

Response to Reviewers

We would like to thank both referees for taking the time to provide detailed feedback on our manuscript. We are pleased that both referees found our discovery that large simultaneous calving events in Porpoise Bay are driven by the break-up of multi-year sea-ice interesting and worth publishing. The referees were less positive about section 4.4 (reconstructing calving cycles) and reviewer 2 suggested this should be removed and that the paper could be considerably shortened.

In line with reviewer comments, we have decided to remove nearly all of the discussion of longer-term calving cycles from the manuscript and re-structure the paper, which does not impact on our main findings. Additionally, we have added further discussion on the 2016 calving event which has progressed further since our initial manuscript submission.

The revised manuscript is shorter and contains fewer figures. In short, the first half of the paper has remained similar, the section on reconstructing glacier calving has been removed, and a more in depth analysis on the drivers of the January 2007 and March 2016 sea-ice break-up has been added, as requested by the reviewers.

We include specific replies in blue to each reviewer and also attach a revised manuscript with changes highlighted in blue:

Reviewer 1

In “Simultaneous disintegration of outlet glaciers in Porpoise Bay (Wilkes Land), East Antarctica, and the long-term speed-up of Holmes Glacier,” Miles et al. present a study which investigates a few East Antarctic tidewater outlets. They document calving activity with a range of remotely sensed imagery and relate calving behavior to sea ice dynamics. Using sea ice concentration as a proxy, they infer recent glacier speedup of 50%. This is an interesting paper, expanding a known glacial (in)stability mechanism from the Arctic to East Antarctica. With some revisions, I certainly recommend it for C1 publication in The Cryosphere. -Allen Pope

[We thank the reviewer for the positive comments regarding the manuscript.](#)

Broad Comments: **The paper leads to some really interesting points, but some of these are let down by incomplete discussions. The paper would be improved and more useful if the discussion of (1) what could have led to increased glacier velocity and (2) what drove anomalously high melt / ponding were expanded. **Similarly, the conclusions are acceptable but do not place the results in a broader context, including the implications of the new knowledge described in the paper. **This paper includes a lot of figures which help demonstrate and illustrate the arguments in the paper. This is really helpful! However, the figures are often complex imagery – more annotation would help the reader quickly understand what they are supposed to glean from a particular figure. In addition, many figures’ brightness and contrast need to be reviewed for “readability” on screen and in print.

Specific Comments: L13: Indicate specific kinds of remote sensing data that were used.

[Amended: we have removed the section on long-term calving cycles and glacier velocity so the first point raised is no longer an issue. We address the second point by adding lengthy discussion of the possible causes of the anomalously high melt. We have checked all figures and annotated them for greater clarity.](#)

L25: Include a space between “March” and “2016”

Amended.

Abstract: The discussion includes mentions of warming, increased melting, etc. – including a sentence which nods to climate and larger implications may strengthen the abstract.

The abstract has been changed to reflect the revised manuscript and mentions the wider implications re: increased melting, climate change.

L93: The description of the method is VERY vague. What sort of automated mapping method? The goal should be reproducible science, so a fully described method should be included in the paper. At the very least, a citation which describes the method in depth should be included.

We have updated the description of the method. The description now details how method automatically classifies glaciers and sea-ice into polygons based on the pixel statistics of each image.

L126: 18 grid cells equals what area?

Amended, 18 grid cells equates to 11,250 km².

L131: Define ASI acronym

Amended.

~L133: You discuss multiple breakouts – why is only 2007 studied at higher resolutions, and are you sure the data sources are completely intercomparable?

The manuscript no longer discusses multiple breakouts and the longer term calving cycle. Thus, we focus primarily on the 2007 break-out, but have also added some discussion of a very recent event that may have initiated in 2016.

L138: I thought that the figure described a particular region where sea ice concentration was studied. When/why are you getting closer to termini?

Amended. This was an oversight; we now also include the region where the higher resolution sea-ice data was extracted (which is closer to the terminus) in Figure 1 and mention this in the text.

L141: At 27 km spatial resolution, how many points are you really sampling?

Amended.

L155-L157: A bit of a meandering sentence, it almost implies monotonic behavior, which is not the case.

Amended.

L159 & L167: It seems like Frost might not actually fit? More like a hybrid with Sandfjord?

All calving events which we observe in Porpoise Bay only occur after sea-ice has broken away from glacier termini. We clarify this in section 4.4.

L200: Using anomalies rather than absolute concentrations or areas means that sea ice could be lower, but it doesn't actually provide proof that there is a breakup.

We appreciate that anomalies alone do not provide proof of complete break-up. However, when combined with imagery actually showing the break-up, the events would appear to be validated. We could show absolute concentrations instead, but these are very difficult to follow, especially over multiple years due to the strong seasonal variations.

L208: Are you really confident enough to use “cannot”, as opposed to the slightly more flexible “likely did not”?

Section removed in response to Reviewer 2 comments.

L211: Instead of “large,” how about “very large” or “largest”?

Section removed in response to Reviewer 2 comments.

Section 4.4: The first few paragraphs in this section seems more awkward and convoluted than previous sections. The sentence structure and tense seems overly complicated. It would benefit from a style edit so that it flows easier and therefore is more easily comprehended.

This section has been removed in response to Reviewer 2 comments.

L219: “has been” to “was”

Section removed in response to Reviewer 2 comments.

~L251-264: The language in this paragraph seems a bit belabored and the arguments (regarding sea ice) seem a bit circular. Streamline the writing to simplify and clarify. (On a side note: “thus” is repeated closely together, which is also awkward.)

Section removed in response to Reviewer 2 comments.

L291: Consider including inferred velocities for these time periods, too?

Section removed in response to Reviewer 2 comments.

L302: Insert space before open parenthesis

Section removed in response to Reviewer 2 comments.

L308: Okay, it may be the first time it is observed. So what?

We now state its wider importance. If future changes in climate result in a weaker persistence in landfast ice in porpoise bay, it may result in detrimental effects on glacier tongue stability.

L313: “suggest”, not “suggests”

Amended.

L316: Days/weeks is really the realm of weather not climate – clarify the difference between the two and really what the important processes are.

Amended. We now refer to days and weeks as synoptic conditions.

~L322: Temperature might not be driving melt, but something in the model clearly is driving melt. Look at other parameters to identify this. For example, is it wind that could be causing it? That would be logical, and really helpful to identify the driver of such an important process.

We now link melt events to atmospheric circulation anomalies (see section 5.2).

L332: It may be the first time this has been published explicitly – but it is also not surprising. There are a few papers that observe supraglacial lakes on East Antarctic outlets. So why is it important that this has been observed for the first time?

We now clarify the importance of surface melt on sea-ice. In the arctic, this has been linked to sea-ice break-up. Therefore, the fact that we observe ponding on the multi-year sea-ice prior to its fracturing and ultimate break-up suggests that surface melt could have been important.

~L347: Is it possible that the higher melt year saturated/refroze in the snowpack, which then allowed a lower melt year to be able to form melt ponds? I know that is the case on ice shelves, but I'm not sure if that is true in a sea ice context?

This is an interesting point. Studies in the Arctic suggest the trapped latent heat within the sea-ice as melt ponds refreeze may inhibit basal growth of the sea-ice (e.g. Flocco et al., 2015; JGR). We now include this point in the manuscript.

~L362: The sentences around here go in a couple circles about the processes and drivers that you think are most important for the reader to understand. I think it might help to clarify that, in this system, bathymetry and geometry seem to drive the location of calving events which sea ice drives the timing.

Section removed

L376: This is restating earlier conclusions. Maybe only need to say in one place?

Section removed

L380-389: This is really interesting and important glaciologically! The paper would be stronger if this were fleshed out and done so with more rigor. It can very much be a discussion of what is reasonable (not an in-depth analysis), but more should be included. For example, what might changed in accumulation do? Is it possible basal changes played a role? What else could be driving increased velocity?

Section removed

~L399: Yes, sea ice is related to climate – but Antarctic sea ice is very much dependent on more than temperature (which can be seen in regional expansion of Antarctic sea ice). More nuance needs to be brought to this sentence.

The conclusion has been modified to reflect the greater discussion on atmospheric circulation anomalies. However, we note that multi-year landfast ice may respond to a different set of climatic drivers to sea-ice extent, which has been increasing.

L409: You specifically mention “warming” – but it would seem to be more appropriate to discussions in atmospheric or oceanic circulation?

We now discuss in detail the anomalous atmospheric circulation patterns.

L411: Okay – but where else might these processes be important? Expand this conclusion to be broader to have larger implications.

The conclusion has been expanded.

Table 2: No Landsat 8 OLI imagery used? This might be interesting for the recent breakup and data are available from 2013.

The 2016 event started in late March. Therefore, Landsat 8 only made a few passes before the polar night and most of the time it was cloudy.

Figure 1: ****Include a small inset of the entire continent. ****“Moscow University” should be “Moscow University Ice Shelf” ****Scale bar in upper figure**

We have removed figure 1a and added a small inset to Figure 1 (previously 1b).

Figure 2: ****x-axis labels are a little too small ****Caption should note the different vertical scales

Amended

Figure 3: ****Blue is a bit hard to see ****Show outline of this area in Figure 1? Don't worry about it if too crowded. ****Brighten figure so easier to view**

Blue has been changed to yellow and the figure has been brightened.

