15 **Abstract.** Halogen chemistry in the polar regions occurs through the release of halogen elements from different
16 sources. Bromine is primarily emitted from sea salt aerosols and other saline condensed phases associated with
17 sea ice surfaces, while iodine is affected by the release of organic compounds from algae colonies living within
18 the sea ice environment. Measurements of halogen species in polar snow samples are limited to a few sites
19 although there is some evidence that they are related to sea ice extent. We examine here total bromine, iodine
20 and sodium concentrations in a series of 2 m cores collected during a traverse from Talos Dome (72°48' S,
21 159°06' E) to GV7 (70°41' S, 158°51' E), analyzed by Inductively Coupled Plasma Sector Field Mass
22 Spectrometry (ICP-SFMS) at a resolution of 5 cm.

23 We find a distinct seasonality of the bromine enrichment signal in most of the cores, with maxima during the
24 austral spring. Iodine shows average concentrations of 0.04 ppb with little variability. No distinct seasonality
25 is found for iodine and sodium.

26 The transect reveals homogeneous air-to-snow fluxes for the three chemical species along the transect, due to
27 competing effects of air masses originating from the Ross Sea and the Southern Ocean.

28
29 **Keywords:** bromine, iodine, sodium, sea ice, Antarctica, halogens, polar halogen chemistry, Talos Dome.

1. Introduction

Halogen elements play an important role in polar boundary layer chemistry. The release of reactive halogen species from sea ice substrates has been demonstrated to be crucial in the destruction of tropospheric ozone at polar latitudes (so called Ozone Depletion Events) during springtime (Barrie et al., 1988; Simpson et al., 2007; Abbatt et al., 2012).

Although the ocean is the main reservoir of sea salts, various condensed phases of high salinity are found on young sea ice surfaces. During seawater freezing, brine is separated from the frozen water matrix and expulsion processes lead to both upward and downward movement, as temperature decreases (Abbatt et al., 2012).

Therefore, high salinity brine, frost flowers and salty blowing snow make newly formed sea ice surfaces a highly efficient substrate for inorganic halides and for their activation and release in the atmosphere (Saiz-Lopez et al., 2012b, Yang et al., 2008). Some studies have also pointed out the role of open-water sea salts as a significant bromine source (Yang et al., 2005; Sander et al., 2003).

Reactive halogen species are involved in cyclic reactions between halogen radicals, their oxides and ozone. Reactions R1-3 show the main reactions for bromine. Atomic bromine radicals result from photolysis of molecular bromine, leading to formation of bromine monoxide, BrO, through the reaction with ozone:

Self reaction of BrO may form 2 bromine atoms (85%) or a Br₂ molecule (15%) which is readily photolyzed. The mechanism has a catalytic behavior that destroys ozone.

High concentrations of vertical columns of BrO and IO have been confirmed by SCIAMACHY (SCanning Imaging Absorption spectroMeter for Atmospheric Cartography) satellite observations over Antarctic sea ice (Schönhardt et al., 2012).

Bromine can then be recycled and re-emitted from halogen-rich condensed phases (such as sea salt aerosol or other saline solutions) or from sea ice surfaces (Pratt et al., 2013), leading to an exponential increase of bromine in the gas phase (Vogt et al., 1996). Such reactions, known as bromine explosions, lead to enhanced bromine in the atmosphere. A recent 1D chemistry model simulation predicted an increase of bromine deposition on surface snowpack after 24/48 hours of recycling over first year sea ice (Spolaor et al., 2016b). The stability of bromine in the snowpack was investigated at Summit, Greenland (Thomas et al. (2011), to explain the observed mixing ratios of BrO. Measurements in East Antarctica (Legrand et al., 2016) revealed that snowpack cannot account for the observed gas-phase inorganic bromine in the atmosphere.

Bromine enrichment in snow (compared to sodium, relative to sea water) has therefore been recently used to reconstruct sea ice variability from ice cores both in the Antarctic and Arctic regions (Spolaor et al., 2013a, 2016b).

Iodine is emitted by ocean biological colonies and sea ice algae (Saiz-Lopez et al., 2012a; Atkinson et al., 2012) mainly in the form of organic alkyl iodide (R-I) and possibly other compounds. These can be released by wind forced sea spray generation or percolation up to the sea ice surface through brine channels, and are subsequently photolyzed to inorganic species. Plumes of enhanced IO concentrations from satellites and ground based measurements were observed over Antarctic coasts, suggesting a link with biological and chemical sea ice related processes (Schönhardt et al., 2008). Grilli et al. (2013) have shown that ground based IO concentrations in Dumont d'Urville (Indian sector) were more than one order of magnitude lower than in the Atlantic sector (Halley station, Saiz-Lopez et al., 2007), consistent with greater sea ice in the latter. On the other hand, only sporadic events with IO concentrations above detection limits have been observed in the Arctic regions, possibly due to the greater thickness and lower porosity of Arctic sea ice which prevents an efficient release of iodine species in the atmosphere (Mahajan et al., 2010).

