

## Response to the Editors comments

We thank the editor for useful comments and questions, below follows our answers and changes, highlighted in blue after the editor's comments. Blue page (P) and line (L) numbers refer to the revised manuscript (2<sup>nd</sup> revision), and red numbers refer to the marked-up revised manuscript.

A general question/concern for me is the suitability of X-band for the melt pond application. Could the results be used to argue for future X-band missions? Or specific modes? Or should space agencies better invest in C/L-band, perhaps conically scanning to avoid the effect of incidence angle dependency and reduce the wind speed dependency?

This is an important question. Our study indicates a potential for melt pond fraction retrieval from X-band SAR, but it does not prove that this is possible, as we do not present a ready-to-go operational method. However, if X-band is to be used for melt pond retrieval, our study give some guidance in choice of polarimetric channels, incidence angles, mode and wind speeds suitable for melt pond fraction retrieval. According to our findings, the combination of VV and HH channel is useful for melt pond fraction retrieval when wind is present, the incidence angle should preferably be above 30° but below 40°, and in our case StripMap mode, giving a high resolution, were used. The latter does not exclude other modes from being useful; this has to be further investigated. X-band does not seem to have an advantage over C-band, as X-band retrieval theoretically can be done in a narrower wind speed range, and the low noise floor of TerraSAR-X imply a disadvantage. Melt pond fraction retrieval from L-band has not yet been documented. Most of these points are summarized in the second paragraph in the conclusion, but due to the editors questions, we have added the following sentences:

- The following sentence was added (Conclusion P18L588-589, P18L606-607): "Hence, both the HH and VV polarimetric channels are needed for a future  $f_{MP}$  retrieval in X-band."
- The following sentence was added (Conclusion P18L594-596, P18L612-613): "Future studies should focus on incidence angles in the range between 29° and 40°."

How was the significance calculated? I found no explanation of the method. Do you consider the independence of the data? Smoothing reduces the number of degrees of freedom and increases autocorrelation. How was this taken into consideration?

Consideration of significance was lacking from the Method section, but has now been added. Smoothing will of course increase the autocorrelation, and this could be problematic if we were working with higher order statistics. Working with mean values however, this should not be a problem that needs to be accounted for. The following sentence is now added:

- The following sentence was added (Method P11L326, P11L332): "Correlations were considered significant if they had p-values below 0.05."

A specific reviewer comment was: "Give also pixel size of SAR images, only window size in pixels does not tell geometric size on the area.". Could you please add the geometrical sizes of the windows? Pixel spacing is already included in Table 1, and is varying in the four included satellite scenes. Hence the geometrical window size would vary slightly from scene to scene. To make this even clearer, geometrical window size is now specified in the results for T3 and T4:

- The following sentence was rephrased (Results P12L390-392, P13L401-402): "The results are presented both for a 21x 21 and a 51x 51 pixels smoothing window, corresponding to areas 50x40 m and 120x95 m in the across x along flight direction."

- The following sentence was added (Results P14L440-441, P14L452-453): “The results are presented both for a 21x 21 and a 51x 51 pixels smoothing window, corresponding to areas of 65x30 m and 155x65 m in the across x along flight direction.”

I wonder how the original SAR image looks like. Usually it is very instructive to have a look at the original texture and I suggest to show the unfiltered images in comparison to the smoothed versions. Unfiltered SAR scenes would appear as noise, and we therefore do not find them useful to show. Figure 2 shows the floe in T3 and T4 with a moderate smoothing of 11x11 pixels, and can be used for comparison with the extensively smoothed versions presented in Figure 5 and 9. The following change was made to make clear what smoothing was used in Fig. 2:

- Figure caption rephrased, Figure 2: The floe investigated in scene T3 (left) and T4 (right) with a 11x11 pixels smoothing window.

"Scale sensitivity was tested by using a range of different smoothing window sizes ( $13 \times 13$  to  $51 \times 51$  pixels) in the f M P estimation". This sentence comes without a result or conclusion.

We agree that this sentence is slightly misleading and imprecise. We did not test scale sensitivity, but looked at the effect of smoothing scales. To improve this, we have made the following change:

- The following sentence was rephrased (Method P11L333-334, P11L339-340): “The effect of smoothing was tested by using a range of different averaging sliding smoothing window sizes ( $13 \times 13$  to  $51 \times 51$  pixels) in the f M P estimation.”

The unit of f<sub>MP</sub> is confusing, given as a value between 0 and 1 \_and\_ as a percentage. I would expect values between 0 and 100 for the percentage.

This has now been corrected in all figures.

I was also confused about the definition of "empirical" and "global". A regression is an empirical technique. Perhaps use different terms?

We have changed the term “empirical” to “observed”. This is done several places in the manuscript. “Global” has been changed to “region” and “regional”. This is also done several places in the manuscript.

Fig. 6 looks a bit strange. The rectangles seem to have a border color? There are obvious blocky/stripe artefacts from the smoothing. Have you tried to use different window functions? I assume that you used a simple boxcar weighting but I did not find the information explicitly in the manuscript.

The rectangles represent the helicopter photos, and the border color represents the melt pond fraction observed in each photo, hence the rectangles are meant to have different border colors. A sliding averaging window (boxcar) was used in the smoothing; to specify this the following change was made:

- The following sentence was rephrased Method P11L333-334, P11L339-340): “The effect of smoothing was tested by using a range of different averaging sliding smoothing window sizes ( $13 \times 13$  to  $51 \times 51$  pixels) in the f M P estimation.”

Fig. 10 \sigma

This have been corrected.

Fig. 11: What is the meaning of negative melt pond fraction?

Negative melt pond fractions simply imply that the regression fit retrieved from T4 leads to an underestimation of the melt pond fraction in the three other satellite scene. This is commented on in the manuscript, and to be more clear about this, the following change was made:

- The following sentence was rephrased (Results P14L460-461, P15L472-473): "In the three other scenes the estimate is poor; it underestimates fmp, introducing negative fractions."

Eg. 16 use \sin

This is corrected.

20 "Despite this, our findings demonstrate suggest new possibilities in melt pond fraction estimation from SAR, opening for expanded monitoring of melt ponds during melt season. " What are the new possibilities?

21 "In the next step, melt pond estimation from SAR may supplement surveillance from optical satellites, providing melt pond information to climate applications during cloudy conditions." Isn't this a bit too optimistic? If the method would be a feasible all weather approach (still to be proven), we would need long time series and large coverage for climate applications. The application needs at the same time high SAR resolution. This could be maybe in several years ahead but certainly not for the "next step"

Due to this comment from the editor, we have moderated the two last sentences in the abstract:

- Sentences rephrased (Abstract P1L18-20, P1L20-24): "Despite this, our findings suggest new possibilities in melt pond fraction estimation from X-band SAR, opening for expanded monitoring of melt ponds during melt season in the future."

519 "Scharien et al. (2014b) finds that the Bragg criterion is exceeded for melt ponds at wind speeds above  $U_{10} \approx 5$  m/s in X-band, reducing the expected correlation between  $R_{VV}/HH$  and  $f_{MP}$  above this wind speed." Sharien et al. deal with C-band. How do you justify this statement.

This statement referes to Figure 4 in Schareien et al. (2014b), that shows that melt ponds reached a rms height of 1.4 mm (the Bragg criterion) at 5 m/s wind speed. To make this more clear to the reader, the following change has been added:

- The following sentences are changed/rephrased (Discussion P15L475-478, P15L487-489): "In X-band, the Bragg criterion is exceeded for  $s_{RMS} > 1.4$  mm. Scharien et al. (2014b) finds that melt ponds exceed this roughness at wind speeds above  $U_{10} \approx 5$  m/s, reducing the expected correlation between  $R_{VV}/HH$  and  $f_{mp}$  above this wind speed."

623 "Such an algorithm could supplement optical methods, and be used as a tool in climate applications, both as input in climate models and in studies of melt pond evolution mechanisms." Not clear to me how to use the algorithm as "input" for climate models.

We agree with the editor, and have rephrased the sentence:

- The sentence is rephrased (Conclusion P18L584-586, P18L603-604): "Such an algorithm could supplement optical methods, and be used as a tool in climate applications, e.g, in studies of melt pond evolution mechanisms."

635 "In the future, use of X-band scenes can possibly increase the total amount of SAR data accessible for f M P retrieval, despite their limitations compared to C-band scenes." Do you argue for future new X-band SAR systems? Or would C-band (or L-band) be a better choice for the application. This is not clear.

This sentence states that X-band retrieval of melt pond fraction could be a supplement to C-band retrieval in the future, but point back to the stricter limitations concerning wind speed and noise floor in X-band discussed in the preceding sentences. At this point, we have too little information to advise C-band in preference to X-band, even if our results might point in that direction.

644 "...and introduced uncertainties in our results, possibly causing artificially low correlation values" Why artificially? Fig. 2 suggests that the geo-location is not too bad?

As mentioned in the Method-section, the co-location had a maximum areal offset of 27% between the satellite images and the helicopter images. This is a considerable source of error, possibly reducing the correlation values in the manuscript. To make this clearer in the Conclusion, the following change was made:

- Sentence rephrased (Conclusion P18L603-606, P19L621-624): "Challenges in co-location of airborne observations and SAR imagery limited coordinated use of existing data in our study and introduced uncertainties in our results, with areal offsets of up to 27%, possibly causing artificially low correlation values."

Response to review of the revised manuscript by reviewer #1

We thank the reviewer for reviewing our revised manuscript, and for all useful comments provided on the improved manuscript. Below follow our answers and changes, highlighted in blue after each of the reviewer's comments. Blue page (P) and line (L) numbers refer to the revised manuscript (2<sup>nd</sup> revision), and red numbers refer to the marked-up revised manuscript.

## Review of the revised paper

### General comments

The authors have presented detailed, proper answers to all my comments to the previous version of the paper, and made corresponding changes and additions to the paper. I think that the paper has improved considerably. Below are some further comments, the major one is related to the T4 data and its analysis.

The empirical models for the MPF estimation were developed using datasets over a large ice floe. Why were not all co-incident SAR imagery vs. airborne photography used? How results would change if they were?

As this study was performed on drifting sea ice, co-location between SAR scenes and helicopter data is very challenging. This is also commented on in the conclusion of the manuscript. Most of the airborne photos were not possible to be co-located with the satellite observations exact enough to meet our demands of a high quality study. However, for the investigated floe, we managed to do a reliable co-location, and the floe was also the only floe appearing in two of the scenes. We therefore chose to focus on this specific floe in our investigations to secure the quality of the study.

You could also explain this shortly in the paper.

We agree in this, and have added the following sentences in the Method section:

- The following sentences were added (Method P10L301-303, P10L307-309): "This floe was chosen as it allowed for a reliable co-location between airborne images and satellite scenes, and was present in more than one scene. The rest of the airborne track was not possible to co-locate exact enough for a high-quality study."

Results Section could include short introductory at the start about its content.

To meet this request, the following sentences have been added:

- The following sentences have been added (Results P11L342-344, P11L349-351): "This section presents the results of the correlation analysis examining the relation between the investigated polarimetric SAR features and observed  $f_{MP}$ . It then present a brief signal-to-noise analysis, before it focuses on  $f_{MP}$  retrieval in an intermediate and a low-wind case."

Reference Divine et al. (2016, in review) describes the method to estimate DTM and surface roughness from stereo camera photos, but as its 'in review' readers do have access to it, any published references? Conference papers? I have to say I don't personally like these 'in review' references, as they may not get published in the end.

We agree that "in review" references are not optimal. Divine et al (2016) is now published, and the reference was updated in the bibliography and in the manuscript.

ENL is a far more complicated issue, and we do not see how including this would strengthen the manuscript. We are not statistically modelling the speckle distributions, and only look at the mean values after smoothing.

I was thinking about radiometric resolution:  $10 \cdot \log_{10}(1 + 1/\sqrt{\text{ENL}})$ , but it is likely insignificant for mean  $\sigma_{\text{0}}$  values. I have estimated ENL over textureless open water areas. Your comment on the subject was ok.

Section 3.2 Data set: line 272. Reader gets an idea that NESZ was subtracted from SAR imagery, and then images are analyzed, but later Section 4.1 results are presented with and without noise

reduction in SAR imagery. I think you should selected either way, or does having both add great value to your results and paper?

We agree in this, and have changed Table 4 to include only values retrieved after NESZ subtraction. Table caption and reference to the table in the manuscript has been updated after this change. The following changes have also been added:

- Sentences has been rephrased (Discussion P17L549-554, P17L562-569) “ $\alpha_1$  was found significantly correlated with  $f_{MP}$  in scene T3. This is likely a result of the expected relation between  $\alpha_1$  and  $R_{VV/HH}$  (vanZyl, 2011). In scene T4, several of the polarimetric SAR features were found related to melt pond fraction before NESZ subtraction, after NESZ subtraction, only the standard deviation of  $|p|$  showed a relationship. This indicates that the correlations only reflected the low signal-to-noise ratio of the scene, as has previously been described in oil/water discrimination (Minchew et al. 2012).”

Section 4.1, lines 386-397 and Table 4: For SAR scene T4 acquired at very low wind speed, HH and VV sigma0 decreases with increasing melt pond fraction. This makes sense as there are more low backscatter smooth melt pond surface with increasing mpf. However, RVV/HH also decreases with increasing mpf (negative Spearman’s correlation in Table 4), I found this puzzling as smooth surface should have high RVV/HH. In addition, in (Scharien et al. 2014a), Figure 5, RVV/HH is not decreasing with increasing mpf. Scharien et al. had strong positive relationship between RVV/HH and mpf is low wind speed (1.1 m/s) case. In Figure 10 of Yackel et al. (2000) s0VV slightly increases with increasing mpf under low wind speed conditions (1.5 m/s).

Something wrong in your SAR data, too large contamination by SAR noise? If not, how do you explain the observations? Would be nice to see RVV/HH vs. mpf plot for the T4 case. How RVV/HH vs. mpf in T4 case changes if you set a lower signal-to-noise ratio for s0 data, for example 5dB, i.e. only those RVV/HH datapoints with SNR larger than 5 dB for s0HH and s0VV are accepted? I think you need to investigate further your T4 data.

