  m (SIN) for the ESA derived changes. This  
530 corresponds to an increase in elevation change accuracy of 56% and 12% for the LRM and  
531 SIN-mode, respectively, for the JPL product compared to ESA L2 elevation changes. The  
532 estimated elevation changes also show an increase in precisions for the JPL product of 56%  
533 and 45% for the LRM and SIN-mode, respectively, compared to its ESA counterpart.

534 The estimated elevation changes of the Greenland Ice Sheet, excluding the peripheral  
535 glaciers, over the period January 2011 to January 2015 show significant differences between  
536 products (JPL and ESA) in both spatial patterns and the total magnitude (Figures 3 & 4). The  
537 estimated volume change rate from the surface-fit method is  $-289 \pm 20$  km<sup>3</sup> a<sup>-1</sup> for the JPL-  
538 product and  $-224 \pm 38$  km<sup>3</sup> a<sup>-1</sup> for the ESA-product with a mean difference of 65 km<sup>3</sup> a<sup>-1</sup>. The  
539 surface-fit and crossover-method produced on the order of ~20 million and ~2.5 million usable  
540 elevation changes, respectively, providing high spatial sampling. Due to the constraint put into

541 the JPL processor the ESA L2 data produced slightly more surface-fit observations (~10%), as  
542 more surface elevations were accepted.

543 The ESA product produces a more positive elevation change pattern, which can be  
544 attributed to the 2012 melt event that introduced a large positive bias with a magnitude of ~0.5  
545 m (Nilsson et al., 2015a). Larger differences in the marginal areas for the surface-fit methods  
546 are also observed. The positive signal detected in the interior of the ESA surface-fit-solution can  
547 also be found in the basin time series, correlating well with the timing of the summer of 2012  
548 melt event, which for example can be seen in the time series in Figure 3. These results are in  
549 agreement with earlier work demonstrating the sensitivity of the ESA retracker to the changes in  
550 the volume/surface scattering ratio (Nilsson et al., 2015a).

551 We used ICESat and CryoSat-2 derived surface heights to generate time series over  
552 three regions in Northeast area of Greenland (Zachariæ Isstrøm, Nioghalvfjærdsfjorden and  
553 Storstrømmen glaciers) for comparison purposes. These areas have in recent time shown large  
554 and rapid changes, which has been noted by, e.g., Khan et al. (2014). The selected areas were  
555 defined using hydrological basins derived by Lewis and Smith (2009), seen in (Figure 6), and  
556 were further divided into smaller areas around the termini to highlight performance for areas of  
557 rapid change. The ICESat and CryoSat-2 surface heights were then used to generate annual  
558 time-series from 2003-2015 using (Equation 6) in the surface fit method. The estimated 12 year  
559 time series show overall comparable elevation change rates over both time periods (2003-2009  
560 and 2010-2015), especially in the terminus areas, providing confidence that CryoSat-2 can  
561 actually monitor changes in these areas.

562

563

## 564 7.3 – Seasonal phase and amplitude compared to ICESat

565 The amplitude of the seasonal signal (Equation 4) estimated from the surface-fit (SF)  
566 method show large differences in both magnitude and spatial variability (Figure 5). For the  
567 surface-fit method a difference in amplitude of 54% is observed between the ESA and JPL  
568 products, corresponding to area-averaged amplitude of 0.17 m for the JPL product and of 0.37 m  
569 for ESA product. The comparison with ICESat derived amplitudes from 2003-2009 estimated in  
570 (Sasgen et al., 2012) using the same methodology as used here produced an area-averaged  
571 amplitude of 0.13 m, which is in good agreement with the JPL derived amplitude. This  
572 agreement is also spatially consistent, as seen in (Figure 5), indicating low sensitivity to  
573 seasonal changes in scattering regime of the upper snowpack. The observed difference in  
574 amplitude bias, taking ICESat as the true surface amplitude while acknowledging that no inter-  
575 campaign bias has been applied and further the differences in epochs, is  $0.03 \pm 0.13$  m for the  
576 JPL product and  $0.21 \pm 0.27$  m for the ESA product. The smallest differences are observed at  
577 high altitudes above 2000 m a.s.l., where the three data sets show almost constant amplitude of  
578 0.1 m (ICE/JPL) and 0.2 m (ICE/ESA), providing a factor of two larger amplitude for the ESA  
579 product. Below 2000 m a.s.l., corresponding well to the equilibrium-line-altitude (ELA) of the  
580 Greenland Ice Sheet (Poinar et al., 2015), a rapid increase in amplitude is observed for all  
581 products. This is especially true for the ESA product, which increases its magnitude by a factor  
582 of two.