Figure 4: ****Consider tracing front in a 2nd color in each image to clarify the changes that you want to highlight between images? It is hard to see (as you admit) with the melt, etc. ****You reference the total area calved. Maybe include a hatched area in the last image between the two terminus lines?

It is very difficult to digitize the front in each image because of the abundance of icebergs close to the terminus during the calving event.

Figure 6: Increase brightness and contrast to make more easily viewable.

Amended

Figure 7: Anomalies are interesting but is an absolute scale better to demonstrate what you want show?

An absolute scale is very difficult to follow due to the seasonal variations. Therefore, we have stuck with anomalies.

Figure 8: Include 2nd outline in lower image?

Figure removed

Figure 9: ****Maybe darken a little so it prints better? ****Include 2nd outline in lower image?

Figure removed

Figure 10: Increase contrast so more viewable. The edge of the 9 km advance isn't very visible when printed.

Figure removed

Figure 11: Increase contrast in lower image.

Figure removed

Figure 12: Same comment as in text – include inferred velocities for these time periods, too?

This figure is now used to simply indicate the estimated terminus position of Holmes (West) Glacier, see section 4.6.

Figure 13: Add line for 7 Feb? Hatched area to indicate calved area?

Amended. Line added and figure updated with more recent imagery.

Figure 14: ****Include annotation in each image and particularly at circle to help the reader ****Increase contrast to make more viewable.

Further description has been added in the figure caption. Contrast has been increased.

Figure 16: Maybe just report January '14 melt total relative to 2007? I don't think that the timeseries is particularly helpful here.

Figure removed

Figure 17 & 18: Combine these into one figure? Figure 18: ****Be consistent with date format ****Double check permissions and copyright for using a Google Earth image in this publication.

Figure removed. See new figure 13

Reviewer 2

This is an interesting but rather rambling study on the connection between the presence of fast ice and the timing of glacier calving, and its potential impact on glacier flow. The study uses MODIS image data and the record of sea ice concentration from SSM/I (mostly) to demonstrate that during the brief periods of sea-ice-free conditions in Porpoise Bay, significant calving occurs, implicating the fast ice as a stabilizing component. The study then continues to search backward in time for evidence of this relationship, to the earliest satellite data, and then forward in time to an event in early 2016.

We thank the reviewer for appreciating that our study is interesting.

It could be published as it is. . . it is not incoherent. But it does not offer a clear contribution beyond the initial worthwhile documentation that fast-ice break-up leads to rapid iceberg release; or, to say it conversely, the presence of fast ice inhibits calving and drift. The discussion of velocity change seems rather vague, since any speed-up is not able to be directly tied to fast ice break-out and increased calving. The link to surface melting is so tenuous as to be useless. Moreover, the writing style is not brisk and efficient. There is a lot of excess text.

We are pleased that that the reviewer suggests that despite some reservations our study could be published 'as it is'. We disagree that the link to surface melt is 'useless'. We agree that RACMO won't capture katabatic heating events, but we note that there are no weather stations within 100s km of Porpoise Bay, so it is arguably the best dataset available. We now present new imagery from early December 2005 and mid-January 2006, which shows the development of fractures in the landfast ice and link this larger scale atmospheric circulation anomalies. These same fractures eventually rupture initiating the sea-ice break-up in 2007. Therefore, the synoptic conditions throughout December 2005 are likely to have been important in driving the break-up of sea-ice and subsequent glacier calving in 2007, which we now discuss in more detail. During December 2005 we observe surface melt features on the landfast ice. Given that the RACMO model implies that the mean December 2005 melt was exceptional for the region, we suggest that surface melt (along with other associated processes) may have been important process in weakening the landfast ice prior to break-up. To our knowledge no other studies have considered surface melt in landfast ice break-up in Antarctica. We simply highlight that this could be an important process and is worth considering.

The central discovery of the study appears to be a major glacier calving event in late summer of 2007, during a period of extended sea ice retreat in Porpoise Bay. Images before, during and after the break-out of the sea ice show the disaggregation of the floating ice tongues in the region. Having found this, the authors extend the search, first backward in time through the sea ice record, and then back still further using the record of early Landsat and declassified Argon / Corona data.

There is another data set available, already processed, of MODIS data. See http://nsidc.org/data/iceshelves_images/index_modis.html This is a processed geolocated record of ~monthly to weekly images going back to 2000. This shows other periods of low sea ice and partial fast ice break-up. Unfortunately, there is a one-year gap around 2001-2002 that could help narrow down the 2002 calving. If you request some additional images, we can add them for this time range.

This manuscript is very long, and could be much better focused. It is not necessary to show every data set that can say something about the 2007 event – the purpose is to document the event and the link with fast ice break-out, and then examine the extent to which glacier flow might change as a result. In particular, it is lengthy to read, first, the discovery of the 2007 event, then the inference of the 2002 and 1986 events, and then the possibility that there was no calving between 1963 and 1973 (and that case is not well-made) and then that there was a recent event.

The paper should present what you've learned overall, not the step-by-step process by which you learned it.

I don't want to spend more time with the study. Nor do I want to berate the writers. So let me simply outline the paper they should write, if they wish to. Figure order is re-arranged. Any figure not listed is not needed.

Introduce the region (Figure 1b) Indicate the location of later figures here. Present the evidence for major break-ups in March 2016 and February 2007: (fig 13);(merge Figure 3-dates?- into Fig 4);(then, Fig2 extended through 2016). Fig6 might be retained, but it does not really help - regional sea ice is not low, yet there is a calving in austral autumn 2006.

Present the sea ice record from SSM/I+SMMR+EMSR for the areas in Fig 1b (using Figure 7) The major bay-wide calving and retreat is clearly timed by the loss of sea ice.

Earlier events large events at the Holmes Glacier front can also be linked, somewhat tentatively to extreme sea ice lows. MODIS data at NSIDC could help greatly here. An examination of this image series could document that the small iceberg pattern does / does not remain fixed (spreading or twisting of the arrangement of the bergs, but no 'individual' motion) during periods of continuous fast ice. Create a new figure from the MODIS data, summarizing what it shows about the small berg pattern evolution over time (this has a bit of Fig 14, but might be more extensive). Don't have to show every event in the 2000-2016 record – just the facts you extract from it.

With this record, i.e. ASAR, sea ice concentration, and MODIS, you have observations that can help you interpret the old record. Create a figure of the 1997, Nov 1973, Jan 1973, and Oct 1963 images, together. Given the field of small bergs trapped in fast ice in this series, make inferences about past calvings of Holmes, and of Frost (Figure 12). I would downplay the calvings of the other small glaciers, it is too confusing to follow it all.

From here, discuss synoptic patterns using reanalysis data that cause (or are associated with) sea ice retreat from this region of Antarctica. I don't think surface melting helps much, and in any case RACMO is not likely to

capture katabatic heating events very well, which could be key in the immediate vicinity of the grounding line. I don't see how Fig 15, 16, 17 or 18 really helps.

This will be a new paper, that you would re-submit for review. It would be half as long. It would conclude things about calving and presence of fast ice, mostly focused on the the 2016, 2007, and 2002 events, but with a few statements about earlier events back to 1963. It would conclude things about berg motion within temporally continuous fast ice, and synoptic climate patterns that favor fast ice break-out and calving in this area.

The manuscript has been shortened and re-structured broadly along the lines the reviewer suggests, but also keeping in mind that Reviewer 1 specifically noted the helpfulness of the Figures and requested additional discussion. To summarise: we have removed the lengthy discussion on reconstructing the calving cycles and now focus on the drivers of sea-ice break-up in 2007 and 2016. We link the 2007 event to atmospheric circulation anomalies weakening the sea-ice in December 2005 prior to its break-up. In contrast, we find no link between atmospheric anomalies and the 2016 event sea-ice break-up. Instead, we link this event the terminus position of Holmes (West) Glacier, pushing the multi-year sea-ice further into the open ocean. As noted in the revised conclusions, despite these different mechanisms, our manuscript clearly demonstrates the importance of landfast sea-ice on major calving events in East Antarctica.

We have reduced the number of Figures, but given that the satellite imagery are the primary source of data for this study, we feel it is very important to show these data on Figures. We also note that Reviewer 1 specifically praises this aspect of the manuscript *"This paper includes a lot of figures which help demonstrate and illustrate the arguments in the paper. This is really helpful!"*

Title: Simultaneous disintegration of outlet glaciers in Porpoise Bay (Wilkes Land), East Antarctica, driven by sea-ice break-up.

