Abstract

33 Observations at the WAIS Divide site show that near-surface snow is strongly altered by
34 weather-related processes such as strong winds and temperature fluctuations, producing features
35 that are recognizable in the deep ice core. Prominent “glazed” surface crusts develop frequently at
36 the site during summer seasons. Surface, snow pit, and ice core observations made in this study
37 during summer field seasons from 2008-09 to 2012-13, supplemented by Automated Weather
38 Station (AWS) data with short and longwave radiation sensors, revealed that such crusts formed
39 during relatively low-wind, low-humidity, clear-sky periods with intense daytime sunshine. After
40 formation, such glazed surfaces typically developed cracks in a polygonal pattern likely from
41 thermal contraction at night. Cracking was commonest when several clear days occurred in
42 succession, and was generally followed by surface hoar growth; vapor escaping through the
43 cracks during sunny days may have contributed to the high humidity that favored nighttime
44 formation of surface hoar. Temperature and radiation observations show that daytime solar
45 heating often warmed the near-surface snow above the air temperature, contributing to upward
46 mass transfer, favoring crust formation from below, and then surface hoar formation. A simple
47 surface energy calculation supports this observation. Subsequent examination of the WDC06A
48 deep ice core revealed that crusts are preserved through the bubbly ice, and some occur in snow
49 accumulated during winters, although not as commonly as in summertime deposits. Although no
50 one has been on site to observe crust formation during winter, it may be favored by greater
51 wintertime wind-packing from stronger peak winds, high temperatures and steep temperature
52 gradients from rapid midwinter warmings reaching as high as -15°C , and perhaps longer intervals
53 of surface stability. Time-variations in crust occurrence in the core may provide paleoclimatic
54 information, although additional studies are required. Discontinuity and cracking of crusts likely
55 explain why crusts do not produce significant anomalies in other paleoclimatic records.

56 **1: Introduction**

57 Visual and thin-section examination of the WAIS Divide deep ice core from West
58 Antarctica revealed an annual signal linked to bubble and grain characteristics [Fitzpatrick et al.,
59 2014], but also numerous crusts. These crusts are bubble-free or nearly so, typically 1 mm or less
60 and one grain in thickness, and are readily identified visually in bubbly ice (Fig. 1). Their
61 presence in greater abundance than seen in most cores [e.g., Alley, 1988] motivated studies to
62 understand their formation, possible influence on other paleoclimatic data, and potential for
63 recording paleoclimatic conditions themselves.

64 Work by Orsi et al. [2015] and Mitchell et al. [2015] showed that no significant artifacts
65 are introduced to paleoclimatic records by the WAIS Divide crusts. Here, we report additional
66 studies showing that summertime crusts form under specific conditions linked to persistent high-
67 pressure systems, so the time-series of crusts likely contains paleoclimatic information; however,
68 many additional issues must be addressed before useful climate histories could be constructed
69 confidently.

70 Bubble-free layers much thicker than the bubble-free crusts discussed here are sometimes
71 observed in ice cores from warm sites, and provide evidence of refrozen meltwater [e.g., Das and
72 Alley, 2005]. These are of interest as paleoclimatic records but have the potential to anomalously
73 distort records of trapped gases or other components of ice cores. Refrozen meltwater can be
74 identified by an excess of trapped heavy noble gases, so Orsi et al. [2015] analyzed WAIS Divide
75 samples containing bubble-free crusts, finding that not enough meltwater was involved to
76 significantly perturb records of other trace gases. Additionally, crusts might greatly modify gas
77 trapping in the firn, but measured nitrogen-isotopic ratios at WAIS Divide show that gravitational
78 fractionation occurs down to the normal trapping depth where normal amounts of air are trapped,

79 demonstrating that the crusts are not both impermeable and laterally extensive at shallow depth
80 [Mitchell et al., 2015; Battle et al., 2011].

81 Here, we report coordinated observations of crust formation over five summers (2008-09
82 to 2012-13) at the WAIS Divide site, involving daily observations of surface evolution, shallow
83 snow-pit studies with a 2-m pit at least once per year, insolation measurements, and near-surface
84 temperature profiling, supplemented with data from an on-site automated weather station (AWS).
85 We find that crusts form most commonly in the summer (45% greater occurrence), but do also
86 form in winter. In summer, crust formation primarily results from the effects of strong diurnal
87 temperature cycling under clear-sky, low-wind, relatively warm conditions. Wintertime
88 observations are not available, but the physical understanding gained from our summertime data
89 suggests hypotheses for formation. Time-trends in the occurrence of summertime crusts in the
90 core may reveal changes in the frequency of the persistent high-pressure conditions that generate
91 crusts, although additional work will be required to quantify this.

92 **2: Methods**

93 The main methods used are described here. Additional details are provided in Fegyveresi
94 [2015]. The surface was observed continually by one of us (JF) during the five field seasons
95 extending from 2008-09 to 2012-13 (Table 1). During each austral summer, a back-lit snow pit
96 was also prepared and studied (five total pits). All pits were sited within 1 km radius of the
97 primary ice-core drilling facility, but avoided regions disturbed by camp operations or the “drift
98 tail” of enhanced accumulation downwind of the camp. Following prior practice [e.g., Benson,
99 1962; Koerner, 1971; Alley, 1988], each sampling site involved excavating a pair of ~2 m cubic
100 pits separated by a wall ~0.5 m thick, with one pit left open to supply back-light, and the other a
101 roofed observation pit. Features such as crusts and hoar layers were easily identifiable from the

102 observation pit on the back-lit wall (Fig. 2). Pit walls were observed, mapped, sampled, and
103 photographed (tripod-mounted $> \frac{1}{4}$ s exposures). Each pit was oriented so the prevailing wind
104 direction, approximately north-south, ran from right-to-left along the back-lit wall.

