11

12 **Abstract**

13 During the World Meteorological Organization (WMO) Solid Precipitation Intercomparison Experiment (SPICE),  
14 automated measurements of snow water equivalent (SWE) were made at the Sodankylä (Finland),  
15 Weissfluhjoch (Switzerland) and Caribou Creek (Canada) SPICE sites during the Northern Hemisphere winters of  
16 2013/2014 and 2014/2015. Supplementary intercomparison measurements were made at Fortress Mountain  
17 (Kananaskis, Canada) during the 2013/2014 winter. The objectives of this analysis are to compare automated  
18 SWE measurements with a reference, comment on their performance, and where possible to make  
19 recommendations on how to best use the instruments and interpret their measurements. Sodankylä, Caribou  
20 Creek and Fortress Mountain hosted a Campbell Scientific CS725 passive gamma radiation SWE sensor.  
21 Sodankylä and Weissfluhjoch hosted a Sommer Messtechnik SSG1000 snow scale. The CS725 operating  
22 principle is based on measuring the attenuation of soil emitted gamma radiation by the snowpack and relating

1 the attenuation to SWE. The SSG1000 measures the mass of the overlying snowpack directly by using a  
2 weighing platform and load cell. Manual SWE measurements were obtained at the intercomparison sites on a  
3 bi-weekly basis over the accumulation/ablation periods using bulk density samplers. These manual  
4 measurements are considered to be the reference for the intercomparison. Results from Sodankylä and  
5 Caribou Creek showed that the CS725 generally overestimates SWE as compared to manual measurements by  
6 roughly 30 to 35 % with correlations ( $r^2$ ) as high as 0.99 for Sodankylä and 0.90 for Caribou Creek. The RMSE  
7 varied from 30 to 43 mm water equivalent (mm w.e.) and 18 to 25 mm w.e. at Sodankylä and Caribou Creek,  
8 which had respective SWE maximums of approximately 200 mm w.e. and 120 mm w.e. The correlation at  
9 Fortress Mountain was 0.94 (RMSE of 48 mm w.e. with a maximum SWE of approximately 650 mm w.e.) with  
10 no systematic overestimation. The SSG1000 snow scale, having a different measurement principle, agreed  
11 quite closely with the manual measurements at Sodankylä and Weissfluhjoch throughout the periods when  
12 data were available ( $r^2$  as high as 0.99 and RMSE from 8 to 24 mm w.e. at Sodankylä and 56 to 59 mm w.e. at  
13 Weissfluhjoch, where maximum SWE was approximately 850 mm w.e.). When the SSG1000 was compared to  
14 the CS725 at Sodankylä, the agreement was linear until the start of ablation period when the positive bias in  
15 the CS725 increases substantially relative to the SSG1000. Since both Caribou Creek and Sodankylä have sandy  
16 soil, water from the snowpack readily infiltrates into the soil during melt, even if the soil is frozen. However,  
17 the CS725 does not differentiate this water from the un-melted snow. This issue can be identified, at least  
18 during the late spring ablation period, with soil moisture and temperature observations like those measured at  
19 Caribou Creek. With a less permeable soil and surface runoff, the increase in the instrument bias during  
20 ablation period is not as significant, as shown by the Fortress Mountain intercomparison.