583 Analyzing the amplitude patterns on a regional drainage basin level (Figure 5c) we find  
584 good agreement between JPL CryoSat-2 and ICESat amplitude with ESA data producing  
585 consistently larger amplitudes. Regionally, the highest amplitudes can be observed in the SE of  
586 Greenland in basins (3,4,5) and are consistent with regional precipitation patterns that show  
587 high average precipitation in these areas (Bales et al., 2009; Ettema et al., 2009).

588 The seasonal phase of the peak in amplitude of the seasonal cycle is shown in (Figures 5b and  
589 5c) and shows generally good agreement between the two data sets, providing the timing of the  
590 maximum of the accumulation signal, before the onset of melt, to the months of June/July for  
591 both JPL and ESA CryoSat-2 data sets. The ICESat derived seasonal phase shows a higher  
592 dependence on elevation where the maximum of the accumulation signal is found in late May  
593 below 2000 m and late July/August above 2000 m in elevation. The ICESat discrepancies from  
594 the CryoSat-2 data are found in specific basins. Disagreements between the retrieved phase of  
595 the peak amplitude from Cryosat-2 and ICESat data are due to differences in temporal sampling  
596 as discussed in more detail in Section 8.

#### 597 7.4 – Volume change

598 The two volume change methods produce consistent results from JPL derived elevation  
599 changes, with a difference of around  $1 \text{ km}^3 \text{ a}^{-1}$ . The spread between volume change methods is  
600 larger ( $50 \text{ km}^3 \text{ a}^{-1}$ ) when using ESA L2 data. The larger discrepancy can be mostly related to the  
601 sensitivity of the various methods to the melt event. The surface-fit method produces the most  
602 negative number (least affected by the melt event and has the lowest estimated error) and is  
603 therefore taken as the most reliable estimate for both the JPL and ESA solution.

604 Comparing the estimated volume change to other studies using CryoSat-2 we find that  
605 the JPL product is less negative than that estimated by Helm et al. (2014):  $-375 \pm 24 \text{ km}^3 \text{ a}^{-1}$ .  
606 This difference can be attributed to difference in processing methodology and to the different  
607 epoch of the data used by Helm et al. (2014) of January 2011 to January 2014. Using the  
608 corresponding epoch the JPL data gives a volume change estimate, based on the surface-fit  
609 method, of  $-353 \pm 26 \text{ km}^3 \text{ a}^{-1}$ , well within the stated uncertainty of Helm et al. (2014).

610 To examine the regional behavior of volume change estimates of the Greenland Ice  
611 Sheet, gridded values from the two methods were divided into 8-drainage basins according to  
612 Zwally et al. (2012). When analyzing the elevation time-series at the basin scale clear

613 differences can be observed in the annual and inter-annual behaviors (Figure 4). The northern  
614 and interior basins (1, 2, 7, 8) all exhibit large differences (Table 4:  $0 - 30 \text{ km}^3 \text{ a}^{-1}$ ) in the  
615 estimated volume change rates due to changes in the scattering regime resulting from the 2012  
616 melt event. In the majority of the southern basins (4, 5, 6, 7), located in areas with higher  
617 precipitation, both products show good agreement in both trends and seasonal amplitude  
618 estimated from the surface-fit method.