81 Measurements of sea ice related species such as bromine and iodine could therefore allow a sea ice
82 signature to be obtained from ice core records. Until recently, only sodium has been used to qualitatively
83 reconstruct sea ice at glacial-interglacial timescales (e.g. Wolff et al., 2006), but this proxy has limitations at
84 annual and decadal scales, because of the noise input caused by meteorology and open water sources (Abram
85 et al., 2013). Methane sulfonic acid (MSA) is an end product of the oxidation of dimethylsulfide (DMS), which
86 is produced by phytoplankton synthesis of DMSP. MSA deposition has been successfully linked to Antarctic
87 winter sea ice extent (Curran et al., 2003; Abram et al., 2010) and Arctic sea ice conditions (Maselli et al.,
88 2016) on decadal to centennial scales, although some studies reported that the correlation with satellite sea ice
89 observations is strongly site dependent (Abram et al., 2013). Several atmospheric studies reported no evidence
90 of such link (Preunkert et al., 2007; Weller et al., 2011). Post-depositional processes causing loss and migration
91 in the ice layers have also been widely reported to affect MSA, especially at low accumulation sites (Mulvaney
92 et al., 1992; Pasteur and Mulvaney, 2000; Delmas et al., 2003; Weller et al., 2004; Isaksson et al., 2005; Abram
93 et al., 2008).

94 Victoria Land has been intensively studied for the past two decades. The Taylor Dome (Grootes et al., 2001)
95 and Talos Dome (Stenni et al., 2011) deep ice cores respectively provide 150 kyr and 300 kyr climatic
96 records directly influenced by marine airmasses. Sala et al. (2008) pointed out the presence of marine
97 compounds (ikaite) at Talos Dome, typically formed at the early stages of sea ice formation. Their back
98 trajectory calculations also showed that favourable events for air mass advection from the sea ice surface to
99 Talos Dome are rare but likely to occur. An extensive study by Scarchilli et al. (2011) on provenance of air
100 masses has shown that Talos Dome receives 50% of its total precipitation from the west (Indian Ocean), 30%
101 from the east (Ross Sea and Pacific Ocean) and approximately 15% from the interior. Within the framework
102 of the ITASE program (International Trans-Antarctic Scientific Expedition, Mayewski et al., 2005), several
103 traverses were carried out to evaluate the spatial patterns of isotopic values and chemical species linked to
104 marine influence (Magand et al., 2004; Proposito et al., 2002; Becagli et al., 2004, 2005; Benassai et al.,
105 2005).

106
107 We present here bromine, iodine and sodium deposition in coastal East Antarctica, by investigating
108 their total concentrations within a series of shallow firn cores, covering the 2010-2013 time period. The cores
109 were drilled during a traverse performed in late December 2013 in Victoria Land (East Antarctica), from Talos
110 Dome (72°48' S, 159°06' E) to GV7 (70°41' S, 158°51' E). The variability of these species at sub-annual
111 timescales will inform on timing and seasonality as well as spatial patterns of their deposition. Such
112 information is necessary for the interpretation at longer timescales of these elements and possible depositional
113 or post depositional effects. These sub-annual resolution investigations are still limited to the Indian ocean
114 sector (Law Dome - Spolaor et al., 2014) of Antarctica. The only data available on iodine in the Atlantic sector
115 (Neumayer station) have been reported from a snow pit study by Frieß et al. (2010). This study will test the
116 regional variability of these tracers, providing measurements from the Ross Sea to the Indian ocean sector that
117 remains otherwise unstudied.
118

119 **2. Sampling and analyses**

120 **2.1 Traverse sampling**

121 The traverse was performed in the northern Victoria Land region of East Antarctica (Fig. 1) from the 20th
122 November 2013 to the 8th January 2014. The starting and ending locations were Talos Dome (72°48' S, 159°12'
123 E) and location '6' (see Fig. 1), close to GV7 (70°41' S, 158°51' E), for a total distance of about 300 kilometers.
124 Talos Dome (275 km WNW from Mario Zucchelli station) is located approximately 250 km from the Ross
125 Sea and 290 km from the Indian Ocean. GV7 is a peripheral site on the ice divide coming from Talos Dome,
126 located just 95 km from the Indian Ocean.
127

128 During the transect, seven shallow cores, labelled hereafter TD (Talos Dome), 10, 9, GV7, 8, 7 and 6 were
129 hand drilled to 2 -m depth (except for GV7 which was 2.5 m). The main characteristics of the coring sites are
130 reported in Table 1. Density profiles were obtained from each core immediately after drilling.