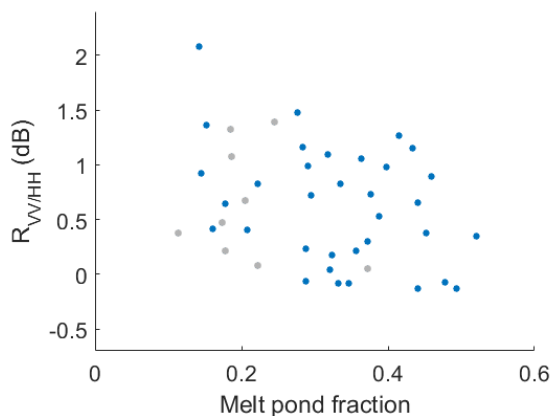

I am should have presented this observation in my first review, sorry about this...but I noticed this now.

These are very interesting comments and questions. First of all, due to the low wind speed in T4 (0.6 m/s), we would expect specular reflection from the ponds. Hence, the backscatter signal from the ponds is most probably weak or lacking, which is mirrored by the decrease in intensity with increasing melt pond fraction. The low SNR could also contribute to mask out a weak melt pond signal. Co-polarisation ratio is expected to increase with melt pond fraction due to the difference in relative permittivity between sea ice and water. However, if there is no signal from the melt ponds, co-polarisation ratio is only representing the sea ice, and is not anymore related to melt pond fraction. The decrease of co-polarisation ratio with melt pond fraction in T4 is, in our opinion, only reflecting slightly different sea ice types/sea ice surface roughnesses surrounding the melt ponds in areas with high and low melt pond fraction. The correlation value of 0.31 is also very low (0.3 would reflect a p-value larger than 0.05), indicating a weak relation. This could be observed in the figure attached below, showing a scatter plot of co-polarisation ratio vs.  $f_{MP}$ .

Scharien et al (2014a) found, as the reviewer states, a strong positive relationship between co-pol ratio and  $f_{MP}$  during low wind speeds (1.1 m/s). There are several differences between our study and Scharien et al (2014a), that could all contribute to the different findings. We had an even lower wind speed during acquisition of T4 (0.6 m/s) and a lower SNR, which could both make a large difference. The study of Scharien was also performed on smooth land-fast sea ice, a larger degree of smoothing was utilized, and the incidence angle was slightly higher. To directly compare the two studies is therefore difficult, and demonstrate the need of investigating a variety of conditions, wind speeds and incidence angles in future studies.

The relation between intensity and  $f_{MP}$  found in Yackel and Barber (2000) is very weak ( $R^2=0.01!$ ). Again, slightly higher wind speed (1.5 m/s), different SNR, different incidence angle, and different sea ice type could all contribute to difference in findings from our study.

The SNR ratio of T4 is low, and as mentioned above, this is absolutely a concern in our study. However, the relation displayed between intensity and  $f_{MP}$  is statistically significant (p-value <0.05). Maybe a higher SNR ratio could have given even better results? A further investigation of the T4 data, and a general study on noise floor effect on sea ice studies with TerraSAR-X would be very interesting, and could be a task of a future study.

To clarify the above-mentioned issues for the reader, the following changes have been made in the manuscript:

- The following sentences were rephrased (Discussion P13L480-492, P15L492-505): “Scene T4 represents a low wind speed situation ( $U_2=0.6$  m/s), and our results indicate specular, or close to specular reflection from the melt ponds in this case. The weak melt pond backscatter, combined with a low SNR, hamper the use of difference in polarimetric properties between sea ice and melt ponds for melt pond fraction retrieval. The weak correlation seen between  $R_{VV/HH}$  and  $f_{MP}$  in Table 4 is most probably reflecting slightly different sea ice surface types surrounding the ponds in areas with low and high melt pond fraction, rather than different polarimetric signatures between melt ponds and sea ice. The low correlation observed between  $R_{VV/HH}$  and  $f_{MP}$  in this low wind case is in agreement with findings in Scharien et al (2012) and (2014b), while Scharien et al. (2014a) found a relation between  $R_{VV/HH}$  and  $f_{MP}$  even at low wind speeds ( $U_{10}=1.1$  m/s). Different wind speeds, incidence angle and sea ice types could all contribute to the deviating findings. The lack of backscatter from the melt pond surfaces compared to the sea ice could potentially be used for  $f_{MP}$  retrieval utilizing  $\sigma^0$ , as the backscatter intensity becomes weaker with increasing  $f_{MP}$ .”

Finally, Yackel and Barber (2000) speculated that MPF may be more closely related to the albedo than to melt pond fraction due to the fact that albedo results from the integration of all surface types (snow, saturated snow, melt ponds) which contribute to the measured MPF. What’s the authors’ view on this; would it be better to investigate the relationship between SAR data and albedo than SAR and melt pond fraction? Please, discuss this in Introduction Section.

This question might have a typing error, and we find it slightly unclear. We interpret the question to ask whether estimated melt pond fraction should be compared to albedo instead of observed melt

pond fraction. Albedo refers to the average reflection of waves in the visible range of the microwave spectrum. As SAR uses microwaves to evaluate the sea ice surface, we find it more credible to utilize differences in the microwave signature between melt ponds and sea ice, or methods that employ statistical features describing fractional mixtures of surfaces.

In our study, albedo is not measured, and would have to be estimated by upscaling from melt pond fraction measurements and in situ measured albedo values of different surface types. This method would inevitably introduce additional uncertainty to the results (see f.ex. Divine et al., 2015 for estimates made for the study area), and is therefore not advisable for our data set. The relationship between albedo and polarimetric features will therefore not be discussed in detail in our manuscript.

My idea was that as backscatter measured with SAR, if pixel size is not too small, is a mixture of backscatter from meltponds, bare ice, snow covered ice, then the backscatter could be more related to albedo than melt pond fraction. Albedo is naturally derivative of mpf. This is what Yackel and Barber (2000) speculated, see page 22068, left column. But you can leave this out the paper.

## Specific comments

### Abstract

“The regression fits gave good estimates of mean melt pond fraction for the full satellite scenes, deviating with less than 4% from the airborne retrieved melt 15 pond fractions in the investigated area.”

Mention shortly the airborne data used in the melt pond fraction estimation.

This comment is slightly unclear for us; we have tried to rephrase the sentence to clarify the origin of the airborne retrieved melt pond fraction:

Sentence rephrased (Abstract P1L11-14, P1L11-15): “The regression fits gave good estimates of mean melt pond fraction for the full satellite scenes, with less than 4% deviation from a similar statistics derived from analysis of low altitude imagery captured during helicopter ice-survey flights in the study area.”

“A smoothing window of 51x51 pixels gave the best reproduction of the width of the melt pond fraction distribution.”

Give also pixel size of SAR images, only window size in pixels does not tell geometric size on the area.

The pixel spacing of each of the SAR satellite scenes are given in Table 1, and as can be seen in the table, they vary slightly from scene to scene. Hence a 51 x51 pixel window would have different geometrical sizes in each satellite scene. We find it cumbersome to include this in the abstract, but have included geometrical window sizes in the results, as commented on in the answer to the editor’s comments.

“optical satellites” better “optical imagery”

The sentence where this term occurred was removed due to the editor’s comments.

## 1 Introduction

I. 36: “Formation and evolution of melt ponds are poorly represented in sea ice models, potentially contributing to an underestimation of the observed sea ice extent reduction in model projections (Flocco et al., 2012; Holland et al., 2012; Flocco et al., 2015).”

Possible to explain shortly the reason for this underestimation? If not, then there are these three refs for the readers.

We would like to keep this paragraph brief, and will therefore leave it up to the readers to go in depth on this.

I. 42: “Several algorithms have been developed for retrieval of melt pond fraction...”

fMP defined before, could be used instead of “melt pond fraction”. Check also whole text for the same issue.

We have now changed melt pond fraction to its abbreviation several places in the manuscript.

I. 104: “TerraSAR-X offers very high resolution multi-polarimetric data,...”

What do you mean by multi-polarimetric data? You have dual-polarisation TSX SAR images.

Multi-polarimetric data is a collective term for data with more than one polarization. To be more precise, we have changed the sentence:

- The following sentence was rephrased (Introduction P4L99-100, P4L102-103): “TerraSAR-X offers very high resolution dual-polarimetric images,...”

You could add at the end of Introduction Section short overview of the content paper Sections. Like “First, Section 2 presents ...”

As all chapters have self-explanatory titles, and the last paragraph of the introduction already explains the presented work in conceptual terms, we have decided to avoid this extra text in the manuscript.

## 2 Melt ponds in SAR imagery

I. 118: “During very calm conditions, the SAR signal of melt ponds is mainly specular.”

Maybe better “scattering from melt ponds is mainly specular”

We agree in this and have done the following change:

- Sentence rephrased (Melt ponds in SAR imagery P4L112-113, P4L116-117): “During very calm conditions, the scattering from melt ponds is mainly specular.”

p. 3, I. 127: “The coverage of melt ponds varies during the melt season, starting out with a high fractional cover, and reducing as the ponds drains. At the end of the melt season, the melt ponds refreezes.”

I think melt pond fraction first increases, has a maximum level, and then decreases, ending up with remaining ponds refreezing, see e.g Fig. 6 in Rösel, A., Kaleschke, L., and Birnbaum, G.: Melt ponds on Arctic sea ice determined from MODIS satellite data using an artificial neural network, The Cryosphere, 6, 431–446, doi:10.5194/tc-6-431-2012, 2012.

We agree that the sentences were slightly unprecise, and have done the following changes:

- Sentences rephrased (Melt ponds in SAR imagery P4L121-123, P4L125-129): “The coverage of melt ponds varies during the melt season, increasing from melt onset until it reaches a maximum level, and then gradually reducing as the ponds starts to drain \cite{Barber2001}. At the end of the melt season, the remaining melt ponds refreeze.”

I. 184: “The sea ice surface roughness was found to high to fill the criterion...”

‘too high’

The spelling error was corrected.

I. 201: “Entropy (H) is a part of the H=A= polarimetric decomposition, based on the eigenvectors and eigenvalues of T , describing SAR scattering mechanisms.”

This sentence should have a reference to the polarimetric decomposition.

A reference to Cloude and Pottier (1997) was added to the sentence.

## 3 Methods

Figure 2 in greyscale could show better sigma0 variation.

The figure is now in greyscale.

## 4 Results

I. 375: “and values in parentheses show results after before NESZ subtraction of the signal”

...NESZ subtraction in the SAR imagery...

The sentence was removed as information about the results before NESZ subtraction have been removed from the paper.

Figure 4: gray and blue dots does not separate well; very long minus sign on -0.49

The color of the dots have been slightly modified, and the minus sign is removed (it should be +)

Figure 6 and 10: what is the spatial size of the images in km?

The spatial size of the images is 0.3 x 1.1 km, this has been added in the figure captions.

## 5 Discussion

I. 558 “From the helicopter images, some of the very low RVV/HH values observed at the investigated floe in scene T3 were from slightly deformed areas, possibly explaining the negative ratios. However, no general trend in low RVV/HH values in deformed areas was found in our study.”

Paper: Sea ice type and open water discrimination using dual co-polarized C-band SAR, T Geldsetzer and J J Yackel, Canadian Journal of Remote Sensing Vol. 35 , Iss. 1, 2009 4

may have interesting results in the context of your paper. Average RVV/HH larger than 0 dB for various ice types, but <0 dB observations also exist.

In Figure 4 large amount of negative RVV/HH values, not saying they are wrong, but kinda puzzling...calibration error between TSX HH and VV channels? If so, I guess there is nothing you can do to correct it.

We agree that negative co-polarisation ratio values seem a bit odd. As we have written in the manuscript, the negative values might relate to multiple scattering from deformed areas, but there could be other reasons as well, for instance those described by Geldsetzer et al (2009). Scharien et al (2014b) also reports negative co-polarisation ratio values (see Figure 8) both for bare ice and ponds. We cannot exclude calibration errors between the HH and VV channels, but as you write, this is hard to verify and correct. T3 is also well above the noise floor, so low SNR cannot explain the negative values. We have decided to include a reference to Geldsetzer and Scharien in the text, slightly expanding the above referred sentences:

- Sentences and references added (Discussion P16L522-524, P16L535-537): “Other small scale surface scattering processes could also have caused low  $R_{VV/HH}$ , negative values have also been reported in other FYI studies, e.g., Geldsetzer and Yackel (2009) and Scharien et al. (2014b).”

## 6 Conclusions

I. 632: “At very low wind speeds (0.6 m/s), the backscatter signal from the melt ponds became too low for fMP retrieval based on polarimetric features. In that case, s0VV was found suitable for fMP estimation.”

If SNR is too low for polarimetric features, then why it is not too low for s0? Again, the T4 data may be too contaminated with SAR noise for mpf retrieval studies.

The above-referred sentence discusses the weak or lacking backscatter from the melt ponds in T4, which in our opinion is related to low wind speed at the acquisition time. The low SNR might also contribute to mask the melt pond signature in the SAR images. The consequence of a lacking signal from the melt ponds is that the difference in polarimetric properties between melt ponds and sea ice cannot be used for melt pond detection in this case. However, the lack of backscatter from the melt ponds would lead to a lower backscatter intensity in the areas with high melt pond fraction. This could explain the relation between sigma VV for melt pond fraction in the case of T4. We have tried to clarify this in the manuscript:

- The following sentences were rephrased (Conclusion P18L595-597, P18L613-615): “At very low wind speeds (0.6 m/s), the backscatter signal from the melt ponds became too low for  $f_{MP}$  retrieval based on polarimetric features due to specular reflection. In that case,  $\sigma_{VV}^0$  was found suitable for  $f_{MP}$  estimation, due to the lower intensity in areas with high  $f_{MP}$ .”