21

## 1 1 Introduction

2 The measurement of snow water equivalent (SWE) is vital for flood and water resource forecasting, drought  
3 monitoring, climate trend analysis, and hydrological and climate model initialization (Barnett et al., 2005; Gray  
4 et al., 2001; Bartlett et al., 2006; Laukkanen, 2004). Many of these applications require accurate and timely  
5 information about how much water is being held within the snowpack (Pomeroy and Gray, 1995). SWE  
6 measurements can be made in-situ, either manually or via automated instrumentation, or derived from remote  
7 sensing platforms, and are usually expressed as units of mass per area ( $\text{kg m}^{-2}$ ) or in equivalent units of  
8 millimetres of water equivalent (mm w.e.). Manual measurements of SWE are typically made using a multi-  
9 point bulk density sampling technique along an established transect or snow course (WMO, 2008). Snow  
10 course measurements are often time consuming and expensive, especially if required in remote locations  
11 (Pomeroy and Gray, 1995). This means that manual SWE measurements may be infrequent or only undertaken  
12 when the snowpack is estimated to be at its seasonal maximum. Prohibitive costs of manual snow course  
13 observations have led to the reduction of these measurements by many agencies, including Environment and  
14 Climate Change Canada, where operational snow course numbers have decreased from over 100 in the 1980s  
15 to less than 30 (Barry, 1995; Brown et al, 2000). Since the early 1990s, manual SWE measurements have been  
16 augmented or replaced by remote sensing techniques such as passive microwave retrievals (Goodison and  
17 Walker, 1995) but these techniques still require accurate and reliable in-situ measurements for ground-truthing  
18 and retrieval development (Derksen et al., 2005; Takala et al., 2011).

19

20 With the reduced availability of manual SWE measurements, automated instruments for the measurement of  
21 SWE are becoming more necessary and more commonplace. Snow pillows have been used for the automated  
22 measurement of SWE in remote locations since the 1960s (Beaumont, 1965) by measuring the overlying  
23 pressure of the snowpack on a fluid filled bladder. The SNOTEL network in the United States is based on snow  
24 pillow measurements (Serreze et al., 1999). More recently, similar measurements are obtained using snow

1 scales that use a weighing surface and load cell to measure the weight of the overlying snow (Beaumont, 1966;  
2 Johnson et al., 2007; Johnson et al., 2011)). Several indirect methods exist to measure SWE that include the use  
3 of neutron probes (Harding, 1989) in which a radiation source is placed under the snowpack and the scattering  
4 of neutrons through the snow is measured by a detector. Cosmic ray proton probes (Kodama et al., 1979;  
5 Rasmussen et al., 2012) work in a similar manner but do not require an active source. The probes described by  
6 Kodama et al. are installed under the snow while the system described by Rasmussen et al. (called COSMOS) is  
7 installed above the snow. Kinar and Pomeroy (2007; 2015a) outline a method of non-invasive sonic  
8 reflectometry through the snowpack to determine snow density, liquid water content, and temperature. Other  
9 passive radiation sensors are mounted above the surface and measure the attenuation of naturally emitted  
10 radiation from the soil as it passes through the snowpack and then relate this attenuation to SWE content  
11 (Choquette et al., 2008; Martin et al., 2008). Each of these instruments and techniques have advantages and  
12 disadvantages, which are not discussed here (see Kinar and Pomeroy (2015b) for a more comprehensive  
13 description of snow measurement methods and related issues). Rather, this analysis assesses the use and  
14 accuracy of two instruments that were tested during the World Meteorological Organization (WMO-Solid  
15 Precipitation Intercomparison Experiment (SPICE) (Nitu et al., 2012; Rasmussen et al., 2012), namely the  
16 Campbell Scientific CS725 and the Sommer Messtechnik SSG1000 snow scale.

17

18 The CS725 (previously known as GMON or GMON3) has been previously field tested by Hydro Québec  
19 (Choquette et al., 2008; Martin et al., 2008) as well as by Wright et al. (2011). Results by Choquette et al. (2008)  
20 showed an average error of +18 % when comparing to 8 manual snow cores over 3 seasons in Quebec. They  
21 obtained a somewhat better agreement with total SWE calculated from density profiles (with an average error  
22 of +5 %) but only had 4 samples over 2 seasons. Wright et al. (2011) showed intercomparison results between  
23 GMON3 sensors and snow pillows, precipitation gauges, and snow courses at Sunshine Village (Alberta,  
24 Canada) and Tony Grove Ranger Station (Utah, USA). Results showed high correlations between the sensor and

1 (unadjusted) accumulated precipitation (0.99) and between the sensor and snow pillow observations (0.99) but  
2 lower correlations (0.83) with snow course observations (during one season at Sunshine Village). The authors  
3 question the quality and inherent biases in the snow course samples but do not comment on the sources of  
4 error or the proximity of the snow course to the instrument.