105 An automatic weather station (AWS) on site at WAIS Divide (named Kominko-Slade in
106 the University of Wisconsin AWS system; Lazzara et al. [2012]), collected data on temperature,
107 air pressure, wind, and humidity starting in the 2009-10 season (all dates and times are GMT).
108 Beginning in 2011-12, upward-facing and downward-facing shortwave Li-Cor LI200
109 pyranometers were added initially 1 m above the surface to measure incoming and outgoing
110 shortwave radiation (0.4-1.1 μm spectral response). Both sensors were newly calibrated and
111 mounted in a cosine-corrected head (for solar angles up to 80°), with typical operational errors in
112 daylight of $\pm 3\%$ (max $\pm 5\%$). A Kipp-Zonen CNR2 net radiometer with upward- and downward-
113 facing pyranometers and pyrgeometers was added on an AWS mounting arm during the 2012-13
114 season, in order to measure both net short and longwave radiation. This instrumentation replaced
115 the previous Li-Cor instrumentation. The pyranometers operated with a spectral response of 0.3 –
116 2.8 μm , operational errors of $\pm 3.5\%$, and sensitivity of $15.21 \mu\text{V W}^{-1} \text{m}^{-2}$, while the pyrgeometers
117 operated with a spectral response of 4.5–45 μm , operational errors of $\pm 5.6\%$, and a sensitivity of
118 $12.52 \mu\text{V W}^{-1} \text{m}^{-2}$ respectively; typical impedances were ~ 7 ohms. All AWS relative humidity
119 values reported here are expressed in terms of saturation vapor pressure over ice and corrected for
120 low-temperature offsets (see Anderson, 1994).

121 Also during the 2012-13 season, we calibrated and installed five PRD (platinum
122 resistance detector) strings in the upper 5 m of snow in a 2 km survey line extending
123 approximately upwind (grid-west, true-north) starting ~ 50 meters from the on-site AWS. The
124 strings were designed by one of us (AM) following the procedures in Muto et al. [2011]. Each
125 sensor string was 5 m long and consisted of 16 individual PRDs (HEL-700 series; $\pm 0.03^\circ\text{C}$

126 accuracy, $\pm 0.18^{\circ}\text{C}$ total combined error, including data-logger error) with denser sampling in the
127 shallower snow to capture the greater variability there (see also Supplemental Table S2). Sensor
128 calibration took place over a 60-minute period using a constantly-stirred ice-bath method, and
129 then the newly calibrated sensors were deployed incrementally over a 10-day period starting Dec.
130 15th. Deployment boreholes were drilled using a 4 cm diameter hand-auger, and then back-filled
131 once strings were installed. Campbell logging equipment (CR1000 data logger and AM/16/32
132 Multiplexer) and 12V sealed lead-acid batteries were housed in a foam-insulated wooden box
133 beside each borehole and just below the surface. The first string was placed 50 m from the AWS,
134 and the other strings were placed upwind of it by 10, 100, 1000, and 2000 m (Supplemental Table
135 S3). Measurements were taken every minute over the survey interval. Each 12V battery was
136 swapped out weekly with newly charged replacements to ensure that the sensor strings were
137 continually recording. During each site visit, we took photographs, and noted local
138 meteorological and surface conditions. Each sensor string took approximately 24 hours to
139 equilibrate with the surrounding snow following installation due to the backfilling of the open
140 boreholes with surface snow.

141 We studied crusts in the ice core as well as in the near-surface. As described in
142 Fitzpatrick et al. [2014], the entire deep core and various associated shallower cores were
143 inspected visually during core processing lines at the US National Ice Core Laboratory, primarily
144 by one of us (MS), but with some intercomparisons from other observers. The core was observed
145 on a light table in a darkened booth, and key features were noted on meter-length log books. The
146 crusts were easily visible as thin, glassy, bubble-free or nearly bubble-free layers (e.g. Fig. 1).

147 Annual cycles are visible in the bubbly part of the core, arising from the tendency for
148 near-surface processes to generate coarse-grained, low-density layers including depth hoar in
149 summer [Fitzpatrick et al., 2014; Fegyveresi, 2015]. However, annual-layer dating of the ice core
150 using electrical conductivity (ECM, which is primarily controlled by ice chemistry) and soluble-

151 ion chemistry proved more accurate than dating with visible strata [Buizert et al., 2015; Sigl et al.,
152 2016; WAIS Divide Project Members, 2013]. Here, we estimate the season in which each crust
153 occurs by assigning each summertime peak in the WD2014 time scale to January 1 of its year, and
154 then linearly interpolating; accumulation at the site is relatively evenly distributed through the
155 year, justifying this approximation [Banta et al., 2008; Fegyveresi, 2015, Fegyveresi et al., 2016].

156

157 **3: Observations**

158 **3.1: Near-surface observations**

159 We summarize key observations on crust formation here. Additional information, and
160 complete narrative descriptions of particular crust-forming episodes, are provided in Fegyveresi
161 [2015].

162 Glazed crusts were repeatedly observed to form on the snow surface (Figs. 3 and 4),
163 primarily during late-December and January, with an interval between formation events of
164 roughly one and two weeks (see Figs. 5-8). Crust formation often followed a storm or wind event,
165 and occurred during a time of higher atmospheric pressure, light winds, clear sky, strong
166 insolation, large diurnal temperature cycling, and low relative humidity.

167 As shown in Figure 9, the crusts were often internally complex. The upper few
168 millimeters of the surface snow were anomalously high-density ($> 400 \text{ kg m}^{-3}$) and fine-grained,
169 and might be termed a multi-grain crust. Within this, and especially at the top, were one or more
170 lower-porosity single-grain crusts. To an observer, light reflected off these crusts gave the
171 appearance of a glaze on the snow surface. (e.g. Fig. 4), [see also Orsi et al., 2015, their Fig. 5].