# Signature of Arctic first-year ice melt pond fraction in X-band SAR imagery

**Abstract.** In this paper we investigate the potential of melt pond fraction retrieval from X-band polarimetric synthetic aperture radar (SAR) on drifting first-year sea ice. Melt pond fractions retrieved from a helicopter-borne camera system were compared to polarimetric features extracted from four dual polarimetric X-band SAR scenes, revealing significant relationships. The correlations were strongly dependent on wind speed and SAR incidence angle. Co-polarisation ratio was found to be the most promising SAR feature for melt pond fraction estimation at intermediate wind speeds (6.2 m/s), with a Spearman's correlation coefficient of 0.46. At low wind speeds (0.6 m/s), this relation disappeared due to low backscatter from the melt ponds, and backscatter VV-polarisation intensity had the strongest relationship to melt pond fraction with a correlation coefficient of  $-0.53$ . To further investigate these relations, regression fits were made both for the intermediate ( $R^2_{fit} = 0.21$ ) and low ( $R^2_{fit} = 0.26$ ) wind case, and the fits were tested on the satellite scenes in the study. The regression fits gave good estimates of mean melt pond fraction for the full satellite scenes, deviating with less than 4% from ~~the airborne retrieved melt pond fractions in the investigated~~ a similar statistics derived from analysis of low altitude imagery captured during helicopter ice-survey flights in the study area. A smoothing window of  $51 \times 51$  pixels gave the best reproduction of the width of the melt pond fraction distribution. A considerable part of the backscatter signal was below the noise floor at SAR incidence angles above  $\sim 40^\circ$ , restricting the information gain from polarimetric features above this threshold. Compared to previous studies in C-band, limitations concerning wind speed and noise floor set stricter constraints on melt pond fraction retrieval in X-band. Despite this, our findings suggest new possibilities in melt pond fraction estimation from X-band SAR, opening for expanded monitoring of melt ponds during melt season. ~~In the next step, melt pond estimation from SAR may supplement surveillance from optical satellites, providing melt pond information to climate applications during cloudy conditions.~~ in the future.

## 1 Introduction

Melt ponds form from snow and ice melt water on the Arctic sea ice during spring and summer, and can cover up to 50 – 60% of the sea ice surface (Perovich, 2002; Eicken et al., 2004; Inoue et al., 2008; Perovich et al., 2009; Polashenski et al., 2012). Their presence affects the heat budget of the sea ice by decreasing the surface albedo, which increases the solar absorption in the ice volume and the transmission of solar energy to the ocean (Eicken et al., 2004; Ehn et al., 2011; Nicolaus et al., 2012; Perovich and Polashenski, 2012). The transmission is generally larger for first-year ice (FYI) than for multiyear ice (MYI) due to FYI's lower sea ice thickness. (Light et al., 2008; Nicolaus et al., 2012; Hudson et al., 2013). FYI also often experiences higher melt pond fractions ( $f_{MP}$ ) than MYI (Fetterer and Untersteiner, 1998; Nicolaus et al., 2012). The increased absorption induced by melt ponds accelerates the decay of sea ice, and the intensified warming of the ocean possibly delays the ice growth in the autumn (Flocco et al., 2012; Holland et al., 2012; Hudson et al., 2013; Schröder et al., 2014; Flocco et al., 2015). Formation and evolution of melt ponds are poorly represented in sea ice models, potentially contributing to an underestimation of the observed sea ice extent reduction in model projections (Flocco et al., 2012; Holland et al., 2012; Flocco et al., 2015). An increased number of observations of ~~melt pond fraction~~ ( $f_{MP}$ ) for different sea ice types at regional scale is needed to improve the understanding of the role of melt ponds in the Arctic climate system. Satellite imagery offers good opportunities for such large scale monitoring of melt ponds.

Several algorithms have been developed for retrieval of ~~melt pond fraction~~  $f_{MP}$  from optical satellites, measuring the spectral reflectance from open water, sea ice and melt ponds. The algorithms apply to different multispectral sensors; the enhanced thematic mapper plus (ETM+) on board Landsat 7 (Markus et al., 2003; Rösel and Kaleschke, 2011), moderate-resolution imaging spectro-radiometer (MODIS) on board Aqua and Terra (Tschudi et al., 2008; Rösel et al., 2012; Rösel and Kaleschke, 2012), and medium resolution imaging spectrometer (MERIS) on board Envisat (Zege et al., 2015; Istomina et al., 2015). Commonly, the retrieval algorithms are vulnerable to correction for atmospheric constituents and influences of the viewing angles and the solar geometry. They also require cloud-free conditions, limiting their applicability in the Arctic due to the persistent cloud cover present during summer. Satellite microwave radiometers and scatterometers can on the other hand penetrate clouds, but their resolution is in general too coarse for automated melt pond monitoring (Comiso and Kwok, 1996; Howell et al., 2006).

Satellite synthetic aperture radar (SAR) offers independence of cloud cover, atmospheric constituents, and daylight, combined with high spatial resolution. Several studies have focused on  $f_{MP}$  retrieval from single polarisation SAR, transmitting and receiving either vertical (VV) or horizontal (HH) polarised waves. Jeffries et al. (1997) developed a model for  $f_{MP}$  retrieval over MYI floes in the Beaufort sea from ERS-1 SAR satellite images, but lack of wind consideration limit the validity of the model. Wind speed was found to be a key parameter when Yackel and Barber (2000) demonstrated a significant relation between  $f_{MP}$  and HH intensity on land-fast FYI within the Cana-

dian Arctic Archipelago using SAR satellite scenes from Radarsat-1. The relationship was strong at intermediate wind speeds, but lacking at low wind speeds. Mäkynen et al. (2014) compared  $f_{MP}$  retrieved from MODIS and from a large amount of ENVISAT ASAR satellite scenes. The study area covered both FYI and MYI north of the Fram Strait. The study concluded that  $f_{MP}$  estimation was not possible based on the investigated data set. The above-mentioned studies all focus on C-band frequency ( 5.4 GHz) SAR. Kern et al. (2010) investigated the use of supplementary frequencies for  $f_{MP}$  retrieval on MYI in the Arctic Ocean, and showed promising results in combining C, Ku ( 17.2 GHz) and X ( 9.6 GHz) band data from a helicopter-borne scatterometer. Estimation of  $f_{MP}$  in X-band satellite SAR was further explored by Kim et al. (2013), investigating melt ponds in a TerraSAR-X scene acquired over MYI in the Chukchi Sea. Only large melt ponds were found detectable in the study, leading to an underestimation of  $f_{MP}$ . All in all, retrieval of  $f_{MP}$  from single polarimetric SAR has proven to be difficult.

Dual and quad polarimetric SAR transmit and receive both vertical and horizontal waves, resulting in four possible channel combinations (HH, HV, VH and VV), and give information about the polarisation properties of the backscatter in addition to single channel intensity variations. The channels can be combined into polarimetric SAR features, e.g. channel ratios, reducing the dependency of sensor geometry. Based on C-band scatterometer measurements, Scharien et al. (2012) suggested co-polarisation ratio ( $R_{VV/HH}$ ) to give an unambiguous estimation of  $f_{MP}$  at large incidence angles for land-fast FYI in the Canadian Arctic Archipelago and the Beaufort Sea. The topic was further investigated (Scharien et al., 2014b), and expanded to Radarsat-2 satellite scenes in Scharien et al. (2014a), demonstrating a strong potential of  $f_{MP}$  estimation from C-band dual polarimetric space-borne SAR. Both studies were performed in the central Canadian Arctic Archipelago. The findings were partly confirmed by Fors et al. (2015), who also suggest a relationship between  $f_{MP}$  and the statistical SAR feature relative kurtosis ( $RK$ ) utilizing Radarsat-2 on iceberg-fast FYI and MYI in the Fram Strait. Han et al. (2016) combined multiple polarimetric SAR features in  $f_{MP}$  estimation by machine learning methods, employing the co-polarisation channels of the MYI X-band SAR scene explored in Kim et al. (2013). An additional scene was also included in the study, though without melt pond information. The study showed promising results, but the authors claim that more scenes with various sea ice types and incidence angles are needed to develop a general propose  $f_{MP}$  model. Lack of wind information is also limiting the relevance of the study.

In summary, the main achievements on  $f_{MP}$  retrieval with SAR come from *dual polarimetric* C-band studies on land-fast FYI. The potential of  $f_{MP}$  retrieval with polarimetric X-band SAR has only been explored in one single study by Han et al. (2016), focusing on MYI. Hence, there is a need for more studies on the influence of  $f_{MP}$  on polarimetric X-band SAR imagery. As MYI and land-fast FYI have been the main focus in previous studies, there is also a need to expand to other sea ice types. Drifting FYI is becoming more prominent in the Arctic with the recent shift to a thinner, more

seasonal, and more mobile sea ice cover (Perovich et al., 2015), and the polarimetric SAR signature of  $f_{MP}$  in drifting FYI needs more attention.

The objective of this study is to investigate the potential of ~~melt pond fraction~~- $f_{MP}$  retrieval from level drifting FYI with dual-polarisation X-band satellite SAR. A data set consisting of four high resolution dual-polarisation TerraSAR-X satellite scenes, combined with ~~melt pond fraction~~- $f_{MP}$  retrieved from a helicopter-borne camera system forms the basis of the study. TerraSAR-X offers very high resolution ~~multi-polarimetric data~~dual-polarimetric images, with a strong sensitivity to micro-scale surface roughness due to the high frequency. Both the high resolution and sensitivity to surface roughness can be advantages in  $f_{MP}$  investigations. The data were collected north of Svalbard in summer 2012. We explore the correlation between  $f_{MP}$  and different polarimetric SAR features extracted from the HH and VV channels. Based on the results, we suggest two simple empirical regression fits for  $f_{MP}$  estimation adjusted to an intermediate and a low-wind speed case. The influence and limitations related to wind conditions, incidence angle, noise floor, scale and surface roughness are discussed in light of the results.

## 2 Melt ponds in SAR imagery

The signature of melt ponds in SAR imagery depends on both melt pond properties and radar parameters. Wind at the sea ice surface changes the surface roughness of the melt ponds, and hence their SAR backscatter signature and contrast to the surrounding sea ice. The influence of wind is dependent on fetch length, depth of the ponds, orientation of the ponds and the topography of the surrounding sea ice (Scharien et al., 2012, 2014b). During very calm conditions, the ~~SAR signal of scattering from~~ melt ponds is mainly specular. This occurs at wind speeds of 2 – 3 m/s in 10 m height ( $U_{10}$ ) in C-band, in agreement with findings for ocean surfaces ( $\sim 2.0$  m/s at  $0^\circ C$ ) (Donelan and Pierson, 1987; Scharien et al., 2012, 2014b). A similar threshold in X-band equals  $\sim 2.8$  m/s (Donelan and Pierson, 1987). Refrozen ponds suppress the wind wave surface roughness induced on open ponds, and yield a signature closer to newly formed sea ice (Yackel et al., 2007; Scharien et al., 2014b, a). The size distribution of melt ponds also affects their SAR signature. Ponds smaller than the SAR resolution return a signal mixed with sea ice and possibly leads, while very large melt ponds could fill a resolution cell. Choice of SAR resolution and speckle smoothing window size could hence affect the SAR  $f_{MP}$  signature. The coverage of melt ponds varies during the melt season, ~~starting out with a high fractional cover, and~~ increasing from melt onset until it reaches a maximum level, and then gradually reducing as the ponds ~~drains~~ starts to drain (Barber et al., 2001). At the end of the melt season, the ~~melt ponds refreezes. This evolution is mirrored by a seasonal variation in the sea ice SAR signature (Barber et al., 2001).~~ remaining melt ponds refreeze.

The SAR signature of melt ponds changes with incidence angle of the satellite. Scharien et al. (2012) found a larger decrease in C-band SAR intensity ( $\sigma^0$ ) with increasing incidence angle for

melt ponds than for sea ice. In contrast to sea ice,  $\sigma_{HH}^0$  decreased more than  $\sigma_{VV}^0$  for melt ponds. The most suitable incidence angle ranges for  $f_{MP}$  retrieval is method dependent. SAR frequency also influences the melt pond signature (Kern et al., 2010). X-band is more sensitive to small-scale surface roughness than C-band, as the effect of surface roughness depends on radar wavelength. In addition, the sea ice volume penetration depth decreases with increasing frequency, leading to less volume scattering from sea ice at higher frequencies.

Several dual-polarimetric SAR features have been suggested for  $f_{MP}$  retrieval from SAR, utilizing different expected relations to physical properties of sea ice and melt ponds (Scharien et al., 2012, 2014a; Fors et al., 2015; Han et al., 2016). Eight of these features are included in our study and are described in the following subsection.

## 2.1 Polarimetric SAR features

For a fully polarimetric SAR system, which transmits and receives both horizontally (H) and vertically (V) polarised waves, the scattering matrix can be written as

$$\mathbf{S} = \begin{bmatrix} S_{HH} & S_{VH} \\ S_{HV} & S_{VV} \end{bmatrix} = \begin{bmatrix} |S_{HH}|e^{j\phi_{HH}} & |S_{VH}|e^{j\phi_{VH}} \\ |S_{HV}|e^{j\phi_{HV}} & |S_{VV}|e^{j\phi_{VV}} \end{bmatrix}, \quad (1)$$

where  $|\cdot|$  and  $\phi_{xx}$  denote the amplitude and the phase of the measured complex scattering coefficients, respectively (Lee and Pottier, 2009). Assuming reciprocity ( $S_{HV} = S_{VH}$ ), the Pauli basis scattering vector,  $\mathbf{k}$ , can be extracted from  $\mathbf{S}$  as

$$\mathbf{k} = \frac{1}{\sqrt{2}} \begin{bmatrix} S_{HH} + S_{VV} & S_{HH} - S_{VV} & 2S_{HV} \end{bmatrix}^\dagger, \quad (2)$$

where  $^\dagger$  denotes the transpose operator (Lee and Pottier, 2009). In our study, we are only utilizing the co-polarisation channels (HH and VV), and so the scattering vector reduces to

$$\mathbf{k} = \frac{1}{\sqrt{2}} \begin{bmatrix} S_{HH} + S_{VV} & S_{HH} - S_{VV} \end{bmatrix}^\dagger. \quad (3)$$

The sample coherency matrix,  $\mathbf{T}$ , is defined as the mean Hermitian outer product of the Pauli basis scattering vector:

$$\mathbf{T} = \frac{1}{L} \sum_{i=1}^L \mathbf{k}_i \mathbf{k}_i^{*\dagger}, \quad (4)$$

where  $\mathbf{k}_i$  is the single-look complex vector corresponding to pixel  $i$ ,  $L$  is the number of scattering vectors in a local neighborhood, and  $*$  denotes the complex conjugate (Lee and Pottier, 2009). Similarly, in the dual-polarisation case, the Lexicographic basis scattering vector,  $\mathbf{s}$ , can be written as

$$\mathbf{s} = \begin{bmatrix} S_{HH} & S_{VV} \end{bmatrix}^\dagger. \quad (5)$$

Based on  $\mathbf{s}$ , the sample covariance matrix,  $\mathbf{C}$ , is defined as

$$\mathbf{C} = \frac{1}{L} \sum_{i=1}^L \mathbf{s}_i \mathbf{s}_i^{*\dagger}, \quad (6)$$

where  $\mathbf{s}_i$  is the single look complex vector corresponding to pixel  $i$  (Lee and Pottier, 2009).