5

6 Instrument intercomparisons that included the SSG1000 have been limited but some results are reported by  
7 Strandén and Grönsten (2014), who showed parallel SWE measurements between snow pillows, snow scales,  
8 and manual snow courses. With mitigating circumstances (e.g. snow drifting and scale issues), they concluded  
9 that the measurement surface area had an impact on the measurement quality and that the Sommer scale  
10 gave “promising results” but that further intercomparison was required.

11

12 One of the over-all objectives of the WMO-SPICE project is to assess the performance of automated  
13 instrumentation for the measurement of snow, including snow on the ground (SoG). This is accomplished by  
14 comparing the tested instruments to an established reference measurement. In total, fifteen countries are  
15 participating in the WMO-SPICE project with about 20 intercomparison sites. Of these, 7 countries and 9  
16 intercomparison sites are hosting SoG instrumentation. The instrumentation for WMO-SPICE has either been  
17 provided by the instrument manufacturers or by the site hosts. For SoG, 13 different instruments are under  
18 test with 9 measuring snow depth and 4 measuring SWE. The CS725 and the SSG1000 SWE instruments  
19 examined here were installed at the Sodankylä (Finland), Caribou Creek (Canada) and Weissfluhjoch  
20 (Switzerland) intercomparison sites (Fig. 1). To supplement the CS725 data collected for WMO-SPICE, data was  
21 added from an additional CS725 instrument installed at the Fortress Mountain ski area in the Kananaskis region  
22 of the Canadian Rocky Mountains.

23

1    2    **Instrumentation and Methods**

2    2.1    **Campbell Scientific CS725**

3    The CS725 (Fig. 2 left) is a passive gamma sensor developed by Hydro Québec in collaboration with Campbell  
4    Scientific (Canada) Corp. (Choquette et al., 2008; Martin et al., 2008). The instrument is installed above the  
5    snow surface and determines SWE by measuring naturally emitted gamma radiation from Potassium and  
6    Thallium sources in the soil that is attenuated by the snowpack. Each gamma ray detected by the sensor  
7    element is counted over a user defined period, the resulting distribution is compared to the distribution when  
8    there was no snow cover, and the difference is used to calculate SWE. The sensor field of view is approximately  
9    120° resulting in a measurement area of approximately 80 m<sup>2</sup> when installed 3 m above the snowpack and with  
10   the collimator attached. The collimator serves to shield the instrument from gamma rays emitted from sources  
11   that are not in the target area. The effective range of the instrument is 0 to 600 mm w.e. with a measurement  
12   accuracy of +/- 15 mm w.e. from 0 to 300 mm w.e. and 15 % from 300 to 600 mm w.e. (Campbell Scientific  
13   CS725 Manual, [https://s.campbellsci.com/documents/ca/manuals/cs725\\_man.pdf](https://s.campbellsci.com/documents/ca/manuals/cs725_man.pdf)).

14

15   The two CS725 instruments for WMO-SPICE were both installed in October 2013 at Sodankylä, Finland, and  
16   Caribou Creek, Canada, and operated over the Northern Hemisphere winters of 2013/2014 and 2014/2015.  
17   Both instruments were mounted so that the bottom of the instrument was approximately 2 m above the  
18   ground and both were installed with the manufacturer provided collimator. Data was output every 6 hours.  
19   The instrument at Sodankylä was moved approximately 10 m during the summer of 2014 to avoid some buried  
20   cables in the measurement area, but any potential impact of the move are considered to be negligible because  
21   of the consistency in the snowpack at this site. The impact of spatial variability is addressed in Section 4.