Authors: B.W.J. Miles^{1*}, C. R. Stokes¹, S.S.R. Jamieson¹

Abstract: The floating ice shelves and glacier tongues which fringe the Antarctic continent are important because they help buttress ice flow from the ice sheet interior. Dynamic feedbacks associated with glacier calving have the potential to reduce buttressing and subsequently increase ice flow into the ocean. However, there are few high temporal resolution studies on glacier calving, especially in East Antarctica. Here we use **ENVISAT ASAR wide swath mode imagery** to investigate monthly glacier terminus change across six marine-terminating outlet glaciers in Porpoise Bay (-76°S, 128°E), Wilkes Land (East Antarctica), between November 2002 and March 2012. This reveals a large **near-simultaneous calving event in January 2007**, resulting in a total of ~2,900 km² of ice being removed from glacier tongues. **We also observe the start of a similar large near-simultaneous calving event in March 2016.** Our observations suggest that **both of these large calving events are driven by the break-up of the multi-year sea-ice which usually occupies Porpoise Bay. However, these break-up events appear to have been driven by contrasting mechanisms. We link the 2007 sea-ice break-up to atmospheric circulation anomalies in December 2005 weakening the multi-year sea-ice through a combination of surface melt and a change in wind direction prior to its eventual break-up in January 2007. In contrast, the 2016 break-up event is linked to the terminus of Holmes (West) Glacier pushing the multi-year sea-ice further into the open ocean, making the sea-ice more vulnerable to break-up. In the context of predicted future warming and the sensitivity of sea-ice to changes in climate, our results highlight the importance of interactions between landfast sea-ice and glacier tongue stability in East Antarctica.**

1. Introduction

Iceberg calving is an important process that accounts for around 50% of total mass loss to the ocean in Antarctica (Depoorter et al., 2013; Rignot et al., 2013). Moreover, dynamic feedbacks associated with retreat and/or thinning of buttressing ice shelves or floating glacier tongues can result in an increased discharge of ice into the ocean (Rott et al., 2002; Rignot et al., 2004; Wuite et al., 2015). At present, calving dynamics are only partially understood (Benn et al., 2007; Chapuis and Tetzlaff, 2014) and models struggle to replicate observed calving rates (van der Veen, 2002; Astrom et al., 2014). Therefore, improving our understanding of the mechanisms driving glacier calving and how glacier calving cycles have responded to recent changes in the ocean-climate system is important in the context of future ice sheet mass balance and sea level.

Calving is a two-stage process that requires both the initial ice fracture and the subsequent transport of the detached iceberg away from the calving front (Bassis and Jacobs, 2013). In Antarctica, major calving events can be broadly classified into two categories: the discrete detachment of large tabular icebergs (e.g. Mertz glacier tongue: Massom et al., 2015) or the spatially extensive disintegration of floating glacier tongues or ice shelves into numerous smaller icebergs (e.g. Larsen A & B ice shelves (Rott et al., 1996; Scambos et al., 2009). Observations of decadal-scale changes in glacier terminus position in both the Antarctic Peninsula and East Antarctica have suggested that despite some degree of stochasticity, iceberg calving and glacier advance/retreat is likely driven by external climatic forcing (Cook et al., 2005; Miles et al., 2013). However, despite some well-documented ice shelf collapses (Scambos et al., 2003; Banwell et al., 2013) and major individual calving events (Masson et al., 2015) there is a paucity of data on the nature and timing of calving from glaciers in Antarctica (e.g. compared to Greenland: Moon and Joughin, 2008; Carr et al., 2013), and particularly in East Antarctica.

Following recent work that highlighted the potential vulnerability of the East Antarctic Ice Sheet in Wilkes Land to ocean-climate forcing and marine ice sheet instability (Greenbaum et al., 2015; Aitken et al., 2016; Miles et al., 2013; 2016), we analyse the recent calving activity of six outlet glaciers in the Porpoise Bay region using monthly satellite imagery between November 2002 and March 2012. In addition, we also observe the start of a large calving event in 2016. We then turn our attention to investigating the drivers behind the observed calving dynamics.

2. Study area

Porpoise Bay (-76°S , 128°E) is situated in Wilkes Land, East Antarctica, approximately 300 km east of Moscow University Ice Shelf and 550 km east of Totten glacier (Fig. 1). This area was selected because it occupies a central position in Wilkes Land, which is thought to have experienced mass loss over the past decade (King et al., 2012; Sasgen et al., 2013; McMillan et al., 2014), and which is the only region of East Antarctica where the majority of marine-terminating outlet glaciers have experienced recent (2000-2012) retreat (Miles et al., 2016). This is particularly concerning because Wilkes Land overlies the Aurora subglacial basin and, due its reverse bed slope and deep troughs (Young et al., 2011), it may have been susceptible to unstable grounding line retreat in the past (Cook et al., 2014), and could make significant contributions to global sea level in the future (DeConto and Pollard, 2016). However, despite some analysis on glacier terminus position on a decadal timescales (Frezzotti and Polizzi, 2002; Miles et al., 2013; 2016), there has yet to be any investigation of inter-annual and sub-annual changes in terminus position and calving activity in the region.

Porpoise Bay is 150 km wide and is typically filled with land-fast multi-year sea-ice (Fraser et al., 2012). In total, six glaciers were analysed, with glacier velocities (from Rignot et al., 2011) ranging from $\sim 440 \text{ m yr}^{-1}$ (Sandford Glacier) to $\sim 2000 \text{ m yr}^{-1}$ (Frost Glacier). Recent studies have suggested that the largest (by width) glacier feeding into the bay - Holmes Glacier - has been thinning over the past decade (Pritchard et al., 2009; McMillan et al., 2014).

3. Methods

3.1 Satellite imagery and terminus position change

Glacier terminus positions were mapped at approximately monthly intervals between November 2002 and March 2012, using Envisat Advanced Synthetic Aperture Radar (ASAR) Wide Swath Mode (WSM) imagery across six glaciers, which were identified from the Rignot et al. (2011b) ice velocity dataset (Fig.1). Additional sub-monthly imagery between December 2006 and April 2007 were used to gain a higher temporal resolution following the identification of a major calving event around that time. During the preparation for this manuscript we also observe the start of another large calving event, which we use Sentinel-1 imagery to monitor its progress (Table 1).

Approximately 65% of all glacier frontal measurements were made using an automated mapping method. This was achieved by automatically classifying glacier tongues and sea-ice into polygons based on their pixel values, with the boundary between the two taken as the terminus position. The threshold between glacial ice and sea-ice was calculated automatically based on the image pixel statistics. In images where the automated method was unsuccessful, terminus position was mapped manually. The majority of these manual measurements were undertaken in the austral summer (December – February) when automated classification was especially problematic due to the high variability in backscatter on glacier tongues as a result of surface melt. Following the mapping of the glacier termini, length changes were calculated using the box method (Moon and Joughin, 2008). This method calculates the glacier area change between each time step divided by the width of the glacier, to give an estimation of glacier length change. The width of glacier was obtained by a reference box which approximately delineates the sides of the glacier.

Given the nature of the heavily fractured glacier fronts and the moderate resolution of Envisat ASAR WSM imagery (80 m) it was sometimes difficult to establish if individual or blocks of icebergs were attached to the glacier tongue. As a result, there are errors in precisely determining terminus change on a monthly time-scale ($\sim \pm 500$ m). However, because our focus is on major calving events, absolute terminus position is less important than the identification of major episodes of calving activity. Indeed, because estimations of terminus position were made at approximately monthly intervals, calving events were easily distinguished because the following month's estimation of terminus position would clearly show the glacier terminus in a retreated position. In addition, each image was also checked visually to make sure no small calving events were missed (i.e. as indicated by the presence of icebergs proximal to the glacier tongue).

3.2 Sea-ice

Sea-ice concentrations in Porpoise Bay were calculated using mean monthly Bootstrap sea-ice concentrations derived from the Nimbus-7 satellite and the Defence Meteorological Satellite Program (DMSP) satellites which offers near complete coverage between October 1978 and December 2014 (Comiso, 2014; <http://nsidc.org/data/nsidc-0079>). To extend the sea-ice record, we also use mean monthly Nimbus-5 Electrically Scanning Microwave Radiometer (ESMR) derived sea-ice concentrations (Parkinson et al., 2004; https://nsidc.org/data/docs/daac/nsidc0009_esmr_seaice.gd.html), which offer coverage

between December 1972 and March 1977. However, from March to May 1973, August 1973, April 1974 and June to August 1975, mean monthly sea-ice concentrations were not available. Sea-ice concentrations were extracted from 18 grid cells, covering 11,250 km² that extended across Porpoise Bay, but not into the extended area beyond the limits of the bay (Fig. 1). Grid cells which were considered likely to be filled with glacial ice were excluded. Pack ice concentrations were also extracted from a 250 x 150 km polygon adjacent to Porpoise Bay. The dataset has a spatial resolution of 25 km and monthly sea-ice concentration anomalies were calculated from the 1972-2016 monthly mean.

Daily sea-ice concentrations derived from the Artist Sea-Ice (ASI) algorithm from Advanced Microwave Scanning Radiometer - EOS (AMSR-E) data (Spreen et al., 2008) were used to calculate daily sea-ice concentration anomalies during the January 2007 sea-ice break-up (<http://icdc.zmaw.de/1/daten/cryosphere/seaiceconcentration-asi-amsre.html>). This dataset was used because it provides a higher spatial resolution (6.25 km) compared to those available using Bootstrap derived concentrations (25 km). This is important because it provides a more accurate representation of when sea-ice break-up was initiated and, due to its much higher spatial resolution, it provides data from much closer to the glacier termini (see Fig.1).

3.3 RACMO

We used the Regional Atmospheric Climate Model (RACMO) V2.3 (van Wessem et al., 2014) to simulate daily surface melt fluxes in the study area between 1979 and 2015 at a 27 km spatial resolution. The melt values were extracted from floating glacier tongues in Porpoise Bay because the model masks out sea-ice, equating to seven grid points. The absolute surface melt values are likely to be different on glacial ice, compared to the sea-ice, but the relative magnitude of melt is likely to be similar temporally.