172 Typically, a glazed crust started as isolated sub-meter to few-meter patches on unshaded
173 regions of the snow surface or sastrugi, which were most consistently exposed to sunlight, and
174 spaced tens of meters to more than 100 m apart. The spatial size and extent of glazed crust
175 patches varied considerably and were not measured directly; however, no single observed crust

176 patch was greater than 100 m in length in any dimension. Over the first days of formation, glazed
177 crusts expanded to form a laterally extensive interconnected surface broken by isolated sub-meter
178 to few-meter unglazed patches on shaded faces of sastrugi. Glazed crusts were most continuous
179 where the surface was smoothest. Reconnaissance surveys extending a few kilometers from camp
180 showed that glazed-crust formation was consistent at least that far.

181 Within 2-3 days of formation, glazed features developed prominent polygonal cracks
182 with few-meter spacing (e.g. Fig. 4). It is likely that these cracks formed by thermal contraction
183 during nighttime cooling, which was driven by the large diurnal temperature swings observed at
184 the time (see below). We excavated some cracks, which could be traced downward from the
185 surface typically ~20-30 cm.

186 A pronounced hoar began forming within 24 hours of the onset of cracking of the glazed
187 crust in each case observed (e.g. Fig. 3). Measured relative humidity was notably higher during
188 hoar formation (see Figs. 5-8) than before, and sometimes (e.g., January 7th, 2010) a fog
189 developed early in the time of hoar formation, providing a source of vapor to the surface hoar
190 from above. Surface glazing was not required for formation of such hoar layers, as one formed
191 quickly on December 30th, 2009 during a very warm ($> -10^{\circ}$) fog episode with elevated measured
192 relative humidity, but without prior formation of surface glaze.

193 Hoar layers that we observed during the field seasons were subsequently either buried,
194 destroyed by wind, or gradually sublimated away over 2-3 additional days. We observed strong
195 winds remove hoar layers, with a threshold of $\sim 7 \text{ m s}^{-1}$ (~ 13 knots). In one case, hoar removal
196 required somewhat lower speed when wind was directed orthogonal to the prevailing direction
197 and thus sastrugi orientation, similar to observations by Champollion et al. [2013] at Dome C,
198 East Antarctica.

199 No above-freezing temperatures were observed by the AWS, but on January 2, 2011, the
200 temperature reached a high of -2.8°C (see Fig. 6; Supplemental Fig. S1). While no direct surface

201 melt was observed, some melt was noted along exposed, vertically cut wall faces near the ice-
202 core drilling facility (Supplemental Fig. S2). A prominent multi-grain crust was observed the next
203 year in snow pits, likely dates from that time, and shows features that are consistent with some
204 melting-refreezing having occurred (Supplemental Fig. S3).

205 The PRD strings document strong variations in subsurface temperature, following the air
206 temperatures as expected. During the cooling phases of diurnal cycles, air temperatures (AWS)
207 and near-surface snow temperatures (S0) dropped well below temperatures deeper in the snow
208 including the shallowest in-snow sensor (S1) at ~20 cm (Figs. 10 and 11), with the surface as
209 much as 3°C colder than snow at 40 cm (S2) depth (e.g. Supplemental Fig. S4). This would have
210 driven upward mass flux from the deeper snow towards the surface. Such conditions often
211 developed when surface hoar was forming from fog, and thus likely with a downward as well as
212 an upward vapor source to the near-surface layer.

213

214 **3.2: Snow-pit observations**

215 Each of the five snow pits showed a clear annual cycle in the visual stratigraphy, but with
216 notable “noise”. Depth hoars occurred primarily in summertime layers and into autumn, but with
217 occasional hoar layers in winter and spring layers. Crusts were also most common in summertime
218 and into autumn, but not restricted to those times. Similar to the observations made by Alley
219 [1988] at other sites in Antarctica, sequences of strata at WAIS Divide typically showed lateral
220 continuity over 2 m scales, although with some variation. Many graded beds were also present,
221 likely indicative of changes during a specific storm event or primarily before the next storm. This
222 was later confirmed on-site with accumulation stakes and measurements following specific large
223 storm events [see also Koffman et al., 2014; Criscitiello et al., 2014].

224 The snow pits from the 2008-09, 2009-10, and 2010-11 seasons at WAIS Divide were
225 mapped here in greatest detail, and meter-wide sub-swaths of their complete pit-wall maps are

226 shown in Figure 12. Complex stratigraphy and variations are clearly discernable, and illustrate the
227 variability within 1 km of each other at WAIS Divide in contiguous years. This is likely
228 indicative of the influence of complex processes of deposition and metamorphism, with frequent
229 occurrences of depositional and erosional features (sastrugi, whalebacks, wind scoops, hollows,
230 etc.). We chose annual layers in the pit maps based upon visual inspection in the field, subsequent
231 examination of photographs of the pits, and overall trends in measured densities (see e.g. Fig. 13).

232 We measured pit bulk densities using 100 cm³ stainless-steel, box-type cutters [e.g.,
233 Conger and McClung, 2009] and a digital scale accurate to 1 gram. Density samples were taken
234 in all five concurrent seasons' pits in duplicate, at ~5 cm intervals, from the pit side-wall (so as
235 not to disturb the back-lit wall). These duplicates were then averaged together for final values.
236 Samples measured in the 2008-09 pit were taken with regards to marked strata, and therefore at a
237 slightly higher frequency. Density measurements from pits of all five seasons yielded an average
238 density of $386.6 \pm 3.2 \text{ kg m}^{-3}$ for the upper 2 meters of snow (Fig. 14), all with a nearly identical
239 linear trend-line slope of $\sim 0.4 \text{ kg m}^{-3} \text{ cm}^{-1}$ with depth.