## 619 8 - Discussion

620 The CryoSat-2 processing methodology presented here is found to produce accurate and  
621 precise measurements of ice sheet elevation and elevation change. The main improvements  
622 have been introduced in the SIN processor with the inclusion of a novel type of land ice  
623 retracker (LMG), advanced phase filtering and the inclusion of a phase ambiguity correction  
624 scheme. This processing approach decreased the RMSE in the surface height retrieval by  
625 approximately 27% (45% and 42% improvement in precision and accuracy). This improvement  
626 further propagated into the quality of the estimated elevation changes for the SIN-mode, with  
627 the same magnitude of improvement (Table-2). The described SIN-processing also generated  
628 surface elevations and elevation changes with lower sensitivity to the local surface slope,  
629 indicating a higher degree of accuracy in the geolocation and surface range estimation.

630 The SIN processing methodology further includes a phase filtering and phase ambiguity  
631 correction scheme. Visual inspections of a large number of tracks have shown more coherent  
632 estimation of the surface locations in the JPL product and further the implementation of the  
633 phase-ambiguity correction greatly reduced the number of track offsets. It was also noted that a  
634 relatively coarse DEM ( $\sim 1 \text{ km}$ ) could be used to resolve phase ambiguities. The detection and  
635 correction of phase ambiguities are relatively straightforward and rely mostly on the relative  
636 accuracy of the DEM. The implementation of the phase ambiguity correction is particularly

637 important when monitoring smaller ice caps and outlet glaciers, where frequent and large track  
638 offsets can bias the estimation of the underlying topography.

639         The new LRM processing methodology focused on optimal retrieval of surface  
640 elevations over the interior parts of the ice sheet. Here the choice of retracking threshold has  
641 proven to be the critical factor to acquire high quality surface elevations and elevation changes.  
642 The choice of 20% leading edge threshold level reduced the sensitivity to changes in the  
643 scattering regime for low slope, high elevation areas. The functional-based retracking algorithm  
644 used in the ESA LRM processor corresponds roughly to a 50% threshold level (Wingham et al.,  
645 2006a), which appears to suffer from a higher sensitivity to changes in the scattering properties  
646 (volume scattering) of the near-surface firn, as the range is reference higher up (later in time) on  
647 the leading edge of the waveform. This effect can be seen in Figure 2a, and that the observed  
648 negative elevation bias (Table-1) for ESA-LRM (-1.0 m) fit well with the bias for the 50% LRM  
649 threshold value shown in Figure 2a. This makes the algorithm more sensitive to annual and sub-  
650 annual changes in snow-packs volume/surface scattering ratio, which can produce spurious  
651 changes in elevation due to changes in the near surface dielectric properties. This is clearly  
652 shown in patterns of ESA product derived elevation changes (Figure 3) where a large elevation  
653 bias was introduced by the 2012-melt event (Nilsson et al., 2015a). The 20% threshold is less  
654 sensitive to these types of changes (Table 1 & 2) and the results are in agreement with previous  
655 work that has demonstrated that the 20% threshold best represents the mean surface inside the  
656 footprint when exposed to a combination of surface and volume scattering (Davis, 1997).

657         Surface elevation changes, derived from multi-temporal radar altimetry observations, are  
658 typically corrected for their correlation to changes in the radar waveform shape. This is to  
659 reduce the effect of changes in the volume/surface scattering ratio of the ice sheets surface  
660 (Davis, 2005; Flament and Rémy, 2012; Wingham et al., 2006b; Zwally et al., 2005). This  
661 inherently adds to the complexity of the processing and analysis, introducing new biases and  
662 error sources in the estimated parameters. For the processing approach presented here many

663 of these steps can be omitted or reduced, as they are an inherent part of the improved  
664 waveform retracking. There have been attempts to remove spurious step-changes in elevation  
665 resulting from sudden changes in surface scattering characteristics (caused by the 2012 melt  
666 event) apparent in the ESA Baseline-B L2 data through post-processing strategies (Nilsson et  
667 al., 2015c and McMillan et al., 2016), but such approaches spread the bias over a longer period  
668 of time making the “jumps” less noticeable in the time series by removing the step-change but  
669 introduces longer-timescale bias of equal magnitude as the scattering layer is buried by less  
670 reflective snow and low-density firn.