3.4 ERA-interim

In the absence of weather stations in the vicinity of Porpoise Bay we use the 0.25° ERA-interim reanalysis dataset (<http://apps.ecmwf.int/datasets/data/interim-full-moda/levtype=sfc/>) to calculate mean monthly wind field and sea surface temperature (SST) anomalies, with respect to the 1979-2015 monthly mean. Wind field anomalies were calculated by using the mean monthly 10 m zonal (U) and meridional (V) wind components. We also used the daily 10 m zonal (U) and meridional (V) components to simulate wind field

vectors in Porpoise Bay on January 11th 2007 and March 19th 2016 which are the estimated dates of sea-ice break-up.

4. Results

4.1 Terminus position change

Analysis of glacier terminus position change of six glaciers in Porpoise Bay between November 2002 and March 2012 reveals three broad patterns of glacier change (Fig. 2). The first pattern is shown by Holmes (West) glacier, which advances a total of ~13 km throughout the observation period, with no evidence of any major iceberg calving that resulted in substantial retreat of the terminus beyond the measurement error (+/- 500 m). The second is shown by Sandford Glacier tongue, which advanced ~1.5 km into the ocean between November 2002 and April 2006, before its floating tongue broke away in May 2006. A further smaller calving event was observed in January 2009. Overall, by the end of the study period, its terminus had retreated around 1 km from its position in November 2002. The third pattern is shown by Frost Glacier, Glacier 1, Glacier 2 and Holmes (East) glaciers, which all advanced between November 2002 and January 2007, albeit with a small calving event in Frost glacier in May 2006. However, between January and April 2007, Frost Glacier, Glacier 1, Glacier 2 and Holmes (East) glaciers all underwent a large near-simultaneous calving event. This led to 1,300 km² of ice being removed from glaciers in Porpoise Bay, although we also note the disintegration of a major tongue from an unnamed glacier further west, which contributed a further 1,600 km². Thus, in a little over three months, a total of 2,900 km² of ice was removed from glacier tongues in the study area (Fig. 3). Following this calving event, the fronts of these glaciers stabilised and began advancing at a steady rate until the end of the study period (March, 2012) (Fig. 2), with the exception of Frost glacier which underwent a small calving event in April 2010.

4.2 Evolution of the 2007 calving event

A series of eight sub-monthly images between December 11th 2006 and April 8th 2007 show the evolution of the 2007 calving event (Fig. 4). Between December 11th 2006 and January 2nd 2007, the land-fast sea-ice edge retreats past Sandford glacier to the edge of Frost glacier and there is some evidence of sea-ice fracturing in front of the terminus of Glacier 2 (Fig. 4b). From January 2nd to January 9th a small section (~40 km²) of calved ice broke away from Frost glacier, approximately in line with the retreat edge of land-fast sea-ice (Fig. 4c). By January

25th, significant fracturing in the land-fast sea-ice had developed, and detached icebergs from Frost, Glacier 1, Glacier 2 and Holmes East glaciers begin to breakaway (Fig. 4d). This process of rapid sea-ice breakup in the east section of the bay and the disintegration of sections of Frost glacier, Glacier 1, Glacier 2 and Holmes East glaciers continues up to March 10th 2007 (Fig. 4g). In contrast, the west section of Porpoise Bay remains covered in sea-ice in front of Holmes west glacier, which does not calve throughout this event. By April 8th, the calving event had ended with a large number of calved icebergs now occupying the bay (Fig. 4h).

4.3 2016 calving event

During the preparation of this manuscript satellite observations of Porpoise Bay revealed another large near-simultaneous disintegration of glacier tongues in Porpoise Bay is currently underway. This event was initiated on March 19th where the edge of the multi-year sea-ice retreated to the Holmes West glacier terminus, removing multi-year sea-ice which was at least 14 years old. By March 24th this had led to the rapid disintegration of an 800 km² section of the Holmes West glacier tongue (Fig. 5). This was the first observed calving of Holmes (West) glacier at any stage between November 2002 and March 2016. Throughout March and April the break-up of sea-ice continued and by May 13th it had propagated to the terminus of Frost Glacier, resulting in the disintegration of large section of its tongue (Fig. 6). By 24th July sea-ice had been removed from all glacier termini in Porpoise Bay at some point during the event, resulting in a total of ~2,200 km² ice being removed from glacier tongues (Fig. 6).

4.4. The link between sea-ice and calving in Porpoise Bay

Analysis of mean monthly sea-ice concentration anomalies in Porpoise Bay between November 2002 and June 2016 (Fig. 7) reveals a major negative sea-ice anomaly occurred between January and June 2007, where monthly sea-ice concentrations were between 35% and 40% below average. This is the only noticeable (>20%) negative ice anomaly in Porpoise Bay and it coincides with the major January 2007 calving event (see Fig. 4). However, despite satellite imagery showing the break-up of sea-ice prior to the 2016 calving event (Fig. 5 and 6), in a similar manner to that in 2007 (e.g. Fig. 4), no large negative anomaly is present in the sea-ice concentration data. This is likely to reflect the production of a large armada of icebergs following the disintegration of Holmes (West) Glacier (e.g. Fig. 6), helping promote a rapid sea-ice reformation in the vicinity of Porpoise Bay. Furthermore, we note that the smaller calving events of Sandford and Frost glaciers all take place after sea-ice

had retreated away from the glacier terminus (Fig. 8). Indeed, throughout the study period, there is no evidence of any calving events taking place with sea-ice proximal to glacier termini. This suggests that glaciers in Porpoise Bay are very unlikely to calve with sea-ice present at their termini.

4.4 Atmospheric circulation anomalies

Atmospheric circulation anomalies in the months preceding the January 2007 and March 2016 sea-ice break-ups reveal contrasting conditions. In the austral summer which preceded the January 2007 break-up there were strong atmospheric anomalies throughout December 2005 (Fig. 9a). During December 2005 there was an anomalous easterly airflow adjacent to Porpoise Bay, which likely represents the weakening of the westerly winds which encircle Antarctica. This is reflected in the band of cooler SST close to the coast which represents the northward shift of the Antarctic Coastal Current in response to the weakened westerlies (e.g. Langlais et al., 2015). A weakened zonal flow combined with high sea surface temperatures (SST) in the south Pacific would allow the advection of warmer maritime air into Porpoise Bay. Consistent with this are the estimates of exceptionally high RACMO2.3 derived melt values in Porpoise Bay during December 2005, which contrasts with the longer term trend of cooling (Fig. 10). However this anomaly was short lived and, by January 2006, the wind field was close to average, although SST remained slightly higher than average (Fig. 9b). In December and January 2006/07, which are the months immediately before and during the break-up of sea-ice, atmosphere anomalies were close to average, with very little deviation from mean conditions in the wind field and a small negative SST anomaly (Fig. 9c). However, on January 11th 2007, which is the estimated date of sea-ice break-up, we note that there was a wind event close to Porpoise Bay (Fig. 11a).

In contrast to the preceding months to the January 2007 event, we find little deviations from average conditions prior to the March 2016 break-up event. In the austral summer which preceded the 2016 breakout (2014/15), there was little deviation from the average wind field and a small increase from average SST (Fig 9d). In December and January 2015/16 there was evidence for a small increase in the strength of westerly winds, and cooler SSTs in the South Pacific (Fig. 9e). However, in February and March 2016 there was no change from the average wind field and slightly cooler SST (Fig. 9f), although we note that on March 19th 2016, the estimated date of break-up initiation, there was a low pressure system passing Porpoise Bay (Fig. 11b).

4.6 Holmes (West) Glacier calving cycle

Through mapping the terminus position in all available satellite imagery (Table 1) dating back to 1963, we are able to reconstruct large calving events on the largest glacier in Porpoise bay, Holmes (West) (Fig. 12). On the basis that a large calving event is likely during the largest sea-ice break-up events, we estimate the date of calving based on sea-ice concentrations in Porpoise Bay when satellite imagery is not available. Our estimates suggest that Holmes (West) Glacier calves at approximately the same position in each calving cycle, including the most recent calving event in March 2016.

5. Discussion

5.1 Sea-ice break-up and the disintegration of glacier tongues in Porpoise Bay

We report a major, near-synchronous calving event in January 2007 and a similar event that was initiated in 2016 and resulted in $\sim 2,900 \text{ km}^2$ and $2,200 \text{ km}^2$ of ice, respectively, being removed from glacier tongues in the Porpoise Bay region of East Antarctica. This is comparable to some of the largest disintegration events ever observed in Antarctica e.g. Larsen A in 1995 ($4,200 \text{ km}^2$) and Larsen B in 2002 ($3,250 \text{ km}^2$); and is the largest event to have been observed in East Antarctica. However, this event differs to those observed on the ice shelves of the Antarctic Peninsula, in that it may be more closely linked to a cycle of glacier advance and retreat, as opposed to a catastrophic collapse that may be unprecedented.

Given the correspondence between the sea-ice and glacier terminus changes, we suggest that these disintegration events were driven by the break-up of the multi-year land-fast sea-ice which usually occupies Porpoise Bay and the subsequent loss of buttressing of the glacier termini. A somewhat similar mechanism has been widely documented in Greenland, where the dynamics of sea-ice melange in proglacial fjords has been linked to inter-annual variations in glacier terminus position (Amundson et al., 2010; Carr et al., 2013; Todd and Christoffersen, 2014; Cassotto et al., 2015). Additionally, the mechanical coupling between thick multi-year landfast sea ice and glacier tongues may have acted to stabilize and delay the calving of the Mertz glacier tongue (Massom et al., 2010) and Brunt/Stancomb-Wills Ice Shelf system (Khazendar et al., 2009). However, this is the first observational evidence directly linking multi-year landfast sea-ice break-up to the large scale and rapid disintegration of glacier tongues. This is important because landfast sea-ice is highly sensitive to climate (Heil, 2006; Mahoney et al., 2007) and, if future changes in climate were to result in a change to the persistence and/or stability of the landfast ice in Porpoise Bay, it may result in detrimental

effects on glacier tongue stability. An important question, therefore, is: what process(es) cause sea-ice break-up?