240 Seasonal interpretations of all five pits indicated an average of ~ 3.75 years of
241 accumulation recorded over the 2 meter depths, which yields an average of $\sim 0.53 \text{ m a}^{-1}$ of
242 accumulation at the average pit snow-density. Converted to water-equivalent, this becomes ~ 0.20
243 $\text{m a}^{-1}_{\text{w.e.}}$ (or $\sim 0.22 \text{ m a}^{-1}_{\text{ice}}$). These values agree closely with recently published values [WAIS
244 Divide Project Members, 2013; Banta et al., 2008; Burgener et al., 2013].

245 We documented obvious crusts and hoar layers for each snow pit. Most commonly, crusts
246 occurred just above depth hoars, but crusts were observed without hoar, and hoar without crust.
247 Both single-grain-thick ($\sim 1 \text{ mm}$) and multi-grain ($\geq 4 \text{ mm}$) crusts were observed, with the
248 common association of single-grain crusts in and usually at the top of multi-grain crusts as noted
249 above. All crusts had densities estimated over 400 kg m^{-3} . Counting a multi-grain crust containing

250 a single-grain crust as one feature, the five 2-meter snow pits revealed an average of $\sim 18.8 \pm 2.5$
251 ($\pm 1\sigma$) total crusts, or approximately 5 crusts per year.

252 **3.3: Ice-core data**

253 In the bubbly ice included in our crust logging (120-577 m depth) in the WAIS Divide
254 core, 10,268 crusts were identified (Fig. 15). A few were discontinuous across the core, or
255 displayed at least a few pores extending through; others appeared largely or completely
256 continuous and impermeable at the scale of the core. Experience with independent observers
257 showed little or no error in crust identification. We cannot rule out the possibility that bubble
258 migration contributed to loss of some crusts in the deepest bubbly ice considered, but the crusts
259 continued to be clear and readily identifiable, so we do not believe that the trend to fewer crusts
260 in the deepest ice is an artifact. We cannot fully exclude the possibility that there is an
261 observational bias related to the drop in crust prevalence over the most recent ~ 250 years, as the
262 crusts are more difficult to discern in the shallow firn and snow.

263 The seasonal distribution of the crusts is shown in Figure 16. Crusts occur year-round,
264 but are $\sim 45\%$ more frequent in summertime accumulation than in wintertime. Certainly, the
265 natural variability in seasonal distribution of snow accumulation and in the timing of peak
266 impurity input mean that details of the shape of the seasonal distribution of crust occurrence are
267 notably uncertain. However, given the high reliability of the annual-layer dating, and the multiple
268 indicators that agree well [Buizert et al., 2015; Sigl et al., 2016; WAIS Divide Project Members,
269 2013], “summer” versus “winter” or “nonsummer” is well-constrained.

270 Time-trends of seasonal crust occurrence are also shown in Supplemental Figure S5,
271 separating the largely sunless winter (May-August) from the sunny spring-summer-fall

272 (September-April, with at least 8 hours of sunlight per day). Both first increase and then decrease
273 slightly over the 2400-year record, but with a larger relative change in the sunlight season.

274

275

276 **4: Synopsis and Discussion**

277 Our observations confirm and extend prior work on this topic [see e.g. Anderson and
278 Benson, 1963]. Depositional processes and metamorphism primarily in the upper few centimeters
279 of near-surface snow, produce prominent layering. Wintertime accumulation, while notably
280 variable, is more homogeneous than summertime deposits, with wind-packed layers prominent in
281 winter, and more-variable layers including crusts and hoar more common in summer [e.g., Sorge,
282 1935; Benson, 1962, Gow, 1965; 1969; Weller, 1969; Colbeck, 1982; Colbeck, 1983; Alley,
283 1988; Alley et al., 1997]. These features are altered during subsequent burial and conversion to
284 bubbly ice, but still produce recognizable features in the ice core that allow identification of
285 annual layers and crusts [e.g., Alley et al., 1997; Fitzpatrick et al., 2014].

286 Our observations at WAIS Divide show repeating events that generate the main features
287 of the summertime accumulation. In a typical event, a storm with strong winds brings snow
288 accumulation, followed by a high-pressure system bringing clear skies, greatly reduced winds,
289 initially low humidity, and strong diurnal variations in sunshine, air temperature, and net surface
290 energy-balance.

291 Early in this clear-sky interval, the wind-packed upper surface develops a millimeter-
292 thick glazed crust or possibly crusts in a few-millimeters-thick multi-grain crust. Strengthening of
293 crusts over one to a few days is followed by polygonal cracking from contraction caused by
294 nighttime cooling. Vapor released through the cracks contributes to rising relative humidity, and
295 surface-hoar deposition in subsequent nights. At WAIS Divide, evolution of the crust-hoar
296 complex typically is truncated by arrival of another storm, which may remove or bury the hoar,

297 and typically buries the crusts below the level of fastest metamorphism, allowing them to be
298 preserved.

299 Not every aspect of a typical event is observed in each case. Crusts form and can be
300 buried by additional snowfall without growth of a surface hoar on top of them. Crusts are
301 somewhat discontinuous, and surface hoar can grow where a crust is absent. And, perhaps most
302 importantly here, a crust that remains near the surface (in the upper few centimeters) for too long
303 may slowly lose mass and cease to be a crust.

304 Our data provide strong constraints on models of many of the observed processes.
305 Surface hoar grew especially at night when relative humidity was high, sometimes with fog, and
306 with deposition occurring on tent ropes or other surfaces as well as on the snow surface (e.g.
307 Supplemental Fig. S6), clearly demonstrating a source of vapor from above. Surface hoar
308 typically formed however, when the upper snow surface was colder than layers beneath,
309 indicating a vapor source from below. Hence, our surface hoars included elements of both
310 depositional and sublimation hoar crystals as defined by Gallet et al. [2014] based on
311 observations at Dome C, East Antarctica (with sublimation growth being the dominant process).