22

23   The third CS725 used in this analysis was not a WMO-SPICE instrument, but was loaned to the University of  
24   Saskatchewan for testing and intercomparison by the instrument manufacturer. This instrument was installed

1 in a clearing near the Fortress Mountain ski resort in the Kananaskis Valley, Alberta, Canada. The CS725 was  
2 mounted at a height of approximately 3.5 m above the ground. The distance to the trees around the  
3 instrument was approximately 10 m from the centre of the instrument, , putting them outside of the response  
4 area. Data collected by this instrument from October 2013 through June 2014 is used in this analysis. Like the  
5 other CS725 instruments, SWE data was output every 6 hours.

6

## 7 2.2 Sommer SSG1000

8 The SSG1000 snow scale (Fig. 2 right) manufactured by Sommer Messtechnik, Austria, measures SWE through  
9 the use of a weighing platform and load cells. Unlike the CS725, it makes a direct measurement of the weight  
10 of the snowpack on top of the weighing platform and converts this weight to SWE. The entire platform consists  
11 of 7 perforated panels, each 0.8 m x 1.2 m, that are attached to a frame and installed level with the surface of  
12 the ground. The entire instrument surface is 2.8 m x 2.4 m (6.72 m<sup>2</sup>) but only the centre panel is weighed by  
13 the load cell. According to the manufacturer, the purpose of the larger surface surrounding the centre  
14 measurement panel is to “stabilize” the overlying snowpack and prevent ice bridging  
15 (<http://www.sommer.at/en/products/snow-ice/snow-scales-ssg>). The SSG1000, as tested for WMO-SPICE, has  
16 a measurement range of 0 to 1000 mm w.e., and a manufacturer stated resolution and accuracy of 0.1 mm  
17 w.e. and 0.3 % of full scale (3 mm w.e.), respectively.

18

19 The SSG1000 snow scales in this analysis were installed in the Sodankylä and Weissfluhjoch SPICE sites. The  
20 Weissfluhjoch instrument was provided by the WSL Institute for Snow and Avalanche Research SLF. Data  
21 collection from the instrument started in October 2013 and continued for the 2013/2014 and 2014/2015  
22 Northern Hemisphere winters. The SSG1000 at Sodankylä was located in the North East quadrant of the SPICE  
23 Field, approximately 22 m southeast of the original location of the CS725. At Weissfluhjoch, it is located in the

1 southwest corner of the instrument field. SWE observations from the instruments were recorded once per  
2 minute during the two intercomparison seasons.

3

4 [2.3 Reference SWE measurements](#)

5 The reference SWE manual measurements for this intercomparison differed by site. All were bulk density snow  
6 samples made with a snow sampling tube of a known diameter that has one end capable of penetrating and  
7 cutting into the snowpack. The tube was inserted into the snowpack either down to the surface of the ground  
8 or to a plate inserted into the snowpack, and the sample was extracted. Along with the sample, the depth of  
9 the snowpack was also obtained. The sampled snow was then either bagged and weighed or was weighed  
10 inside the tube using a cradle and balance. The snow sampler used in Canada is different than the tube used in  
11 Finland and these differences, as well as any other differences in sampling technique, are described below.

12

13 At Caribou Creek, the reference SWE measurements were obtained using an ESC-30 snow tube with a  $30\text{ cm}^2$   
14 cutting area. Farnes et al. (1983) and Goodison et al. (1987) show that the ESC-30, when used correctly and in  
15 ideal conditions, has a mean measurement error of less than 0.5 % of the true SWE. Errors associated with  
16 sampling in less than ideal conditions are discussed later. Bulk density samples at Caribou Creek were taken  
17 just inside the response area of the CS725, bagged, and weighed. A  $30\text{ cm}^2$  sample from within the response  
18 area is assumed to have a negligible impact on future sensor measurements considering the total sensor  
19 response area is  $80\text{ m}^2$ , but it was filled in with discarded snow when possible. These manual SWE  
20 measurements were made about every two weeks in conjunction with a full 5 point snow course across the  
21 Intercomparison Field and into the forest canopy on each side.