671 The result of the validation procedure shows a larger slope dependent bias in the ESA  
672 data, both in the elevation and elevation changes (Figure-1). This is especially true for the  
673 surface elevations, which can be seen in the figures of precision and accuracy (Figure 1a and  
674 1c), where both figures show clear linear slope for the ESA surface heights. In comparison,  
675 estimated elevations from JPL-product show relatively stable statistics over the entire slope  
676 range above  $0.2^\circ$ . The validation of the estimated surface elevation changes, seen in (Figure  
677 1b) and (Figure 1d), shows the effect of the 2012 melt event on the ESA derived elevation  
678 changes below  $0.2^\circ$ . Further, the accuracy of the ESA derived changes show a clear negative  
679 trend as function of increased surface slope. The derived precision of the surface elevation  
680 change increases dramatically above  $0.5^\circ$ , as more complex topography is measured.

681 The JPL CryoSat-2 processing methodology produces seasonal amplitudes that are in  
682 good agreement with those derived from ICESat data, further indicating the processors abilities  
683 to track real and physical changes of the ice sheets surface. The current ESA implementation  
684 produces noisier estimates of elevation change, as indicated by the larger standard deviations  
685 of the residuals in the ESA solutions for the surface-fit and crossover-method. Figure 5 further  
686 shows an amplitude bias in the ESA data compared to the corresponding ICESat reference  
687 amplitudes. The bias is constant above the Greenland ELA located around 2000 m in altitude  
688 but increases linearly as elevations decrease below this. The linear increase in amplitude

689 seems to be connected to the higher and more variable precipitation in the ablation zone where  
690 changes in the variable snow cover produces changes in apparent surface height. This is less  
691 prominent for the JPL SIN and LRM retrackers. The estimated seasonal phase in Figure 5c and  
692 5d show that both JPL and ESA CryoSat-2 elevation products can adequately resolve the  
693 seasonal maximum of the accumulation signal. Both products provide a timing of the maximum  
694 to the month of July over the entire ice sheet, independent of elevation. Assessing the CryoSat-  
695 2 derived maximum one does however notice a difference between CryoSat-2 and the  
696 reference ICESat dataset. This constitutes roughly a  $\pm 1$  month difference depending on the  
697 elevation and the location. The cause of this difference can be attributed to the temporal  
698 sampling of the ICESat mission. During the mission, due to degraded laser lifespan, data was  
699 only collected in campaign mode during the spring and winter times corresponding to roughly  
700 two months of measurements for each period. When the CryoSat-2 data was resampled to  
701 coincide with the ICESat temporal sampling the same elevation and spatial pattern in the phase  
702 of the maximum seasonal amplitude was observed as determined from the ICESat data. No  
703 corresponding change in amplitude was observed. This was done by selecting CryoSat-2 data  
704 corresponding to the same unique months available in the total ICESat record.

705         The two independent methods used to estimate the volume change of the Greenland Ice  
706 Sheet produce consistent volume change estimates. This was especially true for volume  
707 changes derived from the JPL elevations, with a discrepancy of less than  $1 \text{ km}^3 \text{ a}^{-1}$  between  
708 methods. The two methods provided the same estimate of integrated volume change but the  
709 use of the surface-fit is recommended as it produces higher spatial sampling compared to the  
710 crossover-method and lower errors. The good agreement between the methods further  
711 indicates a strong reliability in the estimated volume change rates of the Greenland Ice Sheet  
712 over the four-year period. It also shows the ability of CryoSat-2 to capture both small and large-  
713 scale spatial patterns in the rugged topography along the coastline and in the interior of

714 Greenland. This is especially true in the major outlet glacier systems (e.g., Zachariæ Isstrøm,  
715 Nioghalvfjerdingsfjorden and Storstrømmen).