312 The high density of both single-grain and multi-grain crusts, approaching the density of
313 ice for the glassy single-grained crusts, requires that the density of the crusts was increased over
314 time, as wind packing has not been observed to approach these high densities. Crusts form during
315 days when atmospheric humidity is low, however, and thus when mass is not being added from
316 above. We have not observed bulk melting at the site (with the one possible exception noted
317 above), nor do the gas measurements of Orsi et al. [2015] indicate bulk melting, so the density
318 increase must arise from some combination of vapor diffusion from below and surface or volume
319 mass transfer likely involving pseudo-liquid layers [Dash et al., 2006], as discussed next.

320 The data here show that frequently the upper surface is colder than snow beneath, which
321 will lead to upward mass flux. We lack subcentimetric resolution in thermometry, but physical

322 understanding indicates that very strong gradients likely develop on the centimeter scale just
323 below the upper surface during rapid nighttime cooling. Physical understanding, the data here,
324 and data from previously published studies indicate that intense sunshine generates a temperature
325 maximum in the snow just below the surface (order of 1 cm) especially in low-density, low-
326 thermal-conductivity depth hoar [e.g., Alley et al., 1990; Brandt and Warren, 1993], also
327 contributing to upward vapor transport. Hence, the upper surface is expected to gain mass from
328 below during the crust- and hoar-forming events [Alley et al., 1990]. Windy conditions would
329 drive undersaturated air into and out of pore spaces, removing mass, but crusts form during
330 relatively still times. The temperature gradients (and noted inversions) measured here at WAIS
331 Divide (see also Figs. 10 and 11, and Supplemental Fig. S4) are similar to those observed at
332 GISP2 by Alley et al. [1990] and more than sufficient to move the necessary vapor for crust
333 development.

334 We hypothesize here that these surface conditions cause mass fluxes that fill in open
335 pores in wind-packed layers at the surface to form glazed crusts. A physical model might be
336 based on the following considerations. The thermal conductivity of ice greatly exceeds that of air,
337 so heat transport in near-surface snow is primarily conductive. Ordinarily, the grain curvature
338 adjacent to pores tends to cause diffusive mass loss, enlarging pores by filling necks between
339 grains or other regions of lower vapor pressure. However, because heat flow is primarily through
340 the grain structure, pores in a surface crust will tend to be colder than interconnected grains when
341 the upper surface is colder than the snow beneath, favoring mass transport to the pore surfaces, as
342 shown in Figure 17 [e.g., Sommerfeld, 1983; Fukuzawa and Akitaya, 1993]. Transport may occur
343 by vapor, surface, or volume diffusion; following Alley and Fitzpatrick [1999], vapor diffusion
344 and surface transport in premelted films are likely to dominate. Also, mass loss from relatively
345 warm grain bonds just beneath a growing surface crust by diffusion to the colder crust will tend to

346 lower the crust, increasing the likelihood that a pore in the crust will move downward to intersect
347 a pre-existing grain beneath, increasing the crust density.

348 Due to the inherent limitations with the available sensor equipment, and with the sparsity
349 of usable data for our specific periods of interest, a complete and detailed analysis of radiative
350 forcings was not completed here. However, to further test our hypothesis and to assess the
351 accuracy of our measurements, we did execute a simple surface energy budget (SEB) calculation
352 in order to solve for the ground heat flux term Q_G , and ultimately determine if the AWS sensor
353 data yield flux rates capable of the hypothesized vertical vapor transport in the near-surface snow.
354 Because data from the AWS-mounted net radiometer and thermistor strings were only available
355 for the 2012-13 field season, only that specific time window was used for this simple SEB
356 calculation (see also Figs. 8 and 10).

357 The surface energy budget represents a balance of turbulent, radiative, and ground heat
358 fluxes, which are all coupled through various processes [see e.g. Hulth et al, 2010; Miller et al.,
359 2017]. Because there is no known or observed melting at the WAIS Divide site, and therefore no
360 phase changes in the near-surface snow, a change in any of the SEB terms is thus balanced by
361 changes in other terms. For simplicity, we represent this relationship here as:

$$362 \quad Q_N + Q_S + Q_L + Q_G = 0 \quad (1)$$

$$363 \quad Q_N = S_{NET} + L_{NET} = S\downarrow + S\uparrow + L\downarrow + L\uparrow \quad (2)$$

364 where Q_N is the total net radiation (S_{NET} and L_{NET} are the net short and longwave radiation terms),
365 Q_S and Q_L are the sensible and latent turbulent heat fluxes respectively, and Q_G is the ground heat
366 flux. The net radiation term Q_N was determined by combining the short and longwave radiation
367 data obtained directly from the radiometer (see Fig. 8). Due to limitations with the Kipp-Zonen
368 CNR2 sensor, only the radiative NET terms were available, and not the individual incoming (\downarrow)
369 and outgoing (\uparrow) terms.

370 Based upon the Monin-Obukhov similarity theory, the sensible and latent heat flux terms
371 can be expressed as:

$$372 \quad Q_S = \rho c_p u_* T_* \text{ and } Q_L = \rho L_S u_* q_* \quad (3)$$

373 where ρ denotes air density, c_p is the specific heat of dry air at constant pressure ($1005 \text{ J K}^{-1} \text{ kg}^{-1}$),
374 and $L_S = 2.83 \cdot 10^6 \text{ J kg}^{-1}$ is the latent heat of sublimation. We use bulk method approximations for
375 the turbulent scales of wind speed (u_*), temperature (T_*), and humidity (q_*), and their related
376 stability correction functions [Van As et al., 2005; Andreas, 2002; Fairall et al., 1996; Holtslag
377 and DeBruin, 1988]. We also employed an optimal velocity roughness length ($\sim 0.03 \text{ mm}$) and
378 calculated the related roughness terms using published equations [Miller et al., 2017; Van As et
379 al., 2005; Andreas, 1987]. As previously noted, relative humidity values reported here are
380 expressed in terms of saturation vapor pressure over ice and corrected for low-temperature offsets
381 [see Anderson, 1994]. Specific humidity is calculated from relative humidity using published
382 equations [Van As et al., 2005].