22

23 At Sodankylä, the reference SWE measurement was made using a Finnish bulk density sampling tube, with a  
24 sampling area of  $78.54\text{ cm}^2$ , and balance (Kuusisto, 1984) at roughly the same location in the Intercomparison

1 Field every two weeks. Only one sample was measured at a time. During the winter of 2013/2014, the bulk  
2 density SWE sample was obtained approximately 12 m from the centre of the CS725 measurement area and  
3 approximately 16 m from the centre of the SSG1000. In 2014/2015, after the CS725 was moved, the manual  
4 sampling was done approximately 6 m from the CS725 measurement area and approximately 25 m from the  
5 SSG1000.

6

7 An ESC-30 snow tube was used at the Fortress Mountain site. A full snow survey was conducted at the site  
8 once per month, transitioning to bi-weekly during the ablation period. Although the actual snow survey course  
9 was through the forested area, supplemental measurements were taken in the clearing where the  
10 instrumentation is located. The distance between the sensor and the manual measurements was  
11 approximately 10 m.

12

13 The manual SWE measurements at Weissfluhjoch were performed by-weekly on the SLF study plot using  
14 a bulk density Aluminum sampling tube with a sampling area of 70 cm<sup>2</sup> and length of 55 cm. The weight was  
15 measured with a cradle and balance (Jonas et al., 2009). . The distance between the sensor and manual snow  
16 measurement varied from observation to observation as the location of the snow pit was relocated for each bi-  
17 weekly measurement. The average distance was approximately 20 m.

18

#### 19 2.4 Intercomparisons

20 The intercomparisons are not completely consistent amongst the four sites because of the different  
21 instrumentation and manual methods for measuring reference SWE. At Sodankylä and Weissfluhjoch, the  
22 sensors can both be compared with the manual SWE measurements made nearby, although the manual  
23 measurements are not within the measuring area of either instrument. The timestamps of both instruments  
24 were matched as closely as possible to the manual observation time. Since the CS725 only reports every 6

1 hours, the measurement output closest to the manual observation time was used for the intercomparison.  
2 Since the SSG1000 reports every minute, no time adjustment was necessary. The same procedure was used to  
3 compare the CS725 to the SSG1000. No SSG1000 was present at Caribou Creek or Fortress Mountain and no  
4 CS725 sensors were installed at Weissfluhjoch.  
5  
6 For the CS725, which outputs a SWE value derived from both the Potassium (K) and Thallium (Tl) counts, the  
7 manufacturer suggests that the output with the higher count is generally the most reliable. For Sodankylä, the  
8 K/Tl ratio is always greater than 1 (varying from 3.5 to 8.0) indicating that the Potassium counts are greater  
9 than the Thallium counts. For Caribou Creek, the ratio varies from 2.8 to 4.0. For Fortress Mountain, the ratio  
10 varies from 0.3 to 8.5 but is above 1 approximately 70 % of the time. Therefore, the CS725 analysis is based on  
11 the Potassium output although the statistics for Thallium are shown in parenthesis in Table 1. This will allow us  
12 to determine if there were any obvious differences in the statistics related to the output derived from one  
13 source or the other.

14

### 15 3 Results

#### 16 3.1 CS725 vs. manual

17 The comparison between the CS725 measurements and the manual SWE observations are shown in Fig. 3 with  
18 the Potassium output in red circles and the Thallium output in blue triangles. The black line in the figure  
19 represents the 1:1 line and the error bars represent the manufacturer's stated sensor accuracy. Figure 4 shows  
20 the time series of automated and manual SWE measurements. Figure 5 shows the difference between the  
21 CS725 and the manual measurement (red) and the measured air temperature (blue) through the two seasons.  
22 The regression analysis coefficients and summary statistics are listed in Table 1. The statistics are provided for  
23 each individual season and for the two seasons combined. The statistics for the individual seasons are also

1 refined further to show results for the accumulation period (delineated from the ablation period by the timing  
2 of maximum seasonal SWE). This will help to eliminate the effects of snow melt on both the manual  
3 measurement and the various potential impacts on the CS725 measurement. These figures and tables are  
4 further analyzed for each site in the following subsections.