The SAR intensity ( $\sigma^0$ ) is retrieved from a single polarisation channel, defined by the amplitudes  
165 of the complex scattering coefficients,

$$\sigma_{VV}^0 = \langle |S_{VV}|^2 \rangle \text{ and } \sigma_{HH}^0 = \langle |S_{HH}|^2 \rangle, \quad (7)$$

where  $\langle \cdot \rangle$  denotes an ensemble average. The relation between these basic features and  $f_{MP}$  have been investigated in several studies (Jeffries et al., 1997; Yackel and Barber, 2000; Mäkynen et al., 2014; Kern et al., 2010; Kim et al., 2013). However, carrying information from one single polarisation  
170 channel only, makes them less robust than polarimetric features that hold information from several channels.

Co-polarisation ratio ( $R_{VV/HH}$ ) has so far been the most promising SAR feature for  $f_{MP}$  extraction in C-band (Scharien et al., 2014a). It is defined as the ratio between the intensities of the co-polarisation complex scattering coefficients

$$175 \quad R_{VV/HH} = \frac{\langle |S_{VV}|^2 \rangle}{\langle |S_{HH}|^2 \rangle}. \quad (8)$$

For smooth surfaces within the Bragg scatter validity region,  $R_{VV/HH}$  depends only on the surface complex permittivity and local incidence angle, and is independent of surface roughness (Hajnsek et al., 2003). Both freshwater and saline melt ponds have considerably higher complex permittivity than sea ice, and  $R_{VV/HH}$  has therefore been suggested for  $f_{MP}$  retrieval (Scharien et al., 2012,  
180 2014b, a). The Bragg criterion is fulfilled for  $ks_{RMS} < 0.3$ , where  $k$  is the wavenumber and  $s_{RMS}$  is the root mean square height of the sea ice surface, describing its surface roughness. This corresponds to  $s_{RMS} < 2.8$  mm in C-band, and  $s_{RMS} < 1.4$  mm in X-band. The sea ice surface roughness was found ~~to~~<sup>too</sup> high to fill the criterion in studies north of Spitsbergen and in the Fram Strait (Beckers et al., 2015; Fors et al., 2016b), while Scharien et al. (2014b) found land-fast ice in the central  
185 Canadian Arctic Archipelago to fulfill the criterion at C-band, and partly at X-band. In the same study, melt ponds filled the criterion at wind speeds below 6.4 m/s in C-band, corresponding to  $\sim 5.5$  m/s in X-band (Scharien et al., 2014b). When the Bragg criterion is exceeded,  $R_{VV/HH}$  decreases with increasing surface roughness.  $R_{VV/HH}$  increases with incidence angle, and Scharien et al. (2012) found incidence angles above  $35^\circ$  to be most appropriate for  $f_{MP}$  retrieval based on  
190  $R_{VV/HH}$  in C-band.

Relative kurtosis ( $RK$ ) is a statistical measure of non-Gaussianity, which describes the shape of the distribution of scattering coefficients in SAR scenes. It has previously been used for sea ice segmentation (Moen et al., 2013; Fors et al., 2016a). It is defined as Mardia's multivariate kurtosis

of a sample, divided by the expected multivariate kurtosis of a complex normal distribution

$$195 \quad RK = \frac{1}{L} \frac{1}{d(d+1)} \sum_{i=1}^L \left[ \mathbf{s}_i^{*\dagger} \mathbf{C}^{-1} \mathbf{s}_i \right]^2, \quad (9)$$

where  $d$  is the number of polarimetric channels (Mardia, 1970; Doulgeris and Eltoft, 2010). It has a potential in  $f_{MP}$  retrieval as it is sensitive to mixtures of surfaces. At C-band,  $RK$  was found significantly correlated to  $f_{MP}$  over iceberg-fast sea ice in the Fram Strait (Fors et al., 2015).

Entropy ( $H$ ) is a part of the  $H/A/\bar{\alpha}$  polarimetric decomposition, based on the eigenvectors and  
200 eigenvalues of  $\mathbf{T}$ , describing SAR scattering mechanisms (Cloude and Pottier, 1997).  $H$  is a measure of the randomness of the scattering processes, and is defined as

$$H = - \sum_{i=1}^d p_i \log_d p_i, \quad (10)$$

where  $p_i$  is the relative magnitude of each eigenvalue

$$p_i = \frac{\lambda_i}{\sum_{k=1}^d \lambda_k}, \quad (11)$$

205 and  $\lambda_i$  is the  $i^{th}$  eigenvalue of  $\mathbf{T}$  ( $\lambda_1 > \lambda_2$ ) (Cloude and Pottier, 1997). Only the co-polarisation channels (HH and VV) are included in our study ( $d = 2$ ), and a dual polarisation version of the entropy, denoted  $H'$ , is therefore used (Cloude, 2007; Skrunes et al., 2014).  $H' = 0$  indicates a single dominant scattering mechanism, while  $H' = 1$  indicates a depolarized signal. In the case of dual polarisation,  $H'$  and anisotropy represent the same information as they both only depends on  
210  $\lambda_1$  and  $\lambda_2$ , and anisotropy is therefore not included in our study.

The alpha angle of the largest eigenvalue ( $\alpha'_1$ ) describes the type of the dominating scattering mechanism. It is expressed as

$$\alpha'_1 = \cos^{-1} \frac{|x_1|}{|v_1|}, \quad (12)$$

where  $x_1$  is the first element of the largest eigenvector, and  $|v_1|$  is the norm of the first eigenvector  
215 (Lee and Pottier, 2009). The feature can be written as a function of  $R_{VV/HH}$  for slightly rough surfaces, and will then increase with increasing complex permittivity (van Zyl and Kim, 2011).

Co-polarisation correlation magnitude ( $|\rho|$ ) is defined as

$$|\rho| = \left| \frac{\langle S_{HH} S_{VV}^* \rangle}{\sqrt{\langle S_{HH} S_{HH}^* \rangle \langle S_{VV} S_{VV}^* \rangle}} \right|, \quad (13)$$

and describes the degree of correlation between the co-polarisation channels (Drinkwater et al.,  
220 1992). A perfect correlation returns unity, while depolarisation of the signal will reduce the magnitude. Complex surfaces, multiple scattering surface layers and/or presence of system noise could depolarize the signal (Drinkwater et al., 1992).

Phase difference ( $\angle\rho$ ) is expressed as (Drinkwater et al., 1992)

$$\angle\rho = \angle(\langle S_{HH}S_{VV}^* \rangle). \quad (14)$$

225 As the relative phase of the co-polarisation waves is changed in every scattering event, the mean and standard deviation of  $\angle\rho$  are related to the scattering history (Eom and Boerner, 1991; Drinkwater et al., 1992). Han et al. (2016) found  $H$ ,  $\alpha'_1$ ,  $|\rho|$ , and  $\angle\rho$  to give useful information for  $f_{MP}$  retrieval at X-band.

### 3 Methods

#### 230 3.1 Study region and sea ice conditions

The ICE2012 campaign took place on drifting FYI north of Svalbard, in the southwestern Nansen Basin (Fig. 1), where the research vessel R/V Lance was moored up to an ice floe for eight days. The sea ice cover in the area is generally dominated by first- or second-year ice with only moderate amounts of deformation (Renner et al., 2013). While large seasonal variability exists in the area, 235 summer ice thickness has been fairly stable since 2007. However, Renner et al. (2013) found further indicators for a trend towards younger sea ice in the region. Little deformation and dominance of young ice leads to relatively low sea ice surface roughness, with a root mean square height of around or less than 0.1 m in the region (Beckers et al., 2015). Substantial snow cover can accumulate during spring, however, during the summer season, the snow melts completely contributing to extensive 240 melt pond formation.

During the ICE2012 campaign, regular sea ice thickness and melt pond surveys were performed on the ice and from helicopter. Modal ice thickness in the region was less than in previous years with 0.7 to 0.9 m (Divine et al., 2015). The very close drift ice was fairly level with less than 10% deformed ice. Sea ice surface roughness retrieved from the floe by R/V Lance is given in Table 3. 245 The surface roughness values are expected to be representative for the whole study region, as the sea ice in the area was found to be very uniform (Hudson et al., 2013; Divine et al., 2015). The values also agree well with values derived from laser altimeter observations by Beckers et al. (2015).

At the time of the campaign, all snow had melted and extensive networks of melt ponds led to an average  $f_{MP}$  of 26% of the sea ice area (Divine et al., 2015). The melt ponds were mostly within 250 15 to 30 cm deep, however, extensive melt led to some ponds having melted through the ice slab. The water in the pond networks was therefore mostly saline.

Hudson et al. (2013) report an average thinning of the sea ice next to R/V Lance of over 17 cm between 28 July and 2 August which to a large degree can be explained by absorption of atmospheric and oceanic heat by the ice. Air temperatures were varied little between  $-1$  to  $1.5^\circ\text{C}$ . Combined with 255 the oceanic heat flux, the ice was therefore in continuous melt even at nighttime. Meteorological conditions were dominated by heavy cloud cover with only short spells of incomplete or thin cloud

cover. Ice cores were taken every other day between 27 July and 2 August with an additional core on 28 July for chemical analysis. They confirm the presence of a consistent 4 to 5 cm thick surface scattering layer of white, granular, deteriorated ice. Temperature profiles through the ice were fairly stable with vertical variations between near  $0^{\circ}\text{C}$  at the surface to  $-1$  to  $-1.3^{\circ}\text{C}$  at the bottom. Salinity measurements show very low values in the upper 20 cm with salinities of less than 1 psu and increasing to 3 to 4 psu near the bottom, in agreement with the advanced stage of melt of the ice cover.

### 3.2 Data set

*In situ* and helicopter-borne measurements from ICE2012 are combined with four high-resolution TerraSAR-X (TS-X) satellite scenes. The satellite scenes are StripMap mode acquisitions, with a HH-VV channel combination (see Table 1 and Fig. 1). The scene labeled T1 was acquired in descending orbit, while T2-T4 were acquired in ascending orbits. All scenes were converted to ground range and radiometrically calibrated to  $\sigma^0$ . The noise equivalent  $\sigma^0$  (NESZ) was then subtracted. The absolute radiometric calibration accuracy of TSX is 0.6 dB (Airbus Defence and Space, 2013). For comparison with  $f_{MP}$  retrieved from helicopter-borne data, the scenes were geocoded with ESA's Sentinel-1 toolbox, SNAP (European Space Agency, 2016). All analysis were, however, performed in SLC range and azimuth coordinates. Open water areas were not included in our study. For each satellite scene, these areas were masked out with a simple binary mask. The mask was created by filtering the scenes with a  $13 \times 13$  pixels averaging sliding window, and manually setting a lower sea ice threshold value on  $\sigma_{HH}^0$  in each scene (-18 dB, -17 dB, -16 dB and -18 dB, for T1-T4 respectively). Regions with less than 750 pixels ( $\sim 5000 \text{ m}^2$ ) were merged into the surrounding region (open water or sea ice) to smooth the mask.

A stereocamera system (ICE stereocamera system) was mounted in a single enclosure outside the helicopter during ICE2012 (Divine et al., 2016, in review) (Divine et al., 2016). The system consisted of two cameras (Canon 5D Mark II), combined with GPS/INS (Novatel) and a laser altimeter.  $f_{MP}$  was retrieved from downward-looking images captured by one of the cameras during five helicopter surveys performed between 31 July and 2 August 2012 (see Table 2 and Fig. 1). The footprint of the images was about  $60 \times 40 \text{ m}$  for a typical flight altitude of about 35 m, and the images were not overlapping. A full description of the method is given in Divine et al. (2015). In our study,  $f_{MP}$  was calculated from the processed images without sea water fraction ( $\sim 5700$  images), to better match the sea ice mask. This excluded melt-pond-fractions- $f_{MP}$  from the ice edges and small floes, resulting in a slightly higher  $f_{MP}$  than that obtained in Divine et al. (2015).

The ICE stereocamera system was also used to investigate sea ice surface topography at the floe where R/V Lance was anchored. For this purpose, the cameras shot sequentially with a frequency of 1 Hz to ensure sufficient overlap between subsequent images during the flights. Using photogrammetric technique, the sequences of overlapping images were used to construct a digital terrain model

(DTM) of the sea ice surface. DTMs were generated for five selected segments of the ICE12 ice floe with a spatial resolution of 2 cm. Surface roughness, in form of root mean square height of the sea ice surface ( $s_{RMS}$ ), was estimated from the DTMs using random sampling to account for spatial auto-correlation. Only grid nodes above the water level were used. The accuracy of the retrieved  $s_{RMS}$  were  $\pm 4$  cm according to *in situ* measurements from two test areas. A full description of the method is given in [Divine et al. \(2016, in-review\)](#) [Divine et al. \(2016\)](#).

An automatic weather station located at the floe where R/V Lance was moored during ICE2012 measured wind speed and air temperature 2 m above the sea ice surface (Hudson et al., 2013). Wind speed ( $U_2$ ) was measured with a three-dimensional ultrasonic anemometer (Campbell Scientific Inc., CSAT3), and air temperature was measured with a temperature probe (Vaisala, HMP155) in an unventilated radiation shield. Tab. 1 presents air temperature and 10 minutes averaged wind speed at the time of the satellite acquisitions.