383 Results of this SEB calculation are shown in Supplemental Fig. 7, and values for ground
384 heat flux were determined by solving equation (1) for Q_G . Over the $\sim 24 \text{ hr}$, low-wind period
385 shown highlighted in Figure 8 that features a surface glaze (labeled 'b'), the net ground heat flux
386 Q_G does corroborate a condition favorable for upward (negative) energy flux, particularly during
387 the morning hours of the 24-DEC-2012.

388 We calculated thermal conductivity of the uppermost snow layers as $K = 0.35 \pm 0.05$
389 $\text{Wm}^{-1} \text{K}^{-1}$, from our measured snow pit density data (see Fig. 14), combined with published
390 relations between density and K [Miller et al., 2017; Jordan, 1991]. Then, we used K , Q_G , and the
391 equation for conductive heat flux,

$$392 \quad Q_G = -K \frac{\Delta T}{\Delta z} \quad (4)$$

393 to calculate vertical temperature difference (ΔT), over the top 20 cm (ΔZ) [Van As et al., 2005].

394 Our results yield an average vertical temperature difference of $\sim 3.6 \pm 0.7$ °C over the ~ 24
395 hr, low-wind, glaze period highlighted in Figure 8, or a gradient of ~ 18 °C m^{-1} . This result is
396 consistent with the thermistor string data (see Figs. 10 and 11), which indicate a temperature
397 difference between the near-surface air sensor (AWS), and the shallowest in-snow sensor (S1, 20
398 cm depth) of ~ 3.0 °C during the peak of the inversion and glazing episode on 24-DEC-2012; the
399 near-surface air sensor was ~ 1 m above the surface, and we infer that, as a result, it somewhat
400 underestimated peak ΔT .

401 Our energy-balance calculation, although simple, retains the key physics and follows
402 earlier work. We thus trust the basic result, with agreement between model and measured
403 temperatures, that the energy balance generates sufficient heat fluxes to drive the vapor mass
404 transport needed for glazed-crust development [Pinzer et al., 2012]. We are confident that a more-
405 comprehensive study extending this work would be instructive, with additional sampling and
406 modeling addressing the overall radiative and SEB responses, boundary-layer stability responses,
407 cloud forcings, and vapor mass flux rates.

408 Although summertime crusts dominate in the ice core, many wintertime crusts were
409 identified, raising additional questions. We lack direct observations in winter, and so can only
410 speculate on mechanisms active then. However, the basic picture drawn above for summertime
411 crusts may also apply in winter. The lower temperatures, and lack of intense solar heating, make
412 crust formation less likely. However, stronger wintertime winds would allow greater wind-
413 packing of the upper surface, producing fewer and smaller pores to be filled to make a thin crust,
414 and thus making crust formation easier. Although accumulation is more-or-less evenly distributed
415 through the year, long periods of limited variability observed in AWS data suggest that there may
416 be extended intervals up to weeks in length during the winter when the surface is relatively stable,
417 partially or completely offsetting the slower mass transport from colder temperatures.
418 Furthermore, the AWS data show that mid-winter temperatures have risen as high as -15 °C

419 during strong warming events accompanied by high winds ($> 10 \text{ m s}^{-1}$), and likely linked to
420 transport of air masses from the coast. Such warm air masses paired with these high winds would
421 produce relatively high vapor pressures, contribute to greater surface packing, and promote
422 temperature inversions and upward near-surface vapor flux during the subsequent cooling.

423 The great abundance of crusts at WAIS Divide compared to other ice cores we have
424 studied may be because conditions are “just right” at WAIS Divide. We have observed loss of a
425 wind-packed crust at WAIS Divide, and also at GISP2 in central Greenland; the strong mass loss
426 from the upper $\sim 1 \text{ cm}$ of the snowpack is not conducive to long-term survival of any crust there
427 [e.g., Alley et al., 1990]. Low but nonzero summertime accumulation thus may lead to loss of
428 crusts, whereas higher accumulation after formation buries them below that zone of mass loss and
429 so allows their preservation. The large wintertime variability and high wintertime temperatures at
430 WAIS Divide may be important in generating sufficiently high mass fluxes to produce wintertime
431 crusts.

432 At least in summertime, crusts do seem to record a particular meteorological pattern of
433 storms alternating with still conditions. The time-series of frequency of occurrence of crusts thus
434 would be affected by a change in the frequency of occurrence of these conditions. Turning this
435 into a paleoclimatic indicator would require additional steps, however, as the frequency of
436 preserved crusts could decrease because fewer were formed or because more were destroyed,
437 with different causes. Information on changing frequency of meteorological events might be
438 useful [e.g., Hammer, 1985; Alley, 1988]. We believe that the clear association of crust formation
439 with particular events, and the clear trends in crust occurrence in the core, motivate additional
440 research on topics including crust formation in non-summer seasons, but we do not know whether
441 this ultimately could yield a valuable paleoclimatic indicator.