131 The hand auger had a diameter of 10 cm and consisted of an aluminum barrel equipped with fiberglass
132 extensions. The cores were sampled in the cold laboratory at Cà Foscari University of Venice under a class-

133 100 laminar flow hood. Each core was cut with a commercial hand saw and decontaminated
134 through mechanical chiseling by removing approximately 1 cm of the external layer. Every tool was cleaned
135 each time a piece of sample was decontaminated into three serial baths of ultrapure water, which was changed
136 every 10 washes. The cores were then subsampled at 5 cm resolution (3 cm for the GV7 core) into polyethylene
137 vials previously cleaned with UPW and then kept frozen at -20 °C until analysis.

138 **2.2 Analytical measurements**

139 Total sodium (Na), bromine (Br) and iodine (I) concentrations were determined by Inductively Coupled Plasma
140 - Sector Field Mass Spectrometry (ICP-SFMS Element2, ThermoFischer, Bremen, Germany) at Cà Foscari
141 University of Venice, following the methodology described in Spolaor et al., 2014.

142 The samples were melted one hour before measurements. During this time exposure from direct light was
143 reduced by covering them with aluminum foils, minimizing bromine and iodine photolysis reactions.

144 The introduction system consisted of a cyclonic Peltier-cooled spray chamber (ESI, Omaha, USA). The
145 operational flow rate was kept at 0.4 mL min⁻¹, for an overall sample volume of 5.0 mL. Each sample
146 determination consisted of 5 instrumental detections (less than 2% variations between them). The 5 values
147 were then averaged to provide the final quantification.

148 Each analytical run (10 samples) ended with a HNO₃ (5%) and UPW cleaning session of 3 min to ensure a
149 stable background level throughout the analysis.

150
151 The external standards that were used to calibrate the analytes were prepared by gravimetric method by
152 diluting separate stock 1000 ppm IC solution (TraceCERT® purity grade, Sigma-Aldrich, MO, USA) of the
153 three analytes into a primary solution, which was further diluted for into 6 bromine and iodine standards
154 (0.01, 0.05, 0.1, 0.5, 1 and 4 ppb) and 6 sodium standards (0.5, 1, 5, 10, 50 and 100 ppb).

155 The calibration regression lines showed correlation coefficients $R^2 > 0.99$ (N=6, p=0.05). The detection limits,
156 calculated as three times the standard deviation of the blanks, were 50 and 5 ppt for bromine and iodine
157 respectively and 0.8 ppb for sodium. The reproducibility of the measurements was carried out by repeated
158 measurements of standard samples within the calibration range. The residual standard deviations (RSD) were
159 respectively 5 % (bromine), 3 % (sodium) and 2 % (iodine).

160 Procedural UPW blanks were analyzed periodically to test the cleanliness of the instrument lines.

161
162 Stable isotopes of water (¹⁸O and D) measurements were conducted on sub sample aliquots, which were
163 immediately refrozen and shipped to the Center for Ice and Climate (Copenhagen, Denmark). Analyses were
164 carried out using a Cavity Ring-Down Spectrometer (Picarro, Santa Clara, USA) using the method described
165 by Gkinis et al. (2010). Septum-sealed glass vials were used for these measurements to prevent any sample
166 evaporation during the experimental phases.

167

168 **3. Results and discussion**

169

170 **3.1 Stable water isotopes and snow accumulation**

171

172 The cores were dated based on the seasonal variations identified in the stable water isotopes (both $\delta^{18}\text{O}$ and
173 δD). Midwinters were associated to the relative minima of the isotopic curves (Fig. 2). In case a winter isotopic
174 plateau was found, the center of the plateau was associated to midwinter depth (2011 in core GV7; 2012 and
175 2011 in core 8; 2010 in core 6). Almost all the cores cover the period between 2010 and late 2013, providing
176 four years of snow deposition. The only exception is represented by core 6, whose upper layer is missing.