5.2 What caused the January 2007 and March 2016 sea-ice break-ups?

The majority of sea-ice in Porpoise Bay is multi-year sea-ice (Fraser et al., 2012), and it is likely that multiple climatic processes operating over different timescales contributed to the January 2007 sea-ice break-up event. Although there are no long-term observations of multi-year sea-ice thickness in Porpoise Bay, observations and models of the annual cycle of multi-year sea-ice in other regions of East Antarctica suggest that multi-year sea-ice thickens seasonally and thins each year (Lei et al., 2010; Sugimoto et al., 2016; Yang et al., 2016). Therefore, the relative strength, stability and thickness of multi-year sea ice at a given time period is driven not only by synoptic conditions in the short term (days/weeks), but also by climatic conditions in the preceding years.

In the austral summer (2005/06) which preceded the break-up event in January 2007, there was a strong easterly airflow anomaly throughout December 2005 directly adjacent to Porpoise Bay (Fig. 9a). This anomaly represents the weakening of the band of westerly winds which encircle Antarctica, which is reflected in an exceptionally negative Southern Annular Mode (SAM) index in December 2005 (Marshall, 2003), and which contrasts with the long-term trend for a positive SAM index (Marshall, 2007; Miles et al., 2013). A weaker band of westerly winds combined with anomalously high SST in the Southern Pacific (Fig. 9a) would allow a greater advection of warmer maritime air towards Porpoise Bay. Indeed, RACMO2.3 derived surface melt estimates place December 2005 as the second highest mean melt month (1979-2015) on the modelled output in Porpoise Bay (Fig. 10). To place this month into perspective, we note that it would rank above the average melt values of all Decembers and Januarys since 2000 on the remnants of Larsen B ice shelf. Comparing MODIS satellite imagery from before and after December 2005 reveals the development of significant fracturing in the multi-year sea-ice (Fig. 13a, b). These same fractures are still visible prior to the break-out event in January 2007 and, when the multi-year sea-ice begins to break-up, it ruptures along these pre-existing weaknesses (Fig. 13c). Therefore, this strongly suggests that the atmospheric circulation anomalies of December 2005 played an important role in the January 2007 multi-year sea-ice break-up and near-simultaneous calving event.

The break-up of Landfast sea-ice has been linked to dynamic wind events and ocean swell (Heil, 2006; Ushio, 2006; Fraser et al., 2012). Therefore, it is possible that the wind anomalies

in December 2005 may have been important in initiating the fractures observed in the sea-ice in Porpoise Bay, through changing the direction and/or intensity of oceanic swell. However, this mechanism is thought to be at its most potent during anomalously low pack ice concentrations because pack ice can act as a buffer to any oceanic swell (Langhorne et al., 2001; Heil, 2006; Fraser, 2012). That said, we note that pack ice concentrations offshore of Porpoise Bay were around average during December 2005 (Fig. 7). This may suggest that there are other mechanisms that were important in the weakening of the multi-year sea-ice in Porpoise Bay in December 2005.

In the Arctic, sea-ice melt ponding along pre-existing weaknesses has been widely reported to precede sea-ice break-up (Ehn et al., 2011; Petrich et al., 2012; Landy et al., 2014; Schroder et al., 2014; Arntsen et al., 2015). Despite its importance in the Arctic, it has yet to be considered as a possible factor in landfast sea-ice break-up in coastal Antarctica. As a consequence of the high melt throughout December 2005, the growth of sea-ice surface ponding would be expected, in addition to surface thinning of the sea-ice. High-resolution cloud free optical satellite coverage of Porpoise Bay throughout December 2005 is limited. However, available ASTER imagery in the vicinity of Frost Glacier on the 4th and 31st December 2005 shows surface melt features and the development of fractures throughout the month (Fig. 13 d and e) and high resolution imagery from 16th January 2006 shows the development of melt ponds on the sea-ice surface (Fig. 13 f). Therefore, we suggest it is possible that surface melt had some impact on the fracturing of landfast sea-ice in Porpoise Bay. This may have been caused through hydro-fracture of pre-existing depressions in the landfast ice or surface thinning making it more vulnerable to fracture through ocean swell or internal stresses. Additionally, the subsequent refreezing of some melt ponds may temporally inhibit basal ice growth, potentially weakening the multi-year sea-ice for future break-up (Flocco et al., 2015).

Consistent with the notion that the multi-year sea-ice was already in a weakened state prior to its break-up in 2007, is that the break-up occurred in January, several weeks before the likely annual minimums in multi-year sea-ice thickness (Yang et al., 2016; Lei et al., 2010) and landfast ice extent (Fraser et al., 2012). Additionally, atmospheric circulation anomalies indicate little deviation from average conditions in the immediate months preceding break-up (Fig. 9b, c), suggesting that atmospheric conditions were favourable for sea-ice stability. Despite this, a synoptic event is still likely required to force the break-up in January 2007. Daily sea-ice concentrations in Porpoise Bay in January 2007 show a sharp decrease in sea-ice concentrations after 12th January, representing the onset of sea-ice break-out (Fig 14).

This is preceded by a strong melt event recorded by the RACMO2.3 model, centred on January 11th, which may represent a low pressure system. Indeed, ERA-interim estimates of the wind field suggest strong south-easterly winds in the vicinity of Porpoise Bay (Fig 11 a). Unlike in December 2005, pack ice concentrations offshore of Porpoise Bay were anomalously low (Fig. 7). Therefore, with less pack ice buttressing, it is possible that the melt event, high winds and associated ocean swell may have initiated the break-up of the already weakened multi-year sea-ice in Porpoise Bay.

In contrast to January 2007, we find no link between atmospheric circulation anomalies and the March 2016 sea-ice break-up. In the preceding months to the March 2016 break-up, wind and SST anomalies indicate conditions close to average conditions favouring sea-ice stability (Fig. 9 d, e, f). This suggests another process was important in driving the March 2016 sea-ice break-up. A key difference between the 2007 and 2016 event is that the largest glacier in the bay, Holmes (West), only calved in the 2016 event. Analysis of its calving cycle (Fig. 12) indicates that it calves at roughly the same position in each cycle and that its relative position in early 2016 suggests that calving was ‘overdue’ (Fig. 12). This indicates that the calving cycle of Holmes (West) Glacier is not necessarily driven by atmospheric circulation anomalies. Instead, we suggest that as Holmes (West) Glacier advances, it slowly pushes the multi-year sea-ice attached to its terminus further towards the open ocean to the point where the sea-ice attached to the glacier tongue becomes more unstable. This could be influenced by local bathymetry and oceanic circulation, but no observations are available. However, once the multi-year sea-ice reaches an unstable state, break-up is still likely to be forced by a synoptic event. This is consistent with our observations, where ERA-interim derived wind fields show the presence of a low pressure system close to Porpoise Bay on the estimated date of sea-ice break-up in March 2016 (Fig. 11 b). Whilst we suggest that the March 2016 sea-ice break-up and subsequent calving of Holmes (West) is currently part of a predictable cycle, we note that this could be vulnerable to change if any future changes in climate alter the persistence and/or strength of the multi-year sea-ice, which is usually attached to the glacier terminus.

6. Conclusion

We identify two large near-simultaneous calving events in January 2007 and March 2016 which were driven by the break-up of the multi-year landfast sea-ice which usually occupies the bay. This provides a previously unreported mechanism for the rapid disintegration of

floating glacier tongues in East Antarctica, adding to the growing body of research linking glacier tongue stability to the mechanical coupling of landfast ice (e.g. Khazander et al., 2009; Massom et al., 2010). Our results suggest that multi-year sea-ice break-ups in 2007 and 2016 in Porpoise Bay were driven by different mechanisms. We link the 2007 event to atmospheric circulation anomalies in December 2005 weakening multi-year sea-ice through a combination of surface melt and a change in wind direction, prior to its eventual break-up in 2007. This is in contrast to the March 2016 event, which we suggest is part of a longer-term cycle based on the terminus position of Holmes (West) Glacier that was able to advance and push sea-ice out of the bay. The link between sea-ice break-up and major calving of glacier tongues is especially important because it suggests predictions of future warming (DeConto and Pollard, 2016) suggests that multi-year landfast ice may become less persistent. Therefore, the glacier tongues which depend on landfast ice for stability may become less stable in the future. In a wider context, our results also highlight the complex nature of the mechanisms which drive glacier calving position in Antarctica. Whilst regional trends in terminus position can be driven by ocean-climate-sea-ice interaction (e.g. Miles et al., 2013; 2016), individual glaciers and individual calving events have the potential respond differently to similar climatic forcing.