5

### 6 3.1.1 Sodankylä

7 Throughout the intercomparison periods at Sodankylä, the CS725 overestimated SWE on average by 30 %  
8 (mean relative bias or MRB) as compared to the manual measurements. From Table 1, the regression analysis  
9 for the CS725 as compared to manual SWE over the entire season results in a slope ( $\beta$ ) of 1.24 for 2013/2014  
10 and 1.06 for 2014/2015. The difference in  $\beta$  between the K and Tl outputs is small. The intercepts ( $\epsilon$ ) for the  
11 entire seasons are 8.77 mm w.e. for 2013/2014 increasing to 26.9 mm w.e. for 2014/2015. This difference  
12 might be in part a result of moving the instrument to a new location. The correlation coefficient,  $r^2$ , is 0.92 for  
13 2013/2014 and 0.96 for 2014/2015. With the period of ablation eliminated from the analysis, the impact on  $\beta$   
14 and  $\epsilon$  are relatively small although the intercept  $\epsilon$  decreases almost 9 mm w.e. and 4 mm w.e. for the  
15 respective seasons. The accumulation period  $r^2$  increases to 0.97 and 0.99 for the 2013/2014 and 2014/2015  
16 seasons respectively suggesting that more scatter is introduced into the relationship during the ablation  
17 period. This is discussed further below.

18

19 Figure 4 (top) shows the time series for the 2013/2014 (left) and 2014/2015 (right) seasons at Sodankylä. In this  
20 figure, the overestimation of the CS725 (red and blue lines) can be seen when compared to manual SWE (black  
21 circles). In general, the instrument trends are the same as for the manual measurements with differences  
22 between the measurements increasing after the start of the ablation periods and in January 2014 and  
23 December 2014. Although it appears from Fig. 5 that the difference between the measurements is simply  
24 increasing with time (or SWE amount), we believe that at least part of this increase is a result of melting in the

1 snowpack which occurs during some relatively warm days. In 2013/2014 (Fig. 5, left), a large increase in the  
2 difference occurs after the  $> 0^{\circ}\text{C}$  temperatures in mid to late April. In 2014/2015 (Fig. 5, right), there is a  
3 moderate increase after some  $> 0^{\circ}\text{C}$  temperatures in March but a much larger jump after the beginning of the  
4 ablation period in April.

5

### 6 3.1.2 Caribou Creek

7 The comparison of the CS725 instrument and the manual SWE measurements made at Caribou Creek are  
8 shown in Fig. 3 and summarized in Table 1. As with Sodankylä, the difference between the two sensor outputs  
9 (Potassium vs. Thallium) is negligible. Also like Sodankylä, the CS725 at Caribou Creek consistently  
10 overestimates total SWE such that the MRB is 35 %. However, the relationships between the instrument and  
11 the manual SWE measurements are different than at Sodankylä. At Caribou Creek, the slopes of the regression  
12 line,  $\beta$ , are less than 1 for all scenarios in Table 1 with the exception of the accumulation period in 2014/2015.  
13 The intercepts ( $\epsilon$ ) are all larger than seen at Sodankylä, with the accumulation period in 2014/2015 being the  
14 exception once again. The  $r^2$  values range from 0.90 for the combined (2013/2014 and 2014/2015) data to 0.55  
15 for the accumulation period in 2014/2015.