177

178 The annual deposition signal looks less clear in the two cores that were drilled at the sites with the highest
179 elevation and the closest to the Ross Sea, cores TD and 10, and especially for 2013 in core 10. The two sites
180 are probably the most affected by surface remobilization and isotopic diffusion due to low accumulation.
181 Indeed, non-uniformities in the shallow snow layers such as sastrugi, dunes, wind crusts and other features
182 have been identified as an important aspect of the surface morphology around the Talos Dome area (Frezzotti
183 et al., 2004; 2007).

184

185 The annual accumulation rates were calculated by selecting the depth intervals included within consecutive
186 maximum or minimum $\delta^{18}\text{O}$ values (Table 2). Each snow layer within this interval (i.e. sampling resolution, 5
187 cm) was multiplied by the density of the snow at that depth, the density curves having the same resolution.
188 The contributions were summed over the annual thickness. Table 2 also includes accumulation rates in Victoria
189 Land reported from previous studies. The GV5 site is located between sites 10 and 9 (Fig. 1).

190
191

192 The accumulation rates found during the traverse are in general agreement with the previous works (Becagli
193 et al., 2004; Frezzotti et al., 2007), except for Talos Dome. The accumulation values calculated from the
194 smoothed isotopic profile in Talos Dome are well above those measured by the stake farm (n=41, C.
195 Scarchilli, *personal communication*) for the same years. The inconsistency between the accumulation rates
196 derived from the core and those derived from the stake farm and previous measurements suggests that the
197 isotopic assignments of years may be incorrect at this site, and that the profile contains more years than have
198 been assigned. This core therefore is not used in further calculations. The fluxes of deposition of sodium,
199 bromine and iodine in the other cores along the transect are calculated using the accumulation rates from this
200 work.

201

202 The accumulation pattern along the transect increases from Talos Dome to the Southern Ocean (GV7, 8, 7, 6),
203 as the previous works have also found (Magand et al., 2004; Frezzotti et al., 2007). Scarchilli et al. (2011)
204 already pointed out how Talos Dome receives 50% of its total precipitation from the north-west (Indian Ocean),
205 30% from the east (Ross Sea and Pacific Ocean) and approximately 15% from the interior of the plateau. In
206 this picture, our accumulation data show a decrease from the Indian Ocean moving away from the Indian
207 Ocean coasts and approaching Talos Dome.

208 The sites are located at decreasing altitudes moving from Talos Dome site (highest point) towards the coast
209 facing the Indian sector (site 6). The minimum $\delta^{18}\text{O}$ value found in each core shows a decreasing trend with
210 altitude, with an elevation gradient of $-1.35 \text{ ‰}(100\text{m})^{-1}$. This super-adiabatic lapse rate is confirmed by the
211 surface snow samples collected taken during the 2001/02 ITASE traverse (Magand et al., 2004).

212 3.2 Sodium, Bromine and Iodine

213 Sodium shows a mean concentration of 34 ppb, in agreement with published values in this area (Becagli et al.,
214 2004, Bertler et al., 2005, Severi et al., 2009). Among the three elements, sodium shows the highest standard
215 deviation (21 ppb) because of the high variability of sea spray inputs at coastal sites. Singularities up to 200
216 ppb are probably associated to sea salt rich marine storms. Iodine has an average concentration of 43 ppt,
217 associated with a lower variability (23%) compared to bromine (42%) and sodium (61%).

218 The bromine enrichment has been calculated as the bromine excess with respect to sea water concentrations,
219 $Brenr = [Br]/(0.0062 \cdot [Na])$, where [Br] and [Na] are the bromine and sodium concentrations in the
220 sample and 0.0062 is the bromine-to-sodium concentration ratio in sea water (Millero, 2008). Similarly, non-
221 sea-salt bromine, $[nssBr] = [Br] - 0.0062 \cdot [Na]$. Benassai et al. (2005) have concluded that sea-salt sodium
222 is the dominant fraction (more than 80%) of the total sodium budget in this area. No correction to sodium was
223 therefore applied for this calculation. Despite bromine being a sea salt marker like sodium, it is activated when
224 gas phase HOBr oxidizes bromide over halogen rich sea ice surfaces (i.e. first year sea ice, FYSI) and
225 suspended sea salt aerosol, and exponentially released as Br_2 (R4):

227 Following photolysis, atomic bromine radicals can be converted back to HBr. Therefore, sea ice presence
228 should lead to bromine enrichment or depletion, depending whether deposition is dominated by the depleted
229 sea salt aerosol or by the enriched gas phase HBr. Bromine enrichment has already been linked to sea ice
230 presence in both Arctic and Antarctic coastal sites (Simpson et al., 2005; Spolaor et al., 2013b, 2014, 2016;
231 Vallelonga et al., 2016).