### 3.3 Design of study

An easy recognizable sea ice floe present in two of the investigated satellite scenes (T3 and T4) is the main focus of our study (see Fig. 2). ~~The~~ This floe was chosen as it allowed for a reliable co-location between airborne images and satellite scenes, and was present in more than one scene. The rest of the airborne track was not possible to co-locate exact enough for a high-quality study. The floe had a diameter of  $\sim 3.6$  km, and a collection of 43 images was captured across the floe during the 2<sup>nd</sup> helicopter flight on 2 August 2012 (see Tab. 2). The time offset between the flight and acquisition of T4 was  $\sim 40$  minutes. The position of the helicopter images had to be corrected for sea ice drift to retrieve co-location between the images and the floe captured in T4. As a first step, the image center coordinates were shifted according to drift information from GPS tracks of R/V Lance, positioned  $\sim 25$  km south of the floe at the time of acquisition. Second, the track was manually adjusted by fitting the helicopter images with ground features, such as ice edges and areas with open water. Co-location of the helicopter images and the floe in T3 was based on the one of T4. The maximum error of the co-location was estimated to be 7 m lengthwise and crosswise the flight direction, resulting in a maximum possible areal offset of 27% between the satellite scene and each helicopter image. After co-location, mean and standard deviation of the polarimetric SAR features were calculated for the pixels underlying each of the helicopter images.

The statistical dependence between the extracted SAR features and the corresponding  $f_{MP}$  retrieved from each of the 43 helicopter images was evaluated with the non-parametric Spearman's rank correlation coefficient ( $r$ ). For a sample size of  $n$  images,  $r$  is defined as

$$r = 1 - \frac{6 \sum d_i^2}{n(n^2 - 1)}, \quad (15)$$

where  $d_i$  is the difference in paired rank number  $i$  (Corder and Foreman, 2009). Rank ties are assigned a rank equal to the average of their position in the ascending order of the values. The co-

efficient takes values between -1 and 1, where values of  $\pm 1$  correspond to full correlation, while 0 corresponds to no correlation. A negative sign indicates an inverse relationship. Spearman's correlation coefficient assumes a monotonic relationship. It is used instead of Pearson's linear correlation coefficient, to allow for non-linear correlations. It is also less sensitive to outliers than Pearson's correlation coefficient. Correlations were considered significant if they had p-values below 0.05.

Two regression fits were proposed from the correlation results, representing an intermediate and a low-wind case. A least squares linear fit with bisquare weights was used to construct the regression fits (Hoaglin et al., 1983). The regression fits were applied to the full area of the floe in T3 and T4, and to the full area of the four satellite scenes included in the study (T1-T4). The estimated  $f_{MP}$  distributions were compared and evaluated towards the ~~global-empirical-observed~~  $f_{MP}$  distribution retrieved from all the helicopter flights included in the study (see bottom entries Tab. 2). ~~Scale sensitivity~~ The effect of smoothing was tested by using a range of different averaging sliding smoothing window sizes ( $13 \times 13$  to  $51 \times 51$  pixels) in the  $f_{MP}$  estimation. Incidence angle correction was applied to the scenes for a better comparison, employing the following equation (Kellndorfer et al., 1998)

$$\sigma_{corr}^0 = \sigma^0 \frac{\sin(\theta)}{\sin(\theta_{ref})} \frac{\sin(\theta)}{\sin(\theta_{ref})}, \quad (16)$$

where  $\sigma^0$  is the original backscatter coefficient,  $\theta$  is the center incidence angle of the scene to be corrected, and  $\theta_{ref}$  is the reference incidence angle of scene T4. The correction was only applied in the low-wind case, as it canceled in the intermediate wind case due to the use of a co-polarisation ratio.

## 4 Results

This section presents the results of the correlation analysis examining the relation between the investigated polarimetric SAR features and observed  $f_{MP}$ . It then present a brief signal-to-noise analysis, before it focuses on  $f_{MP}$  retrieval in an intermediate and a low-wind case.

### 4.1 Correlation between polarimetric SAR features and $f_{MP}$

Correlation coefficients ( $r$ ) between  $f_{MP}$  retrieved from the 43 helicopter images of the investigated floe, and the mean and standard deviation of the polarimetric SAR features extracted from the corresponding areas in scenes T3 and T4, are presented in Table 4. Values significant within a 95% confidence interval are highlighted in bold, ~~and values in parentheses show results before NESZ subtraction of the signal.~~ In scene T3,  $R_{VV/HH}$  shows the strongest correlation to  $f_{MP}$ . In addition, the mean of  $\alpha_1$  is significantly correlated to  $f_{MP}$ . None of the other investigated SAR features are significantly correlated to  $f_{MP}$  in scene T3. In scene T4, the mean values of  $\sigma_{HH}^0$ ,  $\sigma_{VV}^0$  and  $R_{VV/HH}$  are significantly correlated to  $f_{MP}$ , the strongest correlation is found for  $\sigma_{VV}^0$ .

Some of the standard deviation values are also correlated to  $f_{MP}$ . ~~Without NESZ subtraction in the calibration, however, almost all features are correlated to  $f_{MP}$ . The large difference before and after NESZ subtraction indicates~~ In scene T4, NESZ subtraction had large influence on the results indicating that the signal is close to, or reaching the noise floor.

365 Figure 3 confirms the low signal-to-noise ratio in T4. We show the 10, 25, 50, 75 and 90 percentiles of  $\sigma_{HH}^0$  (dB) and  $\sigma_{VV}^0$  (dB) retrieved for four different  $f_{MP}$  intervals on the floe present in scene T3 (top) and T4 (bottom), combined with the noise floor of the HH and VV channels. In T3, less than 10% of the signal is below the noise floor ( $\sim -25$  dB). Both  $\sigma_{HH}^0$  and  $\sigma_{VV}^0$  are increasing with  $f_{MP}$ .  $\sigma_{VV}^0$  has the steepest increase, confirming an increase in  $R_{VV/HH}$  with  $f_{MP}$  (Tab. 4). In scene T4, 370 the backscatter signal is weaker and noise floor is higher than in scene T3 ( $\sim -21$  dB), both due to the higher incidence angle of scene T4 (see Tab. 1). This brings as much as 25% of the signal below the noise floor. The strength of the signal decreases with  $f_{MP}$ , implying specular reflection from the melt ponds, supported by the low wind speed (0.6 m/s) at acquisition of scene T4 (see Tab. 1). The difference between  $\sigma_{HH}^0$  and  $\sigma_{VV}^0$  is decreasing with  $f_{MP}$ , confirming an inverse relation between 375  $R_{VV/HH}$  and  $f_{MP}$  in T4 (Tab. 4). In scene T1 and T2, the noise floors are  $\sim 23$  dB, leaving  $\sim 15\%$  of the signal below the noise floor.

The melt ponds affect the polarimetric signatures in scene T3 and T4 differently (Table 4 and Fig. 3), mainly due to different wind conditions, but also due to different incidence angles and noise floors. In the following, we look closer into the feature displaying the strongest correlation to  $f_{MP}$  380 in each of the scenes,  $R_{VV/HH}$  in T3 and  $\sigma_{VV}^0$  in T4.

## 4.2 Intermediate-wind case

In the intermediate-wind case of scene T3,  $R_{VV/HH}$  was found to be the SAR feature with the strongest correlation to  $f_{MP}$ . Combining  $f_{MP}$  retrieved from the 43 helicopter images covering the investigated floe with  $R_{VV/HH}$  extracted from the corresponding areas in scene T3, we see an 385 increase in  $R_{VV/HH}$  with  $f_{MP}$  in Fig. 4, as well as a large variability between the samples. Grey dots correspond to areas with some degree of sea ice deformation, while blue dots correspond to areas with completely level ice. Deformation information is extracted from visual inspection of the helicopter images. The partly negative values of  $R_{VV/HH}$  imply that  $\sigma_{HH}^0 > \sigma_{VV}^0$ . This might be a result of multiple scattering events in the sea ice volume or sea ice surface, possibly connected with 390 sea ice deformation. A majority of the lowest  $R_{VV/HH}$  values are appearing in partly deformed areas. Areas with some degree of deformation also represent the lowest  $f_{MP}$ . A robust least squares linear fit is applied to the scatter plot, displaying a relationship of:

$$f_{MP}(R_{VV/HH}) = 0.49 \cdot R_{VV/HH}(\text{dB}) + 0.30. \quad (17)$$

The goodness of fit of the regression is reflecting large sample variation, with  $R_{fit}^2 = 0.21$  and 395  $RMSE = 0.40$ . This implies a weak correlation, corresponding well to the Spearman's correla-

tion of 0.45 (Table 4). However, the co-location between the helicopter images and the sea ice floe contain some uncertainty (a maximum areal offset of ~~27%~~27%) possibly introducing a random error to the regression, resulting in an artificially low  $R_{fit}^2$ .

Applying the regression fit from on Eq. 17 to the full floe in scene T3 results in the regression  
 400 fit probability density distributions (PDFs) presented in the top panel of Fig. 5. The results are presented both for a  $21 \times 21$  and a  $51 \times 51$  pixels smoothing window. ~~Empirical~~, corresponding to areas of  $50 \times 40$  m and  $120 \times 95$  m in the across  $\times$  along flight direction. Observed distributions of  $f_{MP}$  retrieved from the 43 images covering the floe (floe) and from images in all included flights (~~global~~regional), are also included in the figure. Statistics of the distributions are given in Tables 2 and  
 405 5. The ~~empirical~~global-regional distribution has a slightly higher mean than the ~~empirical~~-floe distribution. Due to the few samples of the floe distribution, we consider the ~~global~~regional distribution more appropriate for comparison with the regression fit distributions. Employing the regression fit with a  $21 \times 21$  pixels smoothing window, equaling the areal size of the helicopter images, results in a mean close to the ~~global-empirical~~observed regional distribution. The regression distribution is how-  
 410 ever too wide compared to the ~~empirical~~observed ones, reflecting the large sample variation seen in Fig. 4. Speckle (noise like interference between scatterers within a resolution cell) in the SAR image might explain the wider distribution. Increasing the smoothing window size reduces speckle, and a better correspondence between the width of the regression and ~~empirical~~observed distributions is achieved by employing a  $51 \times 51$  pixels window. The bottom panel of Fig. 5 displays  $f_{MP}$  estimated  
 415 for the floe in T3 based on eq.17 with a  $51 \times 51$  pixels window. Open water is masked out. The estimation shows a highly spatially variable  $f_{MP}$ , with few homogenous areas. Areas of deformed sea ice displayed with bright colors in Fig. 2 cannot be recognized, even if these areas are expected to have a lower ~~melt-pond-fraction~~ $f_{MP}$ .

Zooming in to the southern part of the area covered by the helicopter survey on the floe in T3, Fig.  
 420 6 displays  $f_{MP}$  estimated from Eq. 17 with the observed  $f_{MP}$  from the helicopter images overlaid. Two different pixels smoothing windows are shown ( $21 \times 21$  and  $51 \times 51$ ). Note that the center pixel underlying each helicopter image frame would give the most representative value for comparison to the observed  $f_{MP}$ , as pixels closer to the frame contain a larger amount of information from outside the frame. The middle panel displays the mean estimated  $f_{MP}$  value for each frame together with  
 425 the observed  $f_{MP}$  values along the track. The maps confirm some overlap between the estimated and observed  $f_{MP}$ , but also illustrates that there is room for improvement. The estimation with a  $51 \times 51$  pixel smoothing window appears less variegated than the  $21 \times 21$  estimation, and the range of the estimated  $f_{MP}$  values also corresponds better to those observed from the helicopter images in the  $51 \times 51$  estimation.

430 Applying the regression fit from Eq. 17 with a  $51 \times 51$  pixel window to the four full SAR scenes included in our study reveals a high correlation between the regression fit distribution and the ~~empirical~~global-observed regional  $f_{MP}$  distribution for T3 (see Fig. 7 and Tables 2 and 5). On the full scene

scale, the regression fit manages to reproduce both the mean and the standard deviation of the ~~global~~ regional distribution representative for the area. Scene T1 and T2 are acquired at  $\sim 8^\circ$  higher incidence angle than scene T3, and  $f_{MP}$  is slightly overestimated in these scenes. From Fig. 7, the overestimation is lower for scene T1 than for T2, possibly reflecting the low wind speed at acquisition of T1 (Tab 1). The least consistency between the regression fit distribution and the ~~empirical~~ observed distribution is, as expected, found for scene T4, confirming the results shown in Table 4 and Fig. 3.

### 4.3 Low-wind case

In the low-wind case of scene T4,  $\sigma_{VV}^0$  was found to have the strongest correlation to  $f_{MP}$  among the investigated SAR features. Combining  $f_{MP}$  retrieved from the 43 helicopter images covering the floe with  $\sigma_{VV}^0$  extracted from the corresponding areas in T4, we see a decrease in  $\sigma_{VV}^0$  with  $f_{MP}$  in Fig. 8. A large variability between the samples can be observed. Grey dots correspond to partly deformed areas, while blue dots represent level ice. As for the intermediate wind case, a robust least square linear fit was applied to the data to describe the relationship between  $\sigma_{VV}^0$  and  $f_{MP}$ :

$$f_{MP}(\sigma_{VV}^0) = -52.83 \cdot \sigma_{VV}^0 + 1.89. \quad (18)$$

Note that  $\sigma_{VV}^0$  is not in dB. Again, the goodness of fit of the regression is reflecting large sample variation, with  $R_{fit}^2 = 0.26$  and  $RMSE = 0.0039$ .