16

17 For both the 2013/2014 and 2014/2015 seasons, the time series for Caribou Creek (Fig. 4 middle) shows a rapid  
18 increase in SWE in early winter related to heavier, wet snowfall events that most likely began as rain and  
19 transitioned to snow. For 2013/2014, the CS725 time series generally follows the trend of the manual SWE  
20 measurements with a large deviation developing mid- to late-March with the onset of seasonal ablation. Figure  
21 5 (middle) shows the time series of the difference between the CS725 and manual SWE (red) and the  
22 temperature time series (blue) for both seasons. In 2013/2014 (Fig. 5 middle left), there is an increase in the  
23 difference that occurs in late January. This could be due to a melt period where temperatures at the site  
24 exceeded  $4^{\circ}\text{C}$  preceding the increase in the instrument bias. A much larger jump in the difference occurs mid-

1 March possibly due to significantly higher temperatures (exceeding 10 °C) earlier that month. In 2014/2015  
2 (Fig. 5 right), the deviation between the measurements occurs earlier in the season (mid- to late-January)  
3 coinciding with a January snow melt period characterized by above 0 °C air temperatures and high wind speeds  
4 (not shown) that resulted in ice layers on top and within the snowpack (which make accurate manual SWE  
5 measurements more difficult) and possibly infiltration of melt water into the frozen sandy soil. Differences  
6 decrease after snowfall events in February only to increase again after the start of ablation in March.

7

8 In reaction to an observed offset after the 2013/2014 intercomparison season, soil moisture and temperature  
9 probes were installed at the Caribou Creek site with the objective of correlating post-calibration, overwinter,  
10 and ablation soil moisture changes with sensor offsets. The instruments were installed at three depths: 0 to 5  
11 cm (vertically), 5 cm (horizontally) and 20 cm (horizontally). Unfortunately, the probes only measure liquid  
12 water(volumetric water content, or VWC) so the analysis is mostly limited to when the soil temperatures (also  
13 measured by the probe) are above 0 °C when we assume that most of the water in the soil is unfrozen.

14

15 Figure 6 shows the time series of soil moisture near the surface (0 to 5cm) along with the difference between  
16 the CS725 and manual measurements (scaled by a factor of 100 for visualization) for the 2014/2015 season.  
17 The red markers indicate when the soil temperature at this level is above 0 °C. It is easy to see from the time  
18 series when the liquid soil moisture (near the surface) freezes in late fall resulting in a rapid drop in measured  
19 VWC. Following the freezing of the near surface layer, which occurs 8 November 2014, the measured soil  
20 moisture in this layer remains static until mid-March 2015 when a period of positive air temperatures (Fig. 5  
21 middle right) raises the near surface soil temperatures above freezing, transitioning frozen soil moisture to  
22 liquid and allowing for further infiltration of snow melt water into the sandy soil. The near surface (0 to 5 cm)  
23 soil temperatures rose above freezing even with snow on the surface. The snowpack was patchy (verified from

1 hourly photos) and shallow, and meltwater was likely percolating through the snow and into the top layers of  
2 the soil.

3

4 The freezing of the 0 to 5 cm depths in early November is preceded by rain/snow events in late October that  
5 are represented by the large jump in CS725 SWE shown in Fig. 4 (middle right) and confirmed with snow depth  
6 measurements (not shown). During the transition from rain to snow and prior to the surface freezing, Fig. 6  
7 shows fluctuations in near surface soil moisture (measured by the soil moisture sensor as volumetric water  
8 content or VWC) related to the precipitation events in late October and early November. The soil moisture  
9 calibration of the CS725 sensor was entered as a gravimetric water content (GWC) of 0.10, which can be  
10 converted to VWC by multiplying by the specific gravity of the soil (Lambe and Whitman, 1969). The specific  
11 gravity of the loose sand near the surface at Caribou Creek was estimated to be 1.4 based on nearby  
12 measurements taken during the BOREAS campaign (Anderson, 2000). The increase in measured VWC from the  
13 calibration value to 0.18 (GWC of 0.13) prior to freezing has the potential to create a small but potentially  
14 perpetuating offset of up to 3 mm w.e. in the CS725 SWE estimates and may explain at least some of the bias  
15 shown by the instrument beginning in mid-December.