232 The distributions of bromine enrichment values are reported in Fig. 3, divided into the cores closest to the Ross
233 sea (TD, 10, 9, blue distribution) and to the Indian ocean (GV, 8, 7, 6, red distribution). The first set of cores
234 show on average higher values (5.7 ± 0.3) than the second (4.2 ± 0.2). The variability (rms) is also higher (3.5

235 ± 0.2) in the first set compared to the 'Indian ocean' set (2.5 ± 0.1), because of greater distance covered by the
236 sampling (165 km compared to 40 km). Overall, the values extend from a minimum of 0.5 to 17 with more
237 than 98% of the samples showing values greater than 1 (i.e. sea water value). A detailed insight on the few <1
238 values revealed that these samples are associated with very high contributions of sodium inputs (>120 ppb),
239 therefore likely associated to strong marine events. Such distribution of enrichment supports the theory that
240 this parameter is, in these coastal sites, affected by sea ice signature.

241 The measurements of the chemical species for the different coring sites along the traverse are reported in Fig.
242 4-5-6 on an age scale (with the exception of Talos Dome which is reported on a depth scale in the
243 supplementary material). Sodium timeseries show great variability: peaks are often found in summer, although
244 they are also observed in winter, e.g. in core 8. These findings confirm that, as previous works pointed out
245 (Curran et al., 1998), in coastal sites storm events carrying open ocean sea salts are more important than sea
246 ice as a sea salt source, although the high level of variability suggests also that meteorology and natural
247 variability play a role (Wagenbach et al., 1998). Bromine and both Br_{enr} and $nssBr$ show annual variations,
248 with maximum values in late spring-summer, confirming ice core measurements by Spolaor et al. (2014),
249 Vallelonga et al (2016), and aerosol measurements by Legrand et al., 2016. Iodine shows a more stable signal
250 throughout the year and high winter singularities or more extended peaks in cores GV7 and 8 respectively.

251 The timing of the bromine enrichment signal in ice cores relies on the combined effect of sea ice and sunlight,
252 responsible for the photochemical production and release of molecular bromine, Br_2 (Pratt et al., 2013). Sea
253 ice area in the $130^\circ E$ - $170^\circ W$ sector was calculated for the 2010-2013 period using publicly available NSIDC
254 passive microwave sea ice concentration data (Meier et al., 2013), by multiplying the sea concentration in each
255 grid pixel by the area of the pixel ($25 \times 25 \text{ km}^2$) and integrating over the domain. The longitude sector was
256 decided on the basis of Scarchilli et al. (2011), who concluded that air masses arriving in this area originate
257 from the Ross sea and from the Indian ocean sector, by analyzing 5 day back trajectories from 1980 to 2001.
258 Figure 1 (panel b) shows the minimum and maximum, found in January 2010 and August 2011, respectively.
259 The monthly sea ice areas from 2010 to 2013 were calculated for such sector and plotted in Fig. 7a (blue); each
260 monthly value was normalized to the total annual sea ice area. The minimum sea ice is found in February,
261 while a longer lasting maximum throughout winter and spring is observed, before a rapid decrease from
262 November. Solar radiation values Fig. 7a (red points) were calculated at $71^\circ S$, $158^\circ E$ using the Tropospheric
263 Ultraviolet and Visible Radiation (TUV) Model within the [300,500] nm wavelength interval. Each point
264 represents a daily average of the 15th day of each month of 2012 and it is considered a monthly representation.

265 The sub annual distribution of bromine enrichment along the transect is shown in Fig. 7b (blue). Each bins
266 contains the cumulative monthly value for every year in every core, normalized by the total value of each year
267 (which may change according to year and location). The histogram is then normalized by the overall sum
268 measured in the transect. The distribution shows a clear sub-annual oscillation with lowest and highest annual
269 contribution in May (autumn) and October-November (late spring), respectively. The combined effect of sea
270 ice and insolation (Fig. 7b, magenta product distribution) shows similar features, with maximum in November,
271 albeit with a much more pronounced springtime increase than seen in the bromine enrichment. Such
272 comparison suggests that the combined effect of sea ice and insolation is related to the seasonality of bromine
273 enrichment. Monthly sea ice area values are reported in Fig. 7c (blue), together with annual averaged values
274 of bromine enrichment (black) and first year sea ice, FYSI (red), calculated as the difference of maximum and
275 minimum sea ice area. A longer record would be needed to evaluate the correlation between bromine
276 enrichment values and FYSI area and investigate a quantitatively link.