Table 1: Satellite imagery used in the study

Satellite	Date of Imagery
ARGON	October 1963 (Kim et al., 2007)
Envisat ASAR WSM	August 2002, November 2002 to March 2012 (monthly)
Landsat	January 1973; February 1991
MODIS	January 2001; December/January 2005/6; March 2016
RADARSAT	September 1997 (Liu and Jezek, 2004)
Sentinel-1	February-July, 2016

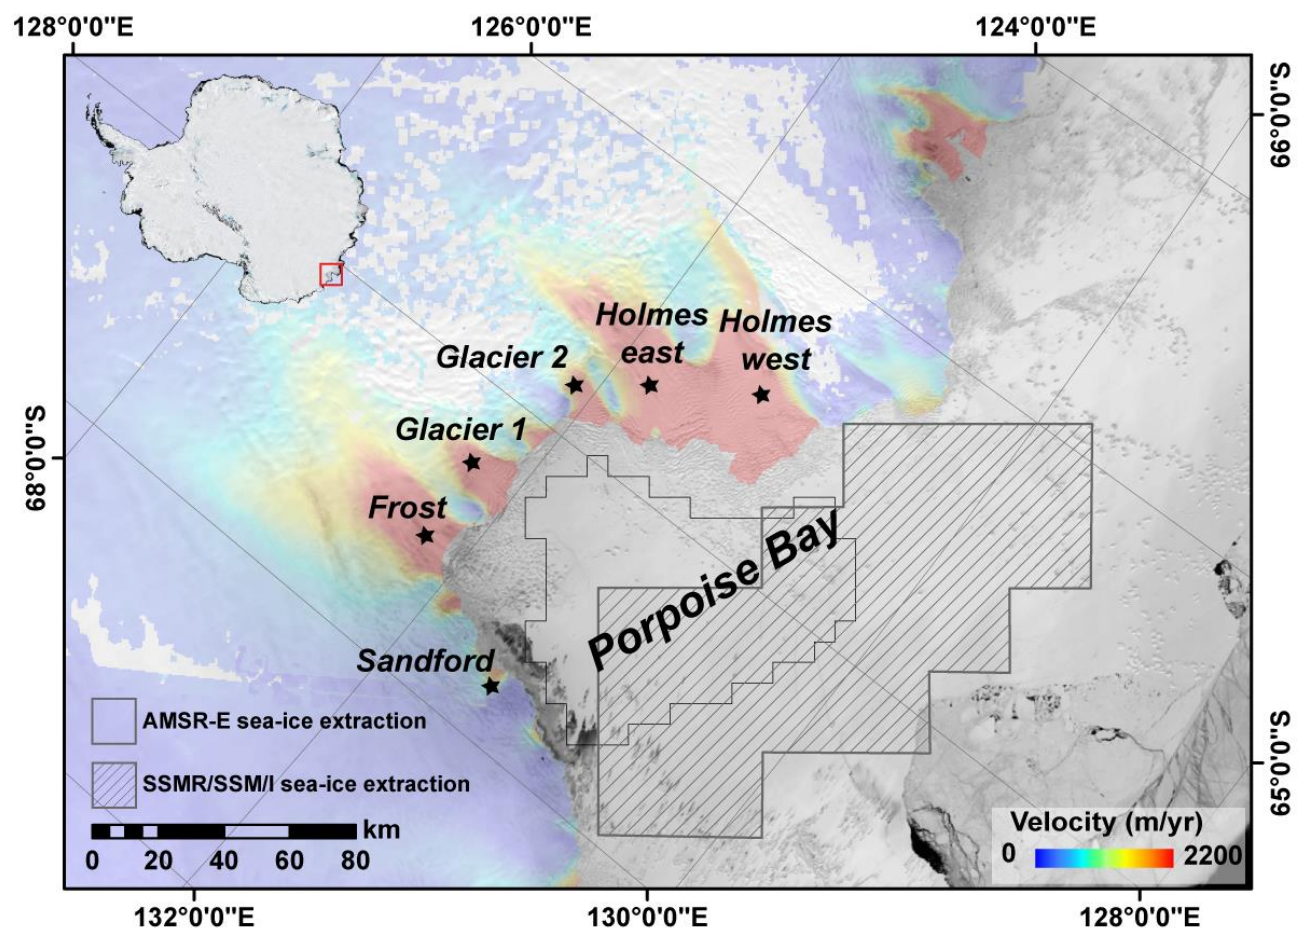

Figure 1: MODIS image of Porpoise Bay, with glacier velocities overlain (Rignot et al., 2011). The hatched polygon represents the region where long-term 25 km resolution SSMR/SSM/I sea-ice concentrations were extracted. The non-hatched polygon represents the region where the higher resolution (6.25 km) AMSR-E sea-ice concentrations were extracted.

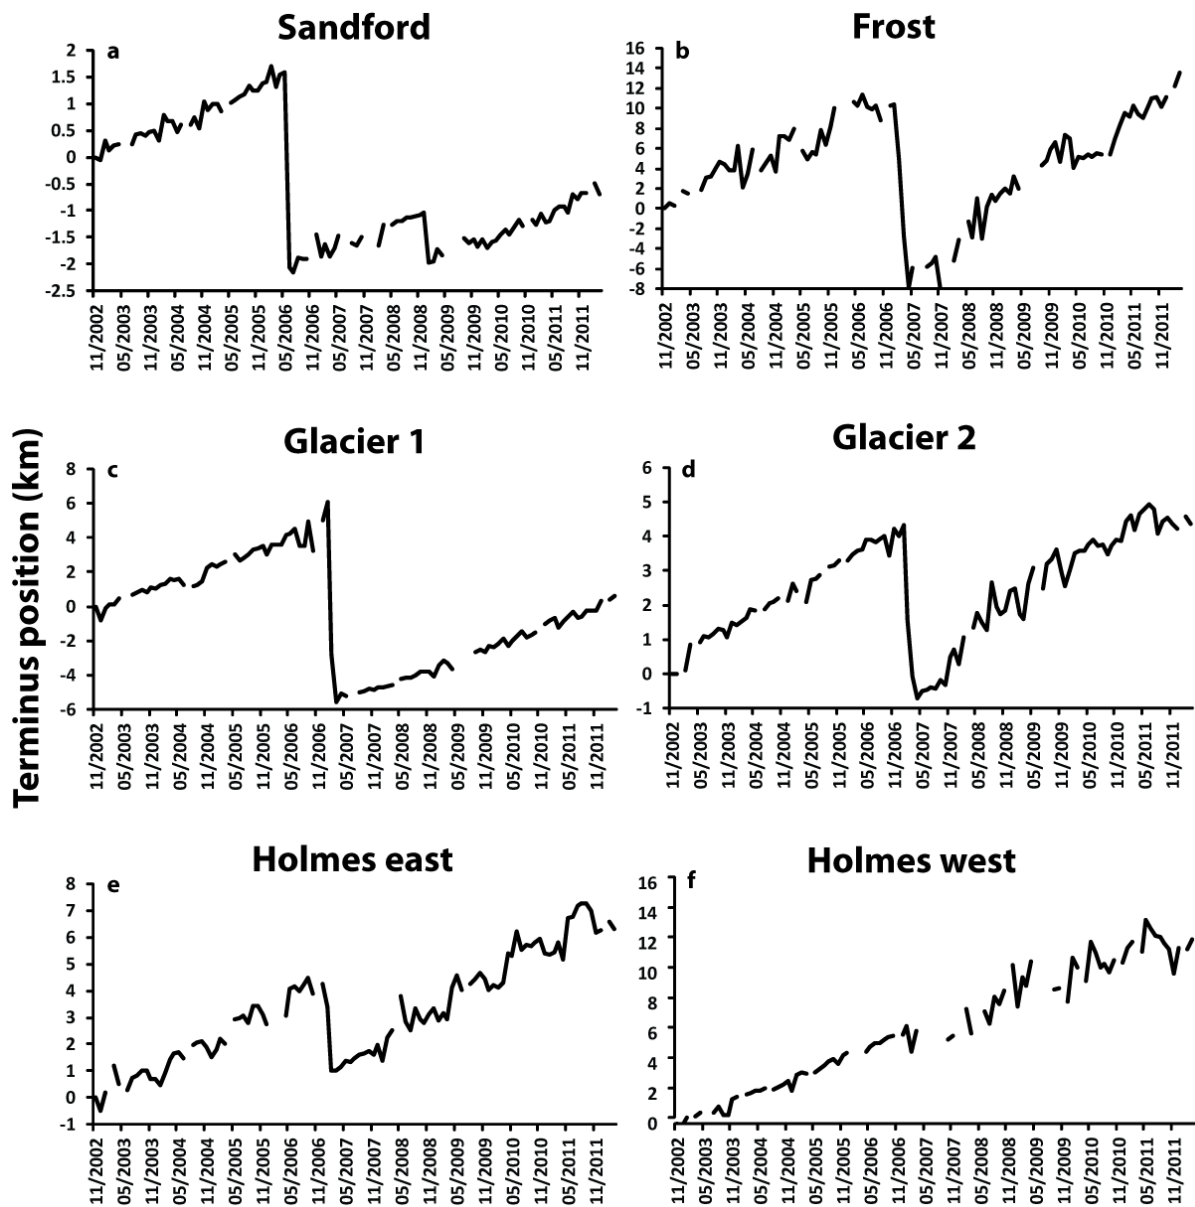

Figure 2: Terminus position change of six glaciers in porpoise Bay between November 2002 and March 2012. Note the major calving event in January 2007 for 5 of the glaciers. Terminus position measurements are subject to +/- 500 m. [Note the different scales on y-axis.](#)