716         Studying the northern parts of the Greenland Ice Sheet we find that CryoSat-2 captures  
717 both intricate and complex behavior in the marginal areas of the ice sheet. This is exemplified in  
718 the NE regions of Greenland (Figure 6) near Zachariæ Isstrøm, Nioghalvfjerdingsfjorden and  
719 Storstrømmen, which all show complex and localized patterns of elevation change. Here,  
720 Nioghalvfjerdingsbrae shows very small changes in elevation during the observational time-span,  
721 while Zachariæ Isstrøm, its major neighbor shows large negative trends in elevation change.  
722 The observed behavior agrees with the observations made in recent studies by Khan et al.  
723 (2014) and Mouginot et al. (2015) who document rapid retreat and drawdown of the ice-front  
724 position of the Zachariæ Isstrøm beginning in 2012. Storstrømmen outlet glacier system also  
725 appears to show signs of rapid thinning at low elevations near the ice-front position while a large  
726 positive signal is observed roughly 100 km upstream of the terminus. This pattern has also been  
727 observed by Joughin et al., (2010) and Thomas et al., (2009), using airborne altimetry and  
728 surface velocity mapping. Rates of elevation change from ICESat and CryoSat-2 data show  
729 good agreement in basin-scale trends (Figure 6b,c) over the 2003-2009 and 2010-2015 time  
730 spans.

731 Mass loss of the Greenland Ice Sheet was estimated for comparison purposes from the Gravity  
732 Recovery Climate Experiment (GRACE) satellite for the matching CryoSat-2 time period of  
733 2011-2015 (Wiese et al., 2015; Watkins et al., 2015). Converting the estimated mass change to  
734 volume change, assuming no changes in firn air content over the study period and an ice  
735 density of  $917 \text{ kg m}^{-3}$  (assessment of changes in firn air content is out of the scope of this  
736 paper), gives an ice sheet wide rate of  $-305 \pm 38 \text{ km}^3 \text{ a}^{-1}$  (updated to Schlegel et al., 2016). This  
737 estimate is corrected for volume changes from peripheral glaciers that lost volume at a rate of  
738 approximately  $-40 \pm 27 \text{ km}^3 \text{ a}^{-1}$  (Box, 2013; Fettweis et al., 2012; Noël et al., 2015). This

739 estimate of peripheral glacier change is in agreement with the estimated volume change of  $-41$   
740  $\pm 8 \text{ km}^3 \text{ a}^{-1}$  from Gardner et al, (2013). The volume rate derived from GRACE data agrees well  
741 with our estimated rate from CryoSat-2, where both results are within the  $1\sigma$  uncertainty of each  
742 other and neglecting changes in firn air content over the period of study. The observed volume  
743 change rates estimated from this study are within the range of previous studies, ranging from -  
744  $186$  to  $-309 \text{ km}^3 \text{ a}^{-1}$  for the time period 2003-2009, summarized by Csatho et al. (2014), using  
745 the same mass to volume conversion applied to the GRACE data. A more recent study by Helm  
746 et al. (2014) of  $-375 \pm 24 \text{ km}^3 \text{ a}^{-1}$  agrees within uncertainties when differences in observation  
747 periods (2011 – 2014 vs. 2011 - 2015) are taken into account. From this comparison we find  
748 that our estimate spans both the estimate of Csatho et al. (2014) and the mass loss estimated  
749 from GRACE, while acknowledging the varied time spans of the different studies.