277 Table 3 shows the average annual iodine concentrations for each location, together with its standard deviation.
278 The mean value (0.043 ppb) is close to the background values found in Antarctic shallow firn cores near the
279 research stations of Neumayer (Frieß et al., 2010) and Casey (Law Dome, Spolaor et al., 2014) respectively.
280 Unlike previous observations of a clear winter peak of iodine with concentrations up to 0.6 ppb (Neumayer)
281 and 0.3 ppb (Law Dome), no clear seasonality is observed for the transect records, with annual variability
282 around 10-15%. Core 7 (Fig. 6) shows some variability which corresponds to winter peaks. High iodine
283 concentrations are observed in core 8 during the 2012 winter, in association to a strong sea salt (sodium) input,
284 although similar strong winter peaks are observed in 2011 at GV7.

285 The low background level and low variability of iodine found along the transect reflect a low input of iodine
286 in this area of Antarctica compared to other locations. This picture is confirmed by satellite measurements,

287 which show average IO concentrations close to detection limit over the area of the transect compared to Law
288 Dome, Neumayer, or any other coastal location (Fig. 8, right panel). The high elevation of the traverse area,
289 compared to the others is likely to play a role in preventing efficient iodine transport from the source areas.

290 Frieß et al. (2010) and Spolaor et al. (2014) have attributed iodine seasonal signal pattern to summertime
291 photochemical recycling of IO from the snowpack, leading to depletion in the summer layers and higher
292 concentrations in winter, when absence of sunlight inhibits photoactivation. The lower variability found across
293 the Northern Victoria Land traverse cores could result from a reduced summer recycling due to low iodine
294 concentrations available the snow.

295 **3.3 Spatial flux variability**

296 Glaciochemistry around Antarctica is very strongly influenced, among several properties, by the distance from
297 the sea and the pathways of the air mass trajectories (Bertler et al., 2005). Atmospheric circulation patterns
298 around the Talos Dome area have been investigated by Scarchilli et al. (2011), who have shown that the main
299 input is represented by the Southern Ocean (Indian sector) with a lower contribution from the Ross Sea.

300 The spatial variability of sodium, bromine, bromine enrichment and iodine is investigated in Fig. 9. The
301 twelve panels display the annual fluxes of Na, Br, I and integrated annual values of bromine enrichment for
302 each core in relation to its distance from the Indian Ocean. Sodium fluxes show the highest values and
303 variability around the closest locations to the Southern Ocean (GV7, 8, 7, 6), where the accumulation
304 increases. After rapidly decreasing within the first 100 km, the sodium flux becomes stable, as the input from
305 the SO decreases but the one from the Ross sea gradually increases. Bromine exhibits a similar behavior to
306 sodium, with a homogeneous flux within cores 10 and 9 and an increase (up to 3 times) in the last 100 km
307 from the SO. Elevation could partly account for the fractionation of sodium and bromine, having the 180 m
308 of height difference separating GV7,8,7 and 6, and 240 m from GV7 to core 10. The effect of elevation yet is
309 combined to the influence of the distance from the source to resolve the two effects. The pattern of bromine
310 enrichment is linked among other things to the different bromine fractionations during the transport in the
311 gas phase and the aerosol phase, compared to sodium. Unlike sodium and bromine, no decrease is observed
312 for bromine enrichment from our data (Fig. 9, second column), although no clear trend can be inferred. This
313 can be due to the multiple origins of air advection (Ross sea /Indian ocean), to their uneven strength or
314 because the distances are not large enough for any difference to be observed.

315 A slightly lower fractionation after 100 km from the SO is observed for iodine, consistent with the
316 homogeneous satellite measurements of IO (Fig. 9, right).

317

318 **4. Conclusions**

319

320 The 2013/14 Talos Dome – GV7 traverse provided an opportunity to expand the existing sodium dataset in
321 Victoria Land and investigate important features of bromine and iodine temporal and spatial variabilities, so
322 far only available in Antarctica at Law Dome and Neumayer station.

323

324 The accumulation rates agree with previous studies, with increasing values from the Ross Sea to the Southern
325 Ocean. Accumulation rates calculated for Talos Dome are higher than previously reported, likely caused by
326 isotopic diffusion and remobilization at this site. Further studies are required at this site in order to access the
327 reproducibility of the climate signal. The locations near the Southern Ocean exhibit high variability due to the
328 higher accumulation.