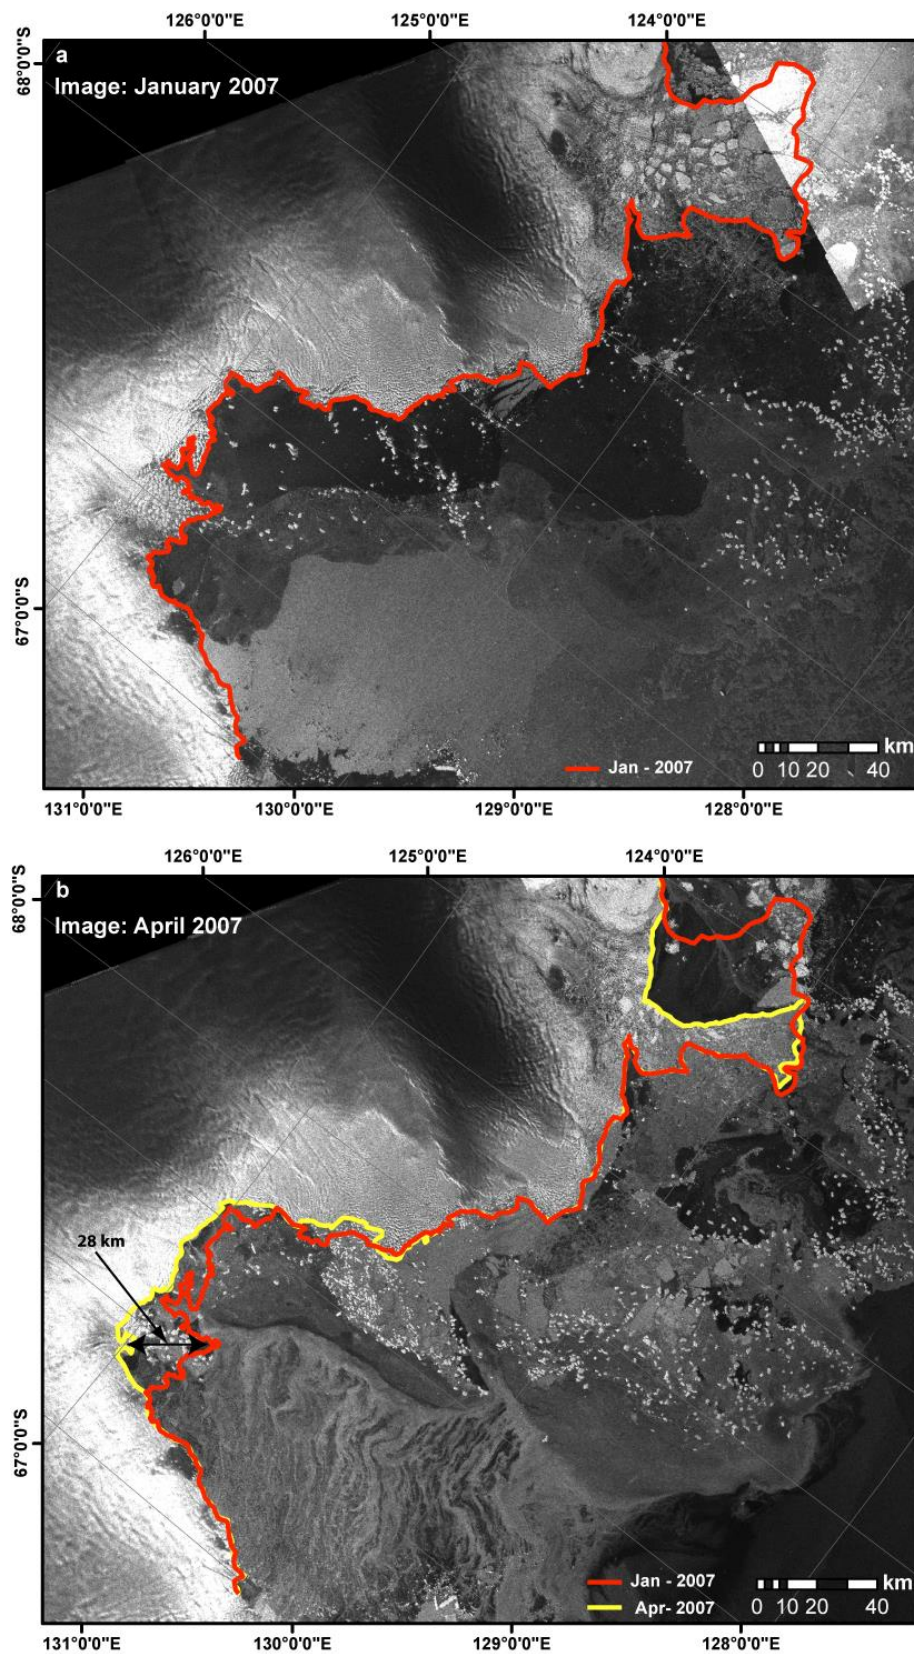

Figure 3: Envisat ASAR WSM imagery in January 2007 **a)** and April 2007 **b)**, which are immediately prior to and after a [near-simultaneous](#) calving event in Porpoise Bay. Red line shows terminus positions in January 2007 and [yellow](#) line shows the positions in April 2007.