442 **5: Conclusions**

443 Summertime observations at the WAIS Divide site show that prominent visible strata
444 form at or very near the surface during summer, by processes that typically are repeated a few
445 times during each summer. A storm produces a wind-packed layer. The following high-pressure
446 system brings light winds, warm days and cool nights, strong sunshine, and low relative
447 humidity. High-density, single-grain-thick glazed crusts preferentially form at the surface during
448 these high-pressure intervals, in as little as a single day, and then strengthen and evolve. Crusts
449 are extensive, although typically broken by sub-meter or few-meter uncrusted regions spaced tens
450 of meters to more than 100 m apart. Daytime solar heating drives upward mass transport to crusts
451 from developing depth hoar beneath, strengthening the crusts. A simple surface energy budget
452 (SEB) calculation shows that sufficient vertical heat fluxes exist to explain both the observed
453 near-surface temperature inversions, and the vapor mass-flux necessary for the associated glazed-
454 crust formation. After formation, crusts are broken by polygonal cracks extending typically 20-30
455 cm deep, likely from contraction during nighttime cooling. Relative humidity then rises in the air
456 above, contributing to growth of surface hoar during nighttime cooling. Subsequent storms
457 typically bury the crust-hoar complexes, although crusts can be lost during evolving surface
458 conditions if not buried below the top one to a few centimeters.

459 Study of the WAIS Divide deep core shows that crusts are preserved through the bubbly
460 ice. Crusts are most common in layers deposited during summertime, but also occur in winter
461 accumulation. Study of AWS data suggests that the intrusion of warm coastal air during winter
462 may generate strong temperature gradients, which may contribute to wintertime crust formation
463 in wind-packed layers.

464 The frequency of occurrence of crusts in the core varies with time, suggesting the
465 possibility that crusts could be used as a paleoclimatic indicator. However, additional work would

466 be required, including addressing whether crust frequency varies because of changes in formation
467 or changes in destruction of crusts previously formed. The crusts do not produce significant
468 anomalies in other ice-core paleoclimatic records, likely at least in part because they are
469 discontinuous and broken by contraction cracks.

470 **6: Data Availability:**

471 Data policy: All data presented here are available via download from NSIDC
472 (<http://nsidc.org>) or from the WAIS Divide data portal (<http://waisdivide.unh.edu>).
473

474 **7: Author Contribution:**

475 A.J. Orsi assisted with field observations and experiments. A. Muto designed the near-
476 surface PRD sensor strings and developed the associated logging code. M. Spencer documented
477 all ice-core crust observations during the WAIS Divide core processing at the National Ice Core
478 Laboratory. J.M. Fegyveresi and R.B. Alley prepared the manuscript with contributions from all
479 co-authors.

480

481 **8: Acknowledgements:**

482 We acknowledge the following funding sources for support of this work: U.S. National
483 Science Foundation Division of Polar Programs grants 0539578, 1043528, 1142085, 1619793.
484 We also acknowledge Donald E. Voigt, Joan J. Fitzpatrick, Eric D. Cravens, and the staff of the
485 U.S. National Ice Core Laboratory in Denver, Colorado, as well as the WAIS Divide Science
486 Coordination Office at the University of New Hampshire, and the Ice Drilling Design and
487 Operations group at the University of Wisconsin. We thank numerous colleagues involved with
488 the WAIS Divide project, especially Kendrick Taylor, Mark Twickler, and Joseph Souney. We
489 thank Bess Koffman, Gifford Wong, Dominic Winski, Aron Buffen, and Logan Mitchell for
490 assistance with snow pit preparation. We thank Jonathan Thom and the University of Wisconsin-
491 Madison Automatic Weather Station Program for assistance with weather station sensor
492 installation. Lastly, we thank our reviewers, whose thoughtful suggestions and questions served
493 to clarify and improve this manuscript. Any use of trade, firm, or product names is for descriptive
494 purposes only and does not imply endorsement.

Figure 1: A thick-section image of a sample prepared from a depth of ~77.260 meters showing two preserved crusts. Both layers are ~1 mm thick and appear mostly bubble-free. All bubbles here appear white, with the surrounding ice black. The general elongated shape of the bubbles is due the proximity of this sample to the bubble close-off depth at WAIS Divide of ~75 meters). This sample is from the secondary WDC05A core at the WAIS Divide site. Image modified from Orsi et al. [2015].

Figure 9: A surface snow sample excavated from a glazed area at WAIS Divide before the onset of polygonal cracking, showing a couplet of an evolved high-density ($> 400 \text{ kg m}^{-3}$), $\sim 3 \text{ mm}$ multi-grain surface crust containing single-grain crusts, and overlying a lower-density ($< 300 \text{ kg m}^{-3}$) hoar layer.