329

330 Sodium and bromine concentrations in the snow samples result in a positive bromine enrichment to seawater,
331 confirming the sea ice influence in the area for the extra bromine deposition. While sodium does not capture
332 clear sub-annual variations associated with sea ice, bromine enrichment shows consistent seasonal variabilities
333 with late spring maxima. There is some evidence that the seasonality is linked to the combined effect of sea
334 ice growth and sunlight, which trigger photochemistry above fresh sea ice. The timing of deposition is coherent
335 among Victoria Land, Law Dome and Dumont d'Urville (Indian sector) and Neumayer (Atlantic sector).
336 Iodine shows an average value of 0.04 ppb, similar to background values observed in the Antarctic coastal
337 locations of Law Dome and Neumayer. Unlike those locations, low iodine annual variability and no consistent
338 seasonality of the signal are observed in the traverse samples.

339

340 The spatial variability study reveals homogeneous fluxes of Na, Br, and I over the transect length, with an
341 increase in absolute values and variability at the sites close to the Indian Ocean, due to high accumulation and
342 proximity to the coasts. Uniform satellite values of BrO and IO over Victoria Land are consistent with the
343 snow measurements. A fractionation due to distance of these potential proxies is not found probably due to the
344 combined double input of air masses from the Ross Sea and the Indian Ocean.

345 A transect covering larger distances and directed towards the interior of the plateau would give an insight on
346 this feature, especially clarifying the spatial pattern of bromine enrichment with respect to differences in gas-
347 phase and aerosol depositions.

348

349

350

351 **Acknowledgements**

352 We thank the scientists who conducted the traverse and provided the samples, the chemistry group in Venice
353 for the chemical measurements as well as the isotope laboratory in Copenhagen for the measurements of the
354 water isotopes. Thank also to Rasmus Anker Pedersen and Emilie Capron for the useful suggestions and
355 comments.

356 This research was carried out in the framework of the Project on Glaciology and Paleoclimatology of the Italian
357 PNRA National Antarctic Program.

358 The research leading to these results has received funding from the European Research Council under the
359 European Community's Seventh Framework Programme (FP7/2007-2013) / ERC grant agreement 610055 as
360 part of the ice2ice project.