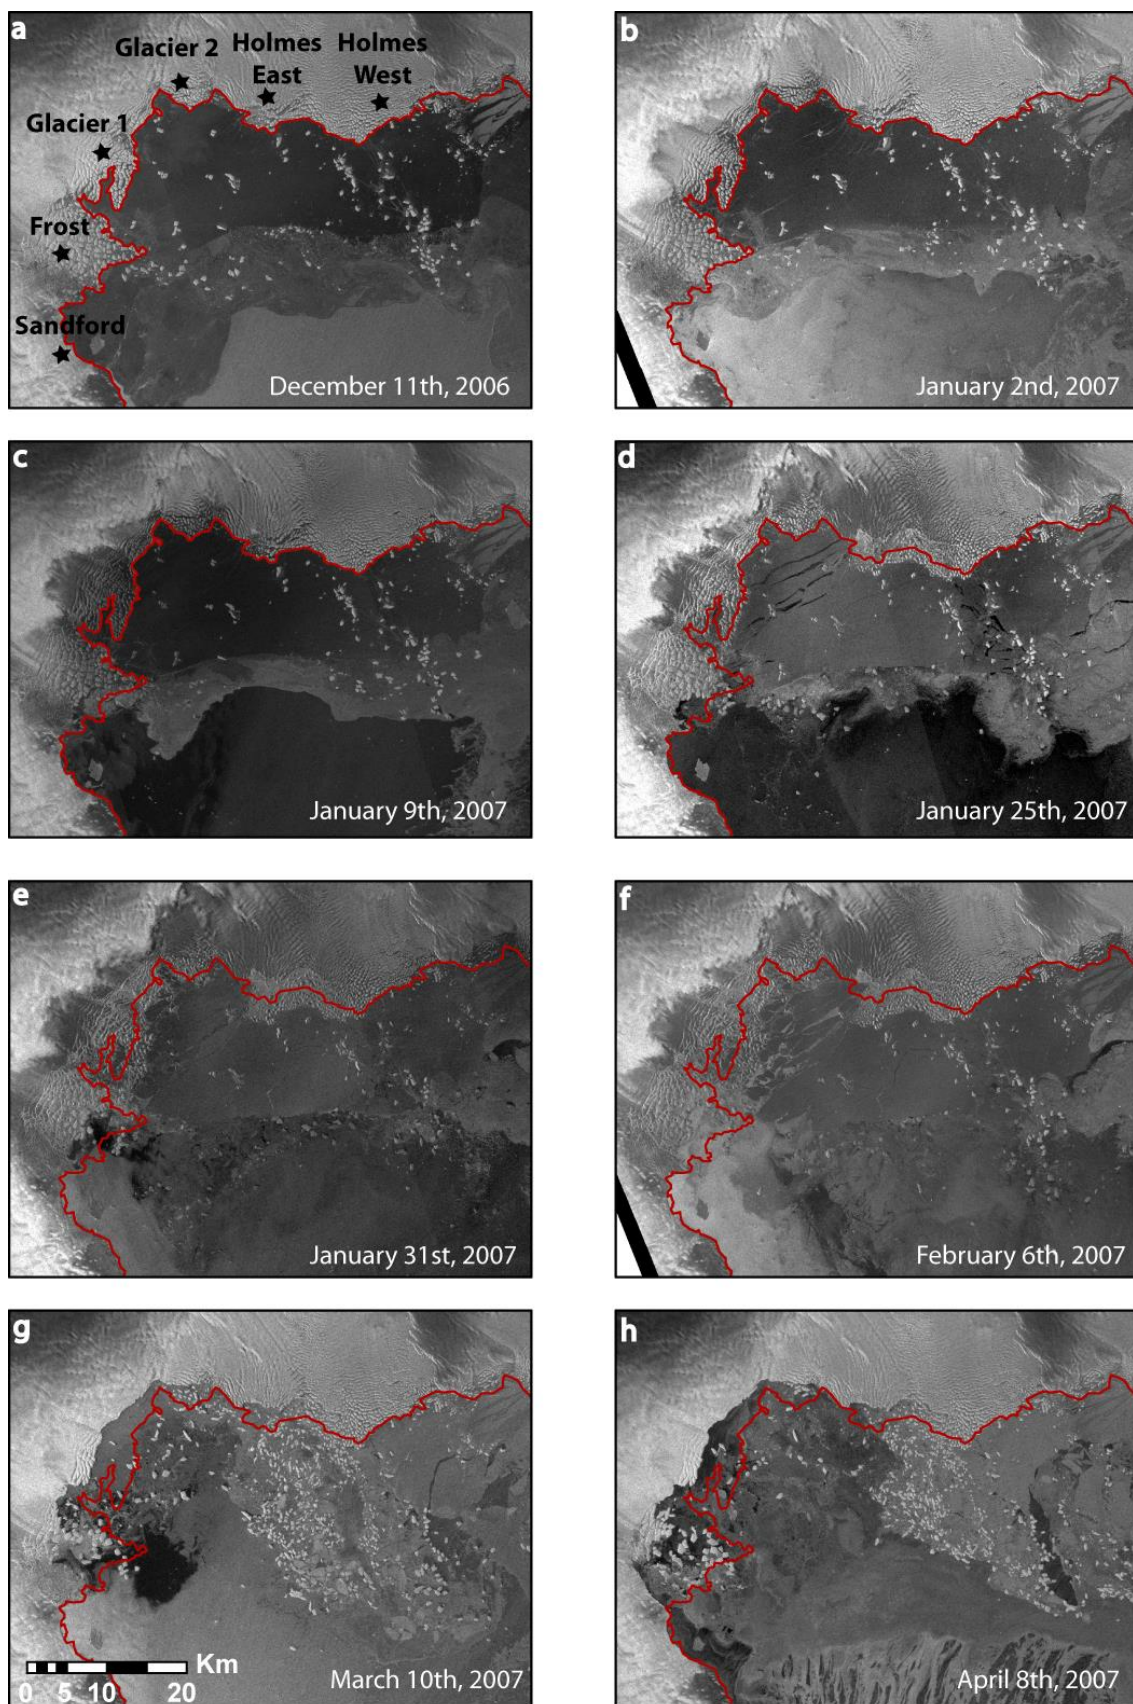

Figure 4: Envisat ASAR WSM imagery showing the evolution of the 2007 calving event. Red line shows the terminus positions from December 11th 2006 on all panels.

Figure 5: MODIS imagery showing the initial stages of disintegration of Holmes (West) Glacier in March 2016. On March 19th a large section of sea-ice breaks away from the terminus (circled), initiating the rapid disintegration process. By the 24th March an 800 km² section of Holmes (west) glacier tongue had disintegrated.

622

623

624

Figure 6: Sentinel-1 imagery showing the evolution of the 2016 calving event. Purple line shows the terminus position from 2nd March on all panels.

Fig 7: Mean monthly sea-ice concentration anomalies from November 2002 to June 2016. The red line indicates sea-ice concentration anomalies in Porpoise Bay and the blue line indicates pack ice concentration anomalies.

Figure 8: Time series of Frost and Sanford Glaciers calving showing that sea-ice clears prior to calving and dispersal of icebergs.

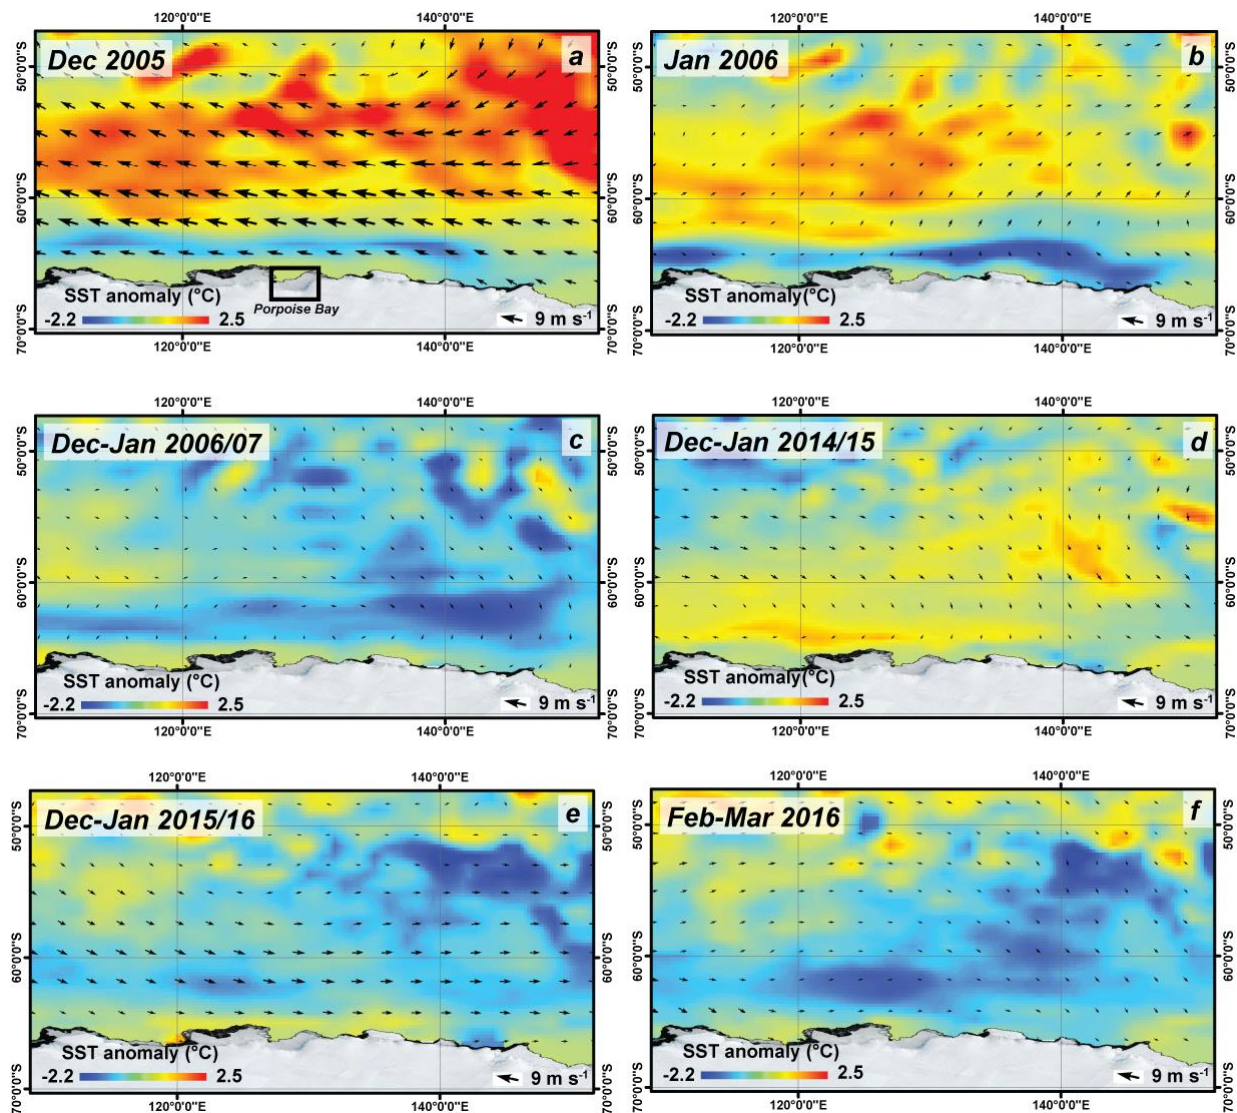

Figure 9: Mean monthly ERA-interim derived wind field and sea surface temperature anomalies in the months preceding the 2007 and 2016 sea-ice break-ups. **a)** December 2005 **b)** January 2006 **c)** Mean December and January 2006/07 **d)** Mean December and January 2014/15 **e)** Mean December and January 2015/16 **f)** Mean February and March 2016.

Figure 10: Mean RACMO2.3 derived December melt 1979-2015 in Porpoise Bay.

Figure 11: ERA-interim derived wind fields for the estimated dates of sea-ice break-up. **a)** January 11th 2007 and **b)** March 19th 2016.

Figure 12: Reconstruction of the calving cycle of Holmes (West) Glacier. All observations are represented by black crosses. The estimated terminus position is then extrapolated linearly between each observation. In periods without observations the date of calving is estimated by negative sea-ice concentration anomalies.

669

670 **Figure 13: a and b)** Modis imagery showing the development of fractures in the landfast
 671 sea-ice between 4th December 2005 and 19th January 2006 ([https://nsidc.org/data/iceshelves](https://nsidc.org/data/iceshelves_images/cgi-bin/modis_iceshelf_archive.pl)
 672 [_images/cgi-bin/modis_iceshelf_archive.pl](https://nsidc.org/data/iceshelves_images/cgi-bin/modis_iceshelf_archive.pl)). c) The landfast sea-ice ruptures along some of
 673 the same fractures which formed in December/January 2005/06, eventually leading to
 674 complete break-up in January 2007. d and e) ASTER imagery showing surface melt features
 675 and the development of smaller fracture between 4th and 31st December 2005. f) High

resolution optical satellite imagery from 16th January 2006 showing sea-ice fracturing and surface melt ponding. This image was obtained from Google Earth.

Figure 14: Daily sea-ice concentrations and RACMO derived melt during January 2007 in Porpoise Bay. Sea-ice concentrations start to decrease after the melt peak on January 11th.