Estimated  $f_{MP}$  PDFs based on Eq. 18 for the full floe in scene T4 are presented in the top panel of Fig. 9 together with ~~empirical~~ observed distributions from the floe and from all flights included in the study. The results are presented both for a  $21 \times 21$  and a  $51 \times 51$  pixels smoothing window, corresponding to areas of  $65 \times 30$  m and  $155 \times 65$  m in the across  $\times$  along flight direction. The regression fit distributions give a good reproduction of the ~~empirical~~ observed mean (see Tables 2 and 5). As in the intermediate-wind case, a smoothing window of  $51 \times 51$  pixels results in a distribution width closer to the ~~empirical~~ observed than a  $21 \times 21$  pixels window. The  $\sigma_{VV}^0$ -based estimation of  $f_{MP}$  with a  $51 \times 51$  smoothing window for the full floe in scene T4 result in a large spatial variability in  $f_{MP}$  (see bottom panel of Fig. 9). In contrast to the  $f_{MP}$  estimation based on  $R_{VV/HH}$  for the floe in scene T3 (Fig. 5), the estimation based on  $\sigma_{VV}^0$  partly manages to produce lower ~~melt-pond-fraction~~  $f_{MP}$  in areas with deformed sea ice.

Figure 10 shows  $f_{MP}$  estimated from Eq. 18 with the observed  $f_{MP}$  from the helicopter images overlaid for two different pixels smoothing windows ( $21 \times 21$  and  $51 \times 51$ ). Note that the center pixel underlying each helicopter image frame would give the most representative value for comparison to the observed  $f_{MP}$ . To illustrate this, the middle panel shows the mean estimated  $f_{MP}$  value for each frame together with the observed  $f_{MP}$  values along the track. In general, a good overlap between the estimated and observed  $f_{MP}$  can be seen, even though some scatter exists. As in Fig. 6, the estimation with a  $51 \times 51$  pixel smoothing window appears less variegated than the  $21 \times 21$

estimation, and the range of the estimated  $f_{MP}$  values also corresponds better to those observed from the helicopter images in the  $51 \times 51$  estimation than to those in the  $21 \times 21$  estimation.

Investigating the regression fit's capacity of estimating  $f_{MP}$  in the 4 full satellite scenes included in the study reveals that it is only applicable to give a good estimate in scene T4 (see Fig. 11 and Table 2 and 5)). In the three other scenes ~~the estimate is poor~~, it underestimates  $f_{MP}$ , ~~and also introduces introducing~~ negative fractions. Incidence angle correction according to Eq. 16 is applied to the figure, accounting for  $\sigma_{VV}^0$  decrease with incidence angle.

## 5 Discussion

The results of this study show that  $f_{MP}$  influences the signature of several X-band polarimetric features. The strongest correlations were found for  $R_{VV/HH}$  and  $\sigma_{VV}^0$ , where linear regression fits gave  $R_{fit}^2$  values of 0.21 and 0.26, respectively. These correlations are not strong enough for the results to be used directly in operational models. However, with improved methods and more satellite data added, our results imply a future potential in retrieving  $f_{MP}$  from X-band SAR. For comparison, the method developed for retrieval of  $f_{MP}$  from MODIS has  $R_{fit}^2$  values ranging from 0.28 to 0.45 (Rösler et al., 2012). As in C-band, parameters like wind speed, incidence angle, surface roughness, and SAR scale and resolution will affect the interpretation of the polarimetric melt pond signature of a X-band SAR scene. In the following, these factors will be discussed based on the results.

Accurate information about wind speed at the time of scene acquisition is crucial in  $f_{MP}$  retrieval from SAR. In scene T3, the intermediate wind speed at acquisition ( $U_2 = 6.2$  m/s) allowed for backscatter from the melt ponds, making use of  $R_{VV/HH}$  for  $f_{MP}$  estimation possible. ~~Scharien et al. (2014b) finds that In X-band, the Bragg criterion is exceeded for melt ponds  $s_{RMS} > 1.4$  mm. Scharien et al. (2014b) finds that melt ponds exceed this roughness at wind speeds above  $U_{10} \approx 5$  m/s in X-band, reducing the expected correlation between  $R_{VV/HH}$  and  $f_{MP}$  above this wind speed. This indicates that even better results could be achieved at lower wind speeds, but it also leaves a very narrow wind speed interval for melt pond retrieval with X-band SAR. Scene T4 represents a low wind speed situation ( $U_2 = 0.6$  m/s), and our results indicate specular, or close to specular reflection from the melt ponds in this case, disrupting. The weak melt pond backscatter, combined with a low SNR, hamper the use of polarimetric SAR features difference in polarimetric properties between sea ice and melt ponds for melt pond estimation as the melt pond signal is too weak. This fraction retrieval. The weak correlation seen between  $R_{VV/HH}$  and  $f_{MP}$  in Table 4 is most probably reflecting slightly different sea ice surface types surrounding the ponds in areas with low and high melt pond fraction, rather than different polarimetric signatures between melt ponds and sea ice. The low correlation observed between  $R_{VV/HH}$  and  $f_{MP}$  in this low wind case is in agreement with findings in Scharien et al. (2012, 2014b). However, the, while Scharien et al. (2014a) found  $R_{VV/HH}$  to increase with  $f_{MP}$  even at low wind speeds ( $U_{10} = 1.1$  m/s). Different wind speeds, incidence angle and sea ice types~~

could all contribute to the deviating findings. The lack of backscatter from the melt pond surfaces compared to the sea ice could potentially be used for  $f_{MP}$  retrieval utilizing  $\sigma^0$ , as the backscatter intensity becomes weaker with increasing  $f_{MP}$ . This is confirmed by Han et al. (2016), suggesting  $\sigma^0$  to be a key feature in  $f_{MP}$  estimation for MYI in X-band during calm winds. On the other hand, our results deviate from findings in C-band, where no correlation was found between  $\sigma_{HH}^0$  and  $f_{MP}$  at low wind speeds ( $U_{10} = 1.5$  m/s) by Yackel and Barber (2000).

Medium to high incidence angles ( $> 35^\circ$ ) have been found most suitable for  $R_{VV/HH}$ -based retrieval of  $f_{MP}$  in C-band (Scharien et al., 2012, 2014b). In our study we found a significant correlation between  $R_{VV/HH}$  and  $f_{MP}$  at an incidence angle of  $29^\circ$  (T3), demonstrating that  $f_{MP}$  has an impact on polarimetric X-band SAR signatures also at lower incidence angles. Scene T1 and T2 are acquired at higher incidence angles ( $36.9^\circ$  and  $37.9^\circ$ ) than T3. In these two scenes,  $f_{MP}$  is overestimated by the  $R_{VV/HH}$ -based regression fit developed for scene T3. This is consistent with Scharien et al. (2014b), showing an increase in  $R_{VV/HH}$  with increasing incidence angle for melt ponds in C-band. In the same study,  $R_{VV/HH}$  for bare ice was not found to increase with incidence angle. The difference in estimated  $f_{MP}$  between scene T1 and T2 is most likely related to the low wind speed in T1, which is below the expected wind speed limit for  $f_{MP}$  estimation based on  $R_{VV/HH}$  in both C and X-band (Scharien et al., 2012, 2014b). However, the different acquisition geometry observed in Fig. 1 could also play a role. At an incidence angle of  $44^\circ$ , a considerable part of the backscatter signal was below the noise floor in our study. The low signal-to-noise ratio of TerraSAR-X limits  $f_{MP}$  retrieval based on  $R_{VV/HH}$  at high incidence angles, leaving the suitable range of incidence angles smaller than for Radarsat -2 (Scharien et al., 2014a). The accuracy of  $f_{MP}$  estimation based on  $\sigma_{VV}^0$  is also strongly dependent on incidence angle, as  $\sigma_{VV}^0$  in general decreases with increasing incidence angle for sea ice. The underestimation of  $f_{MP}$  in scenes T1-T3 is likely related to higher wind speeds at the time of acquisition.

The Brag criterion ( $ks < 0.3$ ) is exceeded when  $s_{RMS} > 1.4$  mm in X-band. The surface roughness estimations performed during the ICE2012 campaign indicates that the sea ice in the study region exceeds this criterion, introducing a roughness dependency of  $R_{VV/HH}$ . This is in agreement with previous findings in the study region (Beckers et al., 2015), but deviates from findings reported by Scharien et al. (2014b), where fast ice at the Central Canadian Archipelago partly filled the criterion in X-band. From the helicopter images, some of the very low  $R_{VV/HH}$  values observed at the investigated floe in scene T3 were from slightly deformed areas, possibly explaining the negative ratios. However, no general trend in low  $R_{VV/HH}$  values in deformed areas was found in our study. Other small scale surface scattering processes could also have caused the low  $R_{VV/HH}$ , negative values have also been reported in other FYI studies, e.g., Geldsetzer and Yackel (2009) and Scharien et al. (2014b). Multiple scattering events in the sea ice surface and sea ice volume may also have contributed to the large sample variations observed in Figs. 4 and 8. Detailed surface roughness

measurements combined with  $f_{MP}$  observations are needed to further investigate the influence of  
540 sea ice surface roughness on  $f_{MP}$  based on  $R_{VV/HH}$ .

The smoothing window size used for direct comparison between  $f_{MP}$  retrieved from the helicopter images and the polarimetric SAR features was appointed by the areal coverage of the helicopter images in our study. However, a  $40 \times 60$  m window (corresponding to  $21 \times 21$  pixels) might not be the ideal scale of investigation. Advancing the regression fits suggested in our study to the full  
545 floe or full scenes with a larger window ( $51 \times 51$  pixels) gave better reproductions of the width of the  $f_{MP}$  distribution retrieved from the helicopter images. A larger window size reduces the amount of speckle in the SAR scenes, which possibly explains the improvement. Even larger window sizes were used in Scharien et al. (2014a), estimating  $f_{MP}$  based on  $R_{VV/HH}$  in a  $7.5 \times 7.5$  km grid from C-band Radarsat-2. Opposite to this, Han et al. (2016) found a  $15 \times 15$  pixels window to give  
550 the best estimate of mean  $f_{MP}$  based on a combination of several SAR features in a TerraSAR-X scene. In climate applications,  $f_{MP}$  estimation from a full scene is more applicable than estimation from small areas within the scene. The large sample variability observed in Fig. 4 might therefore be negligible, as long as the  $R_{VV/HH}$ -based regression fit produces a good estimate of the mean  $f_{MP}$  for a larger area. A wider study of the influence of scale on SAR  $f_{MP}$  retrieval is needed in the  
555 future.

In addition to  $R_{VV/HH}$ , five other dual-polarimetric SAR features were included in our study, ~~after NESZ subtraction~~ most of these showed no statistical significant relationship to  $f_{MP}$  in our data set. This is also an important result, implying useful knowledge for instance in classification of summer sea ice based on X-band imagery. The statistical feature  $RK$  showed a promising relation  
560 to  $f_{MP}$  in C-band on fast ice in the Fram Strait (Fors et al., 2015), but no relation was found in our investigation. Lack of the HV-channel, or less dominant height difference between ponds and sea ice could both possibly explain the absence of correlation.  ~~$H'$  and  $\alpha'_1$  were~~  $H'$  and  $\alpha'_1$  were found significantly correlated with  $f_{MP}$  in scene ~~T4 and T3, respectively.~~ T4 and T3, respectively. ~~This is likely a result of the expected relation between  $\alpha'_1$  and  $R_{VV/HH}$  (van Zyl and Kim, 2011).~~ In scene T4, ~~the correlation to  $H'$  disappeared when NESZ subtraction was included in the calibration~~ several of the polarimetric SAR features were found related to melt pond fraction before NESZ subtraction, after NESZ subtraction, only the standard deviation of  $|\rho|$  showed a relationship. This indicates that the ~~correlation~~ correlations only reflected the low signal-to-noise ratio of the scene, as has previously been described in oil/water discrimination (Minchew et al., 2012). ~~In scene T3, the correlation between  $f_{MP}$  and  $\alpha'_1$  is likely a result of the expected relation between  $\alpha'_1$  and  $R_{VV/HH}$  (van Zyl and Kim, 2011). The correlations found between  $f_{MP}$  and mean and standard deviations of  $|\rho|$  and  $\angle\rho$  in scene T4 are, as for  $H'$ , most likely related to the low wind speed and low signal-to-noise ratio of the scene.~~

The findings in our study deviate from the findings of Han et al. (2016), where  $\sigma_{HH}^0$ ,  $\angle\rho$  and  $\alpha'_1$  were found to be the most prominent polarimetric features in separating melt ponds, sea ice and open  
575 water in high resolution X-band SAR imagery. Differences in sea ice type, sea ice surface roughness,

wind conditions and SAR incidence angle could possibly explain why different polarimetric features are sensitive to  $f_{MP}$  in the two studies. The methods of the two studies are also slightly different, as Han et al. (2016) classify each pixel into melt pond, sea ice or open water, while our study focuses on mixtures of melt ponds and sea ice. Exact wind information lacks in Han et al. (2016), but the wind speed is expected to be low. This could explain why  $\sigma_{HH}^0$  contributes strongly in  $f_{MP}$  estimation, and is then in accordance to our findings. The diverging results in the two studies emphasize the need of investigating melt ponds impact on SAR imagery under different conditions and for a variety of sea ice types. It also stresses the importance of supplementary measurements of parameters like wind speed and sea ice surface roughness.

The correlations found in our study are not very strong. The weak to moderate correlations might suggest a limited sensitivity to  $f_{MP}$  in X-band SAR imagery, but they could also reflect limitations in the data set. The co-location between the helicopter images and the SAR imagery is estimated to have a possible offset of at most 27%, potentially introducing a large random error into our investigation, lowering the correlation values. A larger degree of smoothing than the area covered by the helicopter images allows for might also be needed to improve the results. The absolute radiometric accuracy of TSX scenes could also influence the results of our study, but this influence is expected to be very small compared to other uncertainties. All the above-mentioned issues should be addressed in future studies.

## 6 Conclusions

Melt ponds play an important role in the sea-ice-ocean energy budget, but the evolution of melt pond fraction ( $f_{MP}$ ) through the melt season is poorly monitored. Satellite-borne polarimetric SAR has shown promising results for  $f_{MP}$  retrieval in C-band, but few studies have investigated the opportunities in X-band. In this study we demonstrate statistically significant relations between  $f_{MP}$  and several polarimetric SAR features on drifting FYI in X-band, based on helicopter-borne images of the sea ice surface combined with four dual polarimetric SAR scenes. The study reveals a prospective potential for  $f_{MP}$  estimation from X-band SAR, but also stresses the importance of including wind speed and incidence angle in a future robust  $f_{MP}$  retrieval algorithm. Such an algorithm could supplement optical methods, and be used as a tool in climate applications, both as input in climate models and in e.g. in studies of melt pond evolution mechanisms.