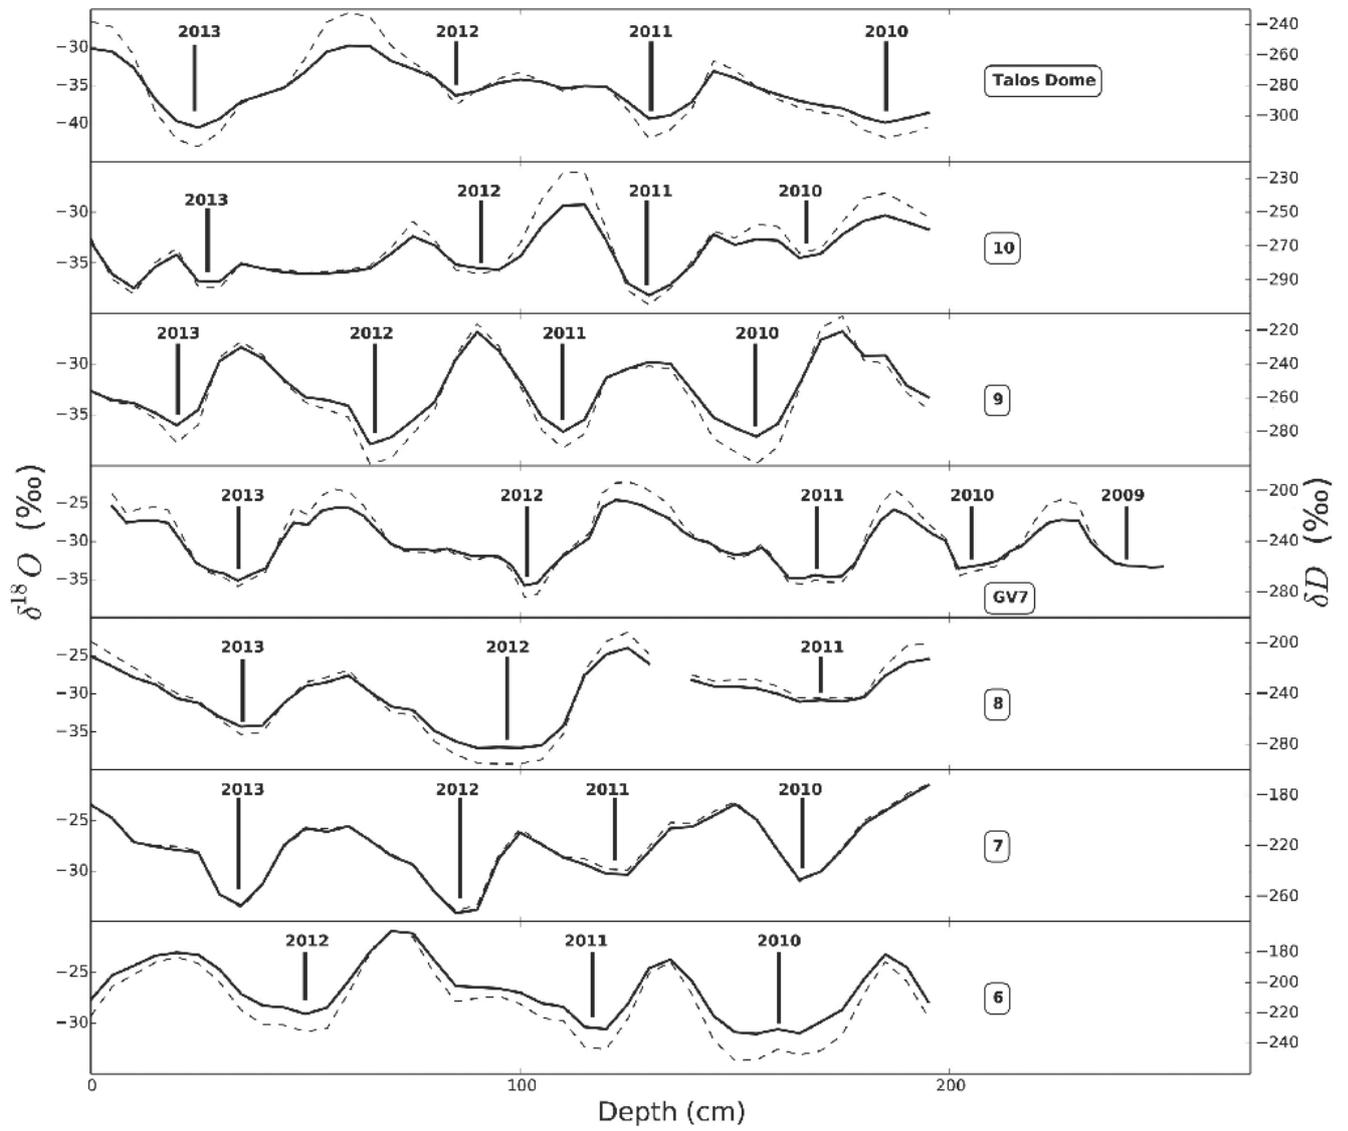

Figure 1. (a) Schematic map of the traverse area and coring sites, marked with stars. The cores were drilled between Nov 20th 2013 and Jan 8th 2014 (early austral summer). (b) Maximum (left, August 2011) and minimum (right, January 2010) sea ice concentrations in the 130°E-170°W sector for the 2010-2013 time interval covered by the core records (NSIDC data from Meier et al., 2013). The traverse location is marked with an ellipse.

676

Figure 6. Variability of $\delta^{18}\text{O}$ (upper panel), Na (middle top panel, left axis), Br (middle top panel, right axis), Br_{cor} (middle bottom panel, left axis), nssBr (middle bottom panel, right axis), and I (bottom panel) in cores 7 (left) and 6 (right). Thick lines represent 3-month running means of the raw data (circles).

698

699 **Figure 7.** (a) Monthly values of sea ice area (blue) within the 130°E-170°W sector from 2010 to 2013 ($\pm 1\sigma$, month variability) and
700 daily average (24 hours) total downwelling spectral irradiance (red), calculated using the TUV model at 71° S, 158° E. Each
701 irradiance calculation was set the 15th day of each month, in 2012. (b) Seasonality of annual bromine enrichment along the traverse:
702 the monthly trend shows a seasonal feature with maximum in Spring. Each line refers to a core of the transect ($\pm 1\sigma$, shaded blue
703 area). The month averages are displayed in black. The systematic uncertainties associated to the dating are shown as vertical error
704 bars. The magenta band represents the product distribution of normalized sea ice area and insolation, expressed in annual percentage.
705 (c) Monthly sea ice area values (blue) from 2010 to 2013, with annual values of FYSI (red) and averaged bromine enrichment
706 (black).