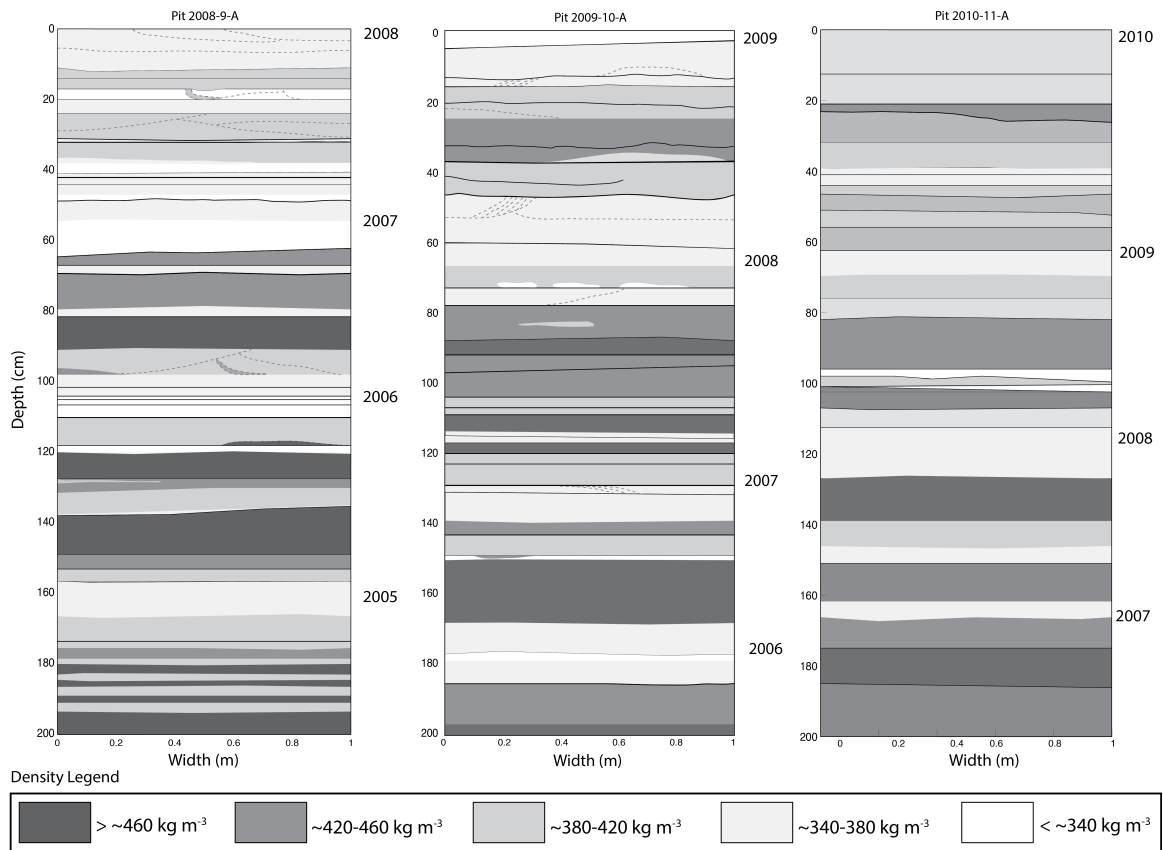

693
694

695 **Figure 10:** Temperature measurements (1 min interval) in snow from the 2012-13 season, from
 696 the upper-most three PRDs (surface down to 40 cm). Data are from the four sensor stations
 697 closest to the station. The shaded area corresponds to an episode of glaze and hoar growth (see
 698 Fig. 8). Distinct near-surface temperature inversions occurred each night during this 3-day period
 699 (see Fig. 11). Sensor #4 was not installed until Dec 22nd, and therefore did not equilibrate until
 700 early on the 23rd as indicated. Air temperature is also shown as recorded by the AWS (errors
 701 listed in Supplemental Table S1). The AWS temperature sensor is located ~1 meter above the
 702 snow surface. All dates and times are GMT (-12 WAIS local time).

Figure 12: Complete wall maps of back-lit snow pits prepared during 2008-09, 2009-10, and 2010-11 WAIS Divide field seasons. Layering and density contrast are noted by degree of shading. Fine- to medium- grained, higher-density snow layers are shown with darker grey coloring, whereas coarse-grained and low-density layers (e.g., depth hoar) are shown in white. Crusts are indicated with solid lines, while dotted lines are used to represent cross-bedding at depth. Years were identified based on approximate depths of peak summers and the average measured densities. The pit wall surfaces trend in parallel with the prevailing wind direction at WAIS Divide (approximately north-south, with north to the right).

 725
 726
 727

Figure 13: A detailed view of data for snow pit 2008-09-A, including wall map, density profile, annual layer picks, and crusts occurrences. Density, layering, and feature preservation are again noted as in Fig. 12. Individual crusts are identified with a labeled “c” along the vertical axis. Seasonal accumulation layers “picked” visually in the pit (shown with red and blue arrows).. These observations indicate a somewhat regular pattern of equally-distributed yearly accumulation at WAIS Divide with clear annual signals.

728
729

730 **Figure 14:** Density profiles measured in snow pits from five concurrent seasons at WAIS Divide
 731 (2008-2012). Each pit showed a high degree of sample-to-sample variability as measured
 732 densities were widely-spaced within the upper 2 meters of snow; estimated annual signals were
 733 still identifiable, however. Measurements yielded an overall average density of $386.6 \pm 3.2 \text{ kg m}^{-3}$
 734 for the upper 2 meters of snow across all 5 pits, with nearly identical linear trend-line slopes of
 735 $\sim 0.4 \text{ kg m}^{-3} \text{ cm}^{-1}$ with depth.

736

737
738

739 **Figure 15:** History of crust occurrence (crusts year^{-1}) in the bubbly-ice zone of the WDC06A
740 core that we studied in detail (~120 – 577 m depth); ages (C.E.) are from the WD2014 depth-age
741 scale). 10,268 unique crusts were documented in the core, for an average rate of 4.3 ± 2 per year
742 (dashed blue line). Data are shown as 20-yr moving averages for ease of view, with an added 1st-
743 order LOESS smoothing trend-curve (200-yr bin-width). The sharp decline in crust prevalence
744 after ~1750 C.E. may be due to observational biasing in the shallow firn and snow.

745

746

747 **Figure 16:** Crust distribution by month (1=January, 2=February,... 12=December) based on

749 interpolating linearly. Crusts occur year-round but more commonly in summer accumulation. The

750 smoothed curve is a 1st-order LOESS trend curve (width = 2). Data shown for 2400-yr record.

751 Inset shows average crusts per month ($\pm 1\sigma$).

Figure 17: Schematic illustrating possible mass and heat transports during during formation of a single-grain glazed crust, when the near-subsurface is warmer than the surface. Heat flow is primarily through the grain structure (blue), so pores (white) in the surface layer will be colder than interconnected grains, favoring mass transport from the grains to those pores, increasing density of the surface layer.

760 **Table 1:** Field observation table (see also Figs. 5, 6, 7, 8).