$R_{VV/HH}$  was found to be the most promising SAR feature for  $f_{MP}$  estimation in our study, in agreement with previous findings in C-band. Hence, both the HH and VV polarimetric channels are needed for a future  $f_{MP}$  retrieval in X-band. The theoretical range of suitable wind speeds ( $< 5$  m/s) and sea ice surface roughnesses ( $s_{RMS} < 1.4$  mm) for  $f_{MP}$  extraction based on  $R_{VV/HH}$  are slightly more limited in X-band than in C-band, but our results show that  $f_{MP}$  also influences the X-band SAR signature when these criteria are partly exceeded. The high noise floor of TerraSAR-X

also restricted use of scenes with incidence angles above  $\sim 40^\circ$ , while an incidence angle of  $29^\circ$  gave better results. [Future studies should focus on incidence angles in the range between  \$29^\circ\$  and  \$40^\circ\$ .](#) At very low wind speeds (0.6 m/s), the backscatter signal from the melt ponds became too low for  $f_{MP}$  retrieval based on polarimetric features [due to specular reflection](#). In that case,  $\sigma_{VV}^0$  was found suitable for  $f_{MP}$  estimation [due to the lower backscatter intensity in areas with high  \$f\_{MP}\$](#) . In the future, use of X-band scenes can possibly increase the total amount of SAR data accessible for  $f_{MP}$  retrieval, despite their limitations compared to C-band scenes.

An extended amount of *in situ* and airborne measurements together with satellite scenes are needed to establish robust  $f_{MP}$  estimation algorithms for X-band SAR. Information about wind speed is crucial for  $f_{MP}$  retrieval, and can be retrieved from existing meteorological models or autonomous buoys measuring wind speed, where no ship or camp is present. Challenges in co-location of airborne observations and SAR imagery limited coordinated use of existing data in our study and introduced uncertainties in our results, [with areal offsets of up to 27%](#), possibly causing artificially low correlation values. Better co-location, for instance through corner reflectors or GPS senders located in the specific study area, should be aimed for in future studies. With a shift towards more seasonal drifting FYI, it is important to include this sea ice type in the studies, despite difficulties in comparing *in situ* and airborne measurements with satellite SAR scenes during drift.

Our study only investigates a few SAR scenes under similar sea ice conditions, and the ability of the suggested regression fits to predict changes in  $f_{MP}$  is not included. This is an important aspect. For development of a robust operational method, future studies should aim to include a larger number of satellite scenes acquired with various sea ice conditions, melt pond evolution stages, wind speeds, and incidence angles. The effect and limitations of sea ice surface roughness and dependency on filtering size and scale should also be further investigated.

*Acknowledgements.* The authors would like to thank the captain, crew and scientists from the Norwegian Polar Institute (NPI) and Airlift AS on-board R/V Lance during the expedition ICE2012 for support and data collection. The TerraSAR-X data are provided by InfoTerra. We acknowledge S. Hudson at NPI for help with meteorological data, and A. Fransson, also at NPI, for providing ice core information. Thanks to W. Dierking at the Alfred Wegner Institute and C. Brekke and T. Eltoft at Department of Physics and Technology, UiT-The Arctic University of Norway for participation in discussions, and to S. N. Anfinsen at Department of Physics and Technology, UiT-The Arctic University of Norway for useful comments on the manuscript. The project was supported financially by Regional Differensiert Arbeidsgiveravgift (RDA) Troms County, by the project "Sea Ice in the Arctic Ocean, Technology and Systems of Agreements" ("Arctic Ocean", subproject "CASPER") of the Fram Centre, and by the Centre for Ice, Climate and Ecosystems at the NPI. [The airborne data collection was also supported by ACCESS, a European Project within the Ocean of Tomorrow call of the European Commission Seventh Framework Programme, grant 265863.](#)

**Table 1.** Overview of the satellite scenes.

Date	Time (UTC)	Scene ID	Incidence angle	Pixel spacing (az. $\times$ ground range)	Wind speed (2 m.a.s.)	Air temperature (2 m.a.s.)
28 Jul 2012	06:52	T1	36.9°	2.4 m $\times$ 1.5 m	1.6 m/s	0.1° C
29 Jul 2012	14:25	T2	37.9°	2.5 m $\times$ 1.5 m	5.1 m/s	1.1° C
31 Jul 2012	13:51	T3	29.4°	2.4 m $\times$ 1.9 m	6.2 m/s	-0.8° C
2 Aug 2012	14:51	T4	44.2°	3.0 m $\times$ 1.3 m	0.6 m/s	0.8° C

**Table 2.** Overview of the images captured during the helicopter flights. Only images without open water fraction are included in the study. The bottom entries show the ~~global~~regional values derived from all five flights, and the local values of the floe investigated in T3 and T4.

Date	Time (UTC)	No. of images	Transect length	Mean $f_{MP}$	Std. $f_{MP}$
31 Jul 2012	7:36-8:10	848	67 km	30.1%	10.0%
1 Aug 2012	7:22-8:34	1364	139 km	31.1%	12.3%
1 Aug 2012	16:45-18:03	1383	154 km	34.8%	12.8%
2 Aug 2012	11:21-12:00	676	78 km	33.0%	13.7%
2 Aug 2012	14:43-16:04	1458	170 km	33.2%	11.4%
<del>Global</del> <u>Regional</u> values	-	5729	608 km	33.2%	11.4%
Floe values	-	43	4 km	30.6%	11.1%

**Table 3.** Estimated sea ice surface roughness ( $s_{RMS}$ ) from five segments at the floe by R/V Lance. Values in parenthesis displays standard deviations (std) of  $s_{RMS}$ .

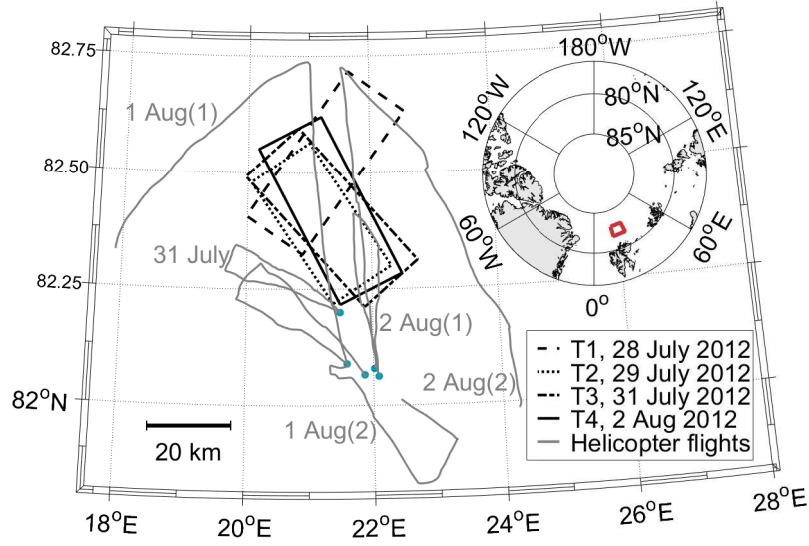

Segment Nr.	Area	$s_{RMS}$ ( $std(s_{RMS})$ )
1	11000 m <sup>2</sup>	6.7 (0.3) cm
2	13530 m <sup>2</sup>	11.0 (10) cm
3	11670 m <sup>2</sup>	7.4 (0.6) cm
4	13820 m <sup>2</sup>	9.0 (0.4) cm
5	12380 m <sup>2</sup>	10.0 (0.4) cm

**Table 4.** Spearman’s correlation coefficient ( $r$ ) between  $f_{MP}$  retrieved from the helicopter images at the investigated floe, and mean and standard deviation of the polarimetric SAR features from the corresponding area in T3 and T4. Bold indicate significant values within a 95% confidence interval, ~~and values in parentheses are retrieved before NESZ subtraction in the calibration process.~~

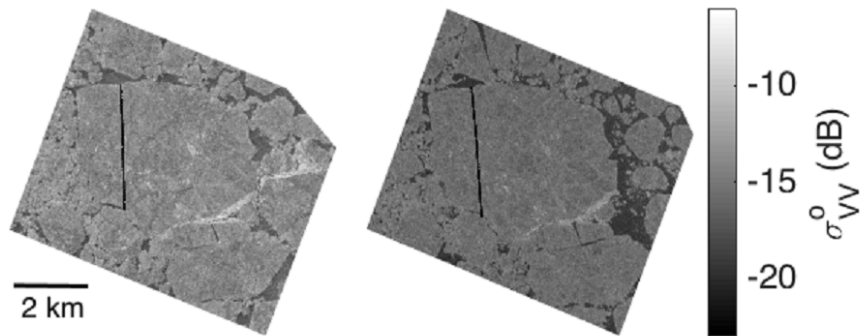

SAR feature	r (T3)		r (T4)	
	Mean	Std.	Mean	Std.
$\sigma_{HH}^0$	0.04 ( <del>0.05</del> )	0.10 ( <del>0.09</del> )	<b>-0.33</b> ( <del>-0.33</del> )	-0.27 ( <del>-0.22</del> )
$\sigma_{VV}^0$	0.21 ( <del>0.21</del> )	0.09 ( <del>0.09</del> )	<b>-0.54</b> ( <del>-0.53</del> )	<b>-0.54</b> ( <del>-0.52</del> )
$R_{VV/HH}$	<b>0.45</b> ( <del>0.46</del> )	0.03 ( <del>0.07</del> )	<b>-0.31</b> ( <del>-0.31</del> )	<b>-0.48</b> ( <del>-0.01</del> )

**Table 5.** Statistics of modeled  $f_{MP}$  distributions.

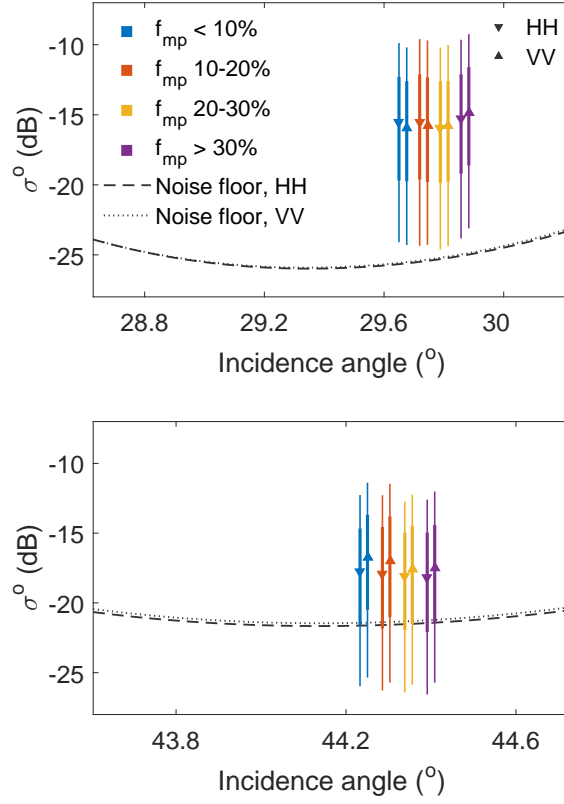

Area	Window size (pixels)	$f_{MP}(R_{VV/HH})$		$f_{MP}(\sigma_{VV}^0)$	
		Mean	Std.	Mean	Std.
T3, floe	$21 \times 21$	34.9%	24.8%	-	-
T3, floe	$51 \times 51$	35.0%	11.0%	-	-
T4, floe	$21 \times 21$	-	-	30.6%	26.0%
T4, floe	$51 \times 51$	-	-	31.4%	16.7%
T1, full scene	$51 \times 51$	36.5%	12.3%	19.0%	29.9%
T2, full scene	$51 \times 51$	45.1%	13.3%	-1.6%	27.8%
T3, full scene	$51 \times 51$	31.2%	11.2%	19.7%	29.7%
T4, full scene	$51 \times 51$	51.9%	12.3%	36.3%	15.7%

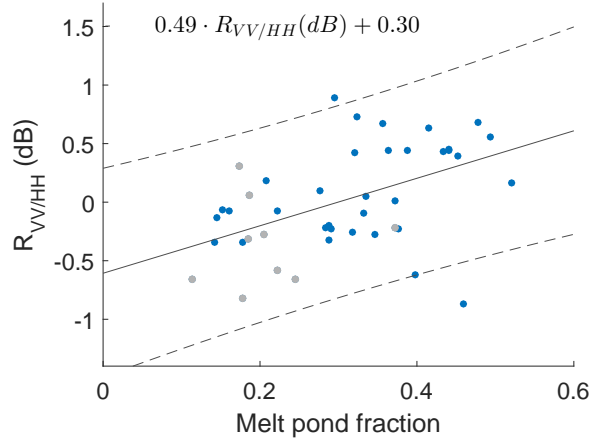

**Figure 1.** Map of the study area north of Svalbard, showing the location of the satellite scenes and the track of the helicopter flights. Blue dots mark the starting points of the flights. The red box in the inset map of the northern hemisphere shows the geographical position of the area displayed.

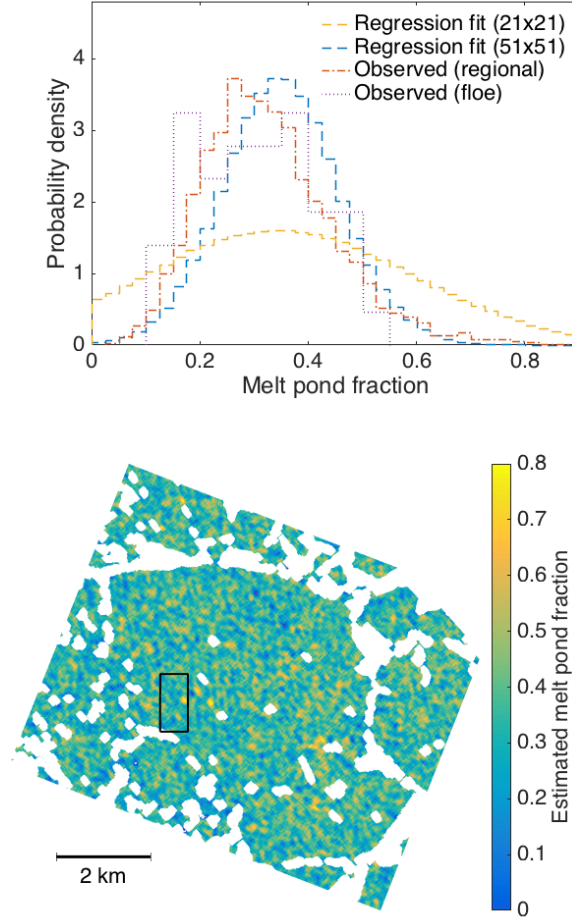

**Figure 2.** The floe investigated in scene T3 (left) and T4 (right) [with a  \$11 \times 11\$  pixels smoothing window](#). The black line marks the transect along which the helicopter image were taken.