## 750 9 – Summary and Conclusion

751 We conclude that the use of an adaptive retracker for the SIN-mode, based on the maximum  
752 gradient method, and the use of 20% threshold retracker for the LRM-mode provide improved  
753 performance to the retracker currently used for the ESA L2 elevation products. It is further  
754 important, especially for the SIN-mode, to apply a leading edge discriminator to identify and  
755 track the leading edge of the waveform. The functional model currently employed in the ESA  
756 processor has, to the author's knowledge, no such discriminator currently implemented. This is  
757 important in the SIN-mode, as it often contains multiple surface returns. The single-return model  
758 applied in the ESA processor will here have issues fitting a waveform containing multiple  
759 surface returns resulting in retrack jitter (Helm et al., 2014).

760 Using the new CryoSat-2 processing methodology for the LRM and SIN-mode we  
761 determine the volume change of the Greenland Ice Sheet to be  $-289 \pm 20 \text{ km}^3 \text{ a}^{-1}$  during the  
762 period January 2011 to January 2015. The validation against airborne ATM surface elevations  
763 and elevation changes showed an average improvement in the RMSE of the measured

764 elevations of 68% and 27% for the LRM and SIN mode respectively compared to ESA Baseline-  
765 B L2 products. The new methodology also provide improved elevation changes with an  
766 reduction in RMSE of 55% and 40% for the LRM and SIN mode respectively, compared to their  
767 ESA L2 derived counterparts.

768 The methodology also showed less sensitivity to changes in near-surface scattering  
769 properties than equivalent ESA products. The new processing methodology showed little effect  
770 of slope-induced errors, providing better performance in the marginal areas of the ice sheets.  
771 These improvements to the CryoSat-2 processing mitigate the need for post-processing to  
772 correct correlations between changes in surface elevation and changes in the waveform shape  
773 (i.e. backscatter and leading edge width etc.) that can introduce biases and add to the  
774 complexity of the processing and analysis.

775 The presented CryoSat-2 processing methodology provides a lower intrinsic error in the  
776 measured elevation, elevation change and volume change estimates, all of which will facilitate  
777 improved understanding of the geophysical process leading to changes in land ice elevation.

778 Given the release of the ESA Baseline-C, which provides improved corrections and processing  
779 mainly for the L1B product, further improvements are expected in the near future.

780 The complete set of grids used in this study is available for the public from the main author (J.  
781 Nilsson) upon request and are provided in geotiff format.

## 782 Acknowledgement

783 We are deeply thankful for the guidance of Laurence Gray and support of David Burgess. We  
784 also thank Sebastian Bjerregaard Simonsen for very fruitful discussions. Further, we thank  
785 Frank Paul at the University of Zurich for providing us with polygon-outlines of the Greenland Ice  
786 Sheet and to the European Space Agency for providing their CryoSat-2 L1b product. We are  
787 very grateful to the editor E. Berthier, the reviewer L. Schröder and an anonymous reviewer for

788 their thoughtful and thorough comments that greatly improve the writing and content of the  
789 manuscript. We also thank Nicole-Jeanne Schlegel and David Wiese at the Jet Propulsion  
790 Laboratory for the use of their GRACE analysis. This publication is contribution 86 of the Nordic  
791 Centre of Excellence SVALI funded by the Nordic Top-level Research Initiative. This work was  
792 supported by funding from the NASA Cryosphere program. The research was conducted at the  
793 Jet Propulsion Laboratory, California Institute of Technology under contract with NASA.

## Rebuttal to editor for tc-2016-109

We would like to thank the editor for accepting our manuscript for publication and yet again for his valuable comments. As requested we have corrected the following last comments from the editor in the manuscript and provided tracked changes.

The editor's comments are marked using (E) and the corresponding response below with (R).

Main manuscript:

(E) L810. Schlegel et al., 2016 should appear in the reference list.

(R) Changed accordingly

(E) L891. "We very grateful to the editor". "are" missing

(R) Changed accordingly

(E) L1121. "as a function retracking threshold". "of the" missing

(R) Changed accordingly

(E) L1158. mention in the legend of this figure that the time series compare the result of two retrackers (as you explain well in the legend of Figure 5 for example).

(R) Extended the first sentence to describe the two solutions shown in the figure