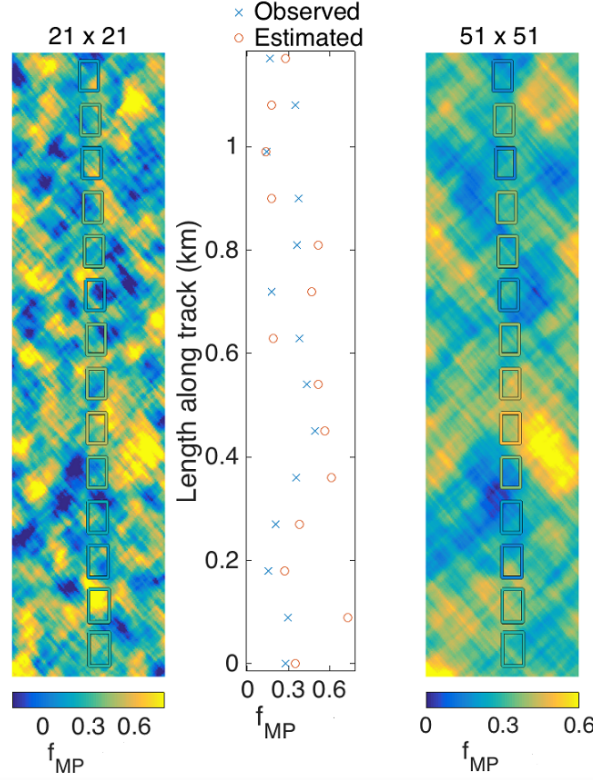

**Figure 3.** Signal-to-noise analysis of HH and VV channels for areas with different  $f_{mp}$  retrieved from the investigated floe in scene T3 (top) and T4 (bottom). The triangles displays the median of  $\sigma_{HH}^0$  (dB) (upward pointing) and  $\sigma_{VV}^0$  (downward pointing). The thin line represents the part of  $\sigma^0$  falling between the 10 and the 90 percentile, while the thick line represents the part of  $\sigma^0$  falling between the 25 and 75 percentile. Hence, the lines indicate the distributions. All markers are offset from the middle position for clarity.

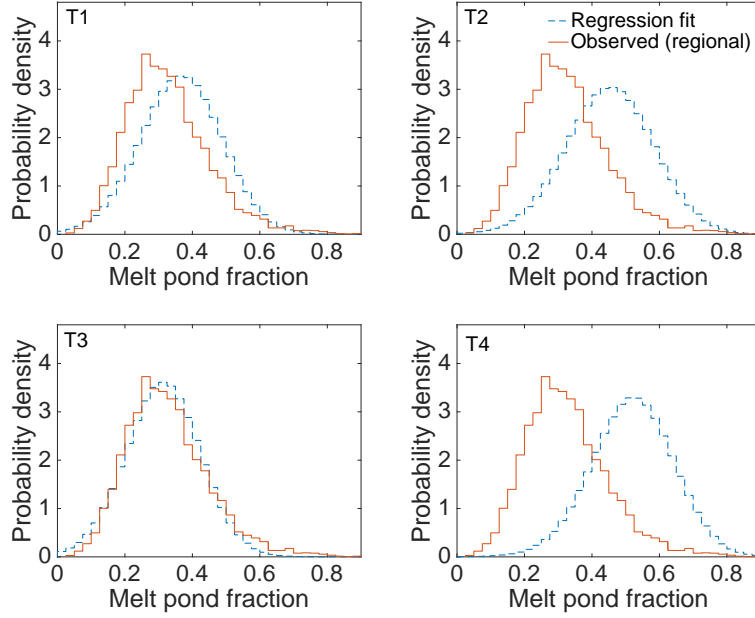

**Figure 4.** Scatter plot displaying  $f_{MP}$  retrieved from the 43 helicopter images covering the investigated floe in T3, and mean  $R_{VV/HH}$  extracted from the corresponding areas. Grey dots represent areas with partly deformed sea ice, while blue dots represent areas of level ice. The trend line represents a robust bisquare weights least squares linear fit of the data, and the dotted line represents the 95% confidence interval of the regression.  $R_{fit}^2$  equals 0.21.

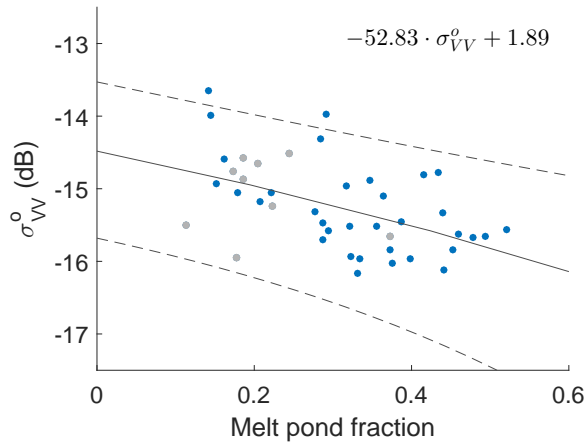

**Figure 5.** Top: Probability density distributions of  $f_{MP}$  for the investigated floe in T3. Curves represent distributions produced by the regression fit based on  $R_{VV/HH}$  with  $21 \times 21$  and  $51 \times 51$  pixels windows, and ~~empirical~~observed distributions from all helicopter flights (~~global~~regional) and from the specific floe (floe). Bottom: Estimated  $f_{MP}$  from the  $R_{VV/HH}$  based regression with a  $51 \times 51$  pixels window for investigated floe in T3. The frame outlines the area displayed in Fig. 6.

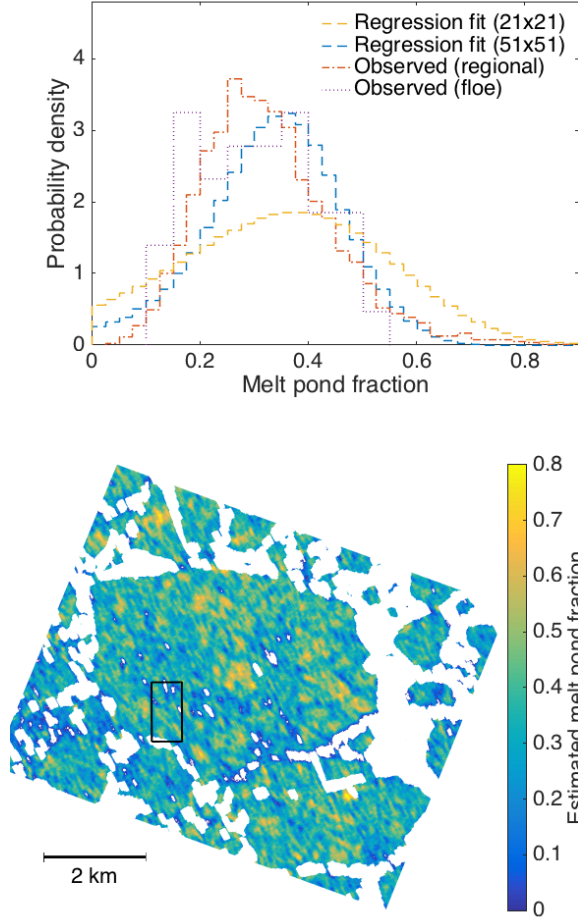

**Figure 6.** Melt pond fraction ( $f_{MP}$ ) estimated from  $R_{VV/HH}$ , with the observed  $f_{MP}$  from the helicopter images overlaid as colored frames. The area displayed is  $0.3 \times 1.1$  km and its position is outlined with a frame in Fig. 5. The estimation is performed with  $21 \times 21$  (left) and  $51 \times 51$  (right) pixels windows. Note that the center pixel underlying each helicopter image frame would give the most representative value for comparison to the observed  $f_{MP}$ , as pixels closer to the frame contain a larger amount of information from outside the frame. The middle panel displays the mean estimated  $f_{MP}$  value for each frame together with the observed value.

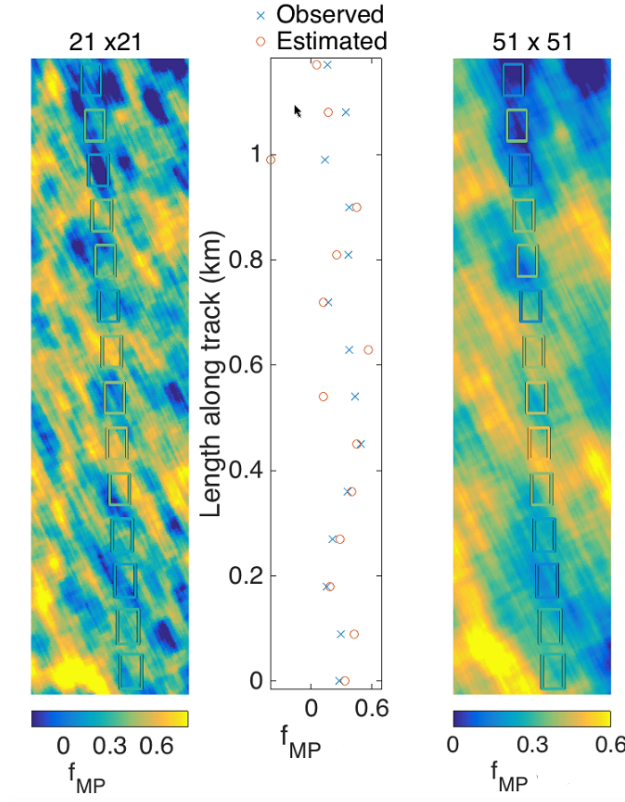

**Figure 7.** Probability density distributions of  $f_{MP}$  for the four investigated scenes (T1-T4). Curves represent distributions produced from the  $R_{VV/HH}$  based regression fit with a  $51 \times 51$  pixels window, and the empirical observed distribution retrieved from all five helicopter flights.

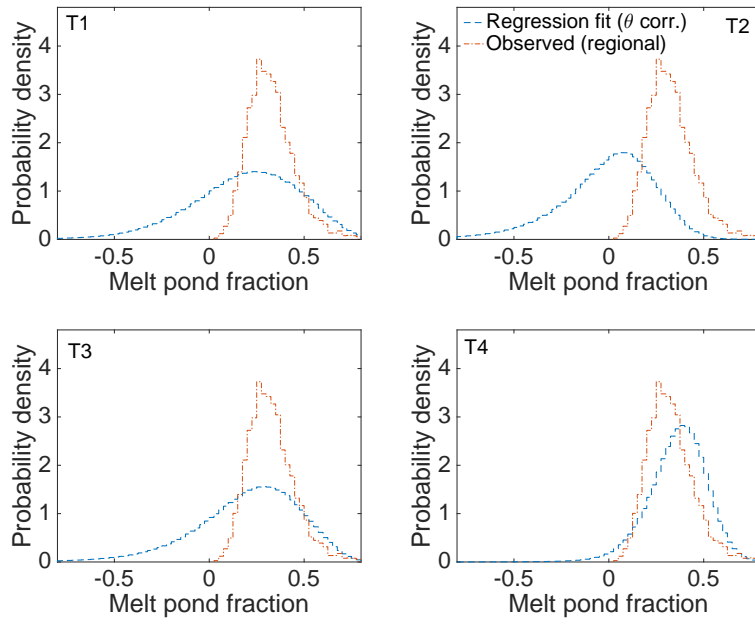

**Figure 8.** Scatter plot displaying  $f_{MP}$  retrieved from the 43 helicopter images covering the investigated floe in T4, and mean  $\sigma_{VV}^0$  extracted from the corresponding areas. Grey dots represent areas with partly deformed sea ice, while blue dots represent areas of level ice. The trend line represents a robust bisquare weights least squares linear fit of the data, and the dotted line represent the 95% confidence interval of the regression.  $R_{fit}^2$  equals 0.26.

**Figure 9.** Top: Probability density distributions of  $f_{MP}$  for the investigated floe in T4. Curves represent distributions produced by the regression fit based on  $\sigma_{VV}^0$  with  $21 \times 21$  and  $51 \times 51$  pixels windows, and **empirical observed** distributions from all helicopter flights (**global****regional**) and from the specific floe (floe). Bottom: Estimated  $f_{MP}$  from the  $\sigma_{VV}^0$  based regression with a  $51 \times 51$  pixels window for investigated floe in T4. The frame outlines the area displayed in Fig. 10.

**Figure 10.** Melt pond fraction ( $f_{MP}$ ) estimated from  $\sigma_{VV}^0$ , with the observed  $f_{MP}$  from the helicopter images overlaid as colored frames. The area displayed is  $0.3 \times 1.1$  km and its position is outlined with a frame in Fig. 9. The estimation is performed with  $21 \times 21$  (left) and  $51 \times 51$  (right) pixels windows. Note that the center pixel underlying each helicopter image frame would give the most representative value for comparison to the observed  $f_{MP}$ , as pixels closer to the frame contain a larger amount of information from outside the frame. The middle panel displays the mean estimated  $f_{MP}$  value for each frame together with the observed value.

**Figure 11.** Probability density distributions of  $f_{MP}$  for the four investigated scenes (T1-T4). Curves represent distributions produced from the  $\sigma_{VV}^0$  based regression with a  $51 \times 51$  pixels window, and the ~~empirical~~observed distribution retrieved from all five helicopter flights.