16

17 In addition to the offset in the CS725 SWE measurements that occurs at the beginning of the season, it was  
18 anticipated that the rapid increase in the difference between the CS725 and Manual SWE at the end of January  
19 2015 could also be attributed to a change in near surface soil moisture, as this was a time of mid-season snow  
20 melt. However, a change in the liquid soil moisture during the melt period could not be detected by the soil  
21 moisture sensors so it is unlikely that the increase in the instrument offset can be attributed to infiltration of  
22 melt water into the sandy soil. A more plausible explanation are manual measurement errors that could result  
23 from attempting to sample a complex snowpack containing ice layers in the pack or at the snow/soil interface.  
24 Ice layers would have formed due to mid-season melt and re-freezing. The increase in the difference between

1 the manual measurement and CS725 in mid- to late-March could be a result of snow melt infiltrating into the  
2 top layers of the sandy soil as the soil thaws or forming a basal ice layer (Woo et al., 1982; Lilbaek and  
3 Pomeroy, 2008) on top of the soil. A corresponding spike in measured soil moisture during early spring snow  
4 melt is shown in Fig. 6.

5

### 6 3.1.3 Fortress Mountain

7 The intercomparison of the CS725 instrument and the manual SWE measurements made at Fortress Mountain  
8 are shown in Fig. 3 (bottom) and summarized in Table 1. Unlike the other two sites, the CS725 and manual SWE  
9 measurements generally fall on the 1:1 line with no systematic overestimation (MRB < -5 %). This can also be  
10 seen in the time series shown in Fig. 4 (bottom). The slope of the regression line is 0.88 with a small decrease  
11 to 0.76 when excluding the ablation period. The intercept is 32.4 mm w.e. increasing to 84.4 mm w.e. when  
12 excluding the ablation period. The  $r^2$  is comparable to Sodankylä at 0.92 (increasing to 0.94 by excluding the  
13 ablation period). It is unfortunate that the sample size is relatively small ( $n=8$ ) but regardless, the instrument  
14 compares quite well to the manual measurements at this site.

15

## 16 3.2 SSG1000 vs. Manual

17 The regression analysis for the SSG1000 intercomparisons is shown in Fig. 7 with the time series for both  
18 seasons shown in Figure 8. The comparison statistics are in Table 2. This analysis, as for the CS725 above, is  
19 organized by site.

20

### 21 3.2.1 Sodankylä

22 The SSG1000 regression analysis with the manual SWE measurements shown in Fig. 7 (top) and summarized in  
23 Table 2 has an  $r^2$  for the entire 2014/2015 period of 0.99 but is only 0.84 for the 2013/2014 period. However,  
24 the SWE data from the SSG1000 is not available for the ablation period in 2014/2015 due to an instrument

1 malfunction. To have a consistent intercomparison for the two seasons, the ablation period (post maximum  
2 SWE) was removed from the 2013/2014 period and the  $r^2$  becomes 0.97, very similar to 2014/2015. Combining  
3 the two seasons, the slope of the regression,  $\beta$ , becomes 0.99 with an offset  $\epsilon$  of -7.27 mm w.e. with an  $r^2$  of  
4 0.88. The MRB for the two seasons combined is -11 %.

5

6 The time series of these data are shown in Fig. 8 (top) for both the 2013/2014 (left) and 2014/2015 (right)  
7 seasons. For both seasons, the sensor measurements track quite well with the manual measurements. The  
8 outliers that appear in Fig. 7 (top) can also be seen in the 2013/2014 time series (Fig. 8 top left) beginning mid-  
9 way through the ablation period. It is unknown if this occurs during the 2014/2015 ablation period because the  
10 data are missing due to a sensor failure caused by water damage to the electronics (an issue later remedied by  
11 the manufacturer).

12

### 13 3.2.2 Weissfluhjoch

14 The regression analysis for the SSG1000 and the manual SWE measurements is shown in Fig. 7 (bottom) with  
15 the time series in Fig. 8 (bottom). This alpine site has a much deeper snowpack than either Caribou Creek or  
16 Sodankylä but comparable to Fortress Mountain, which unfortunately did not have concurrent SSG1000  
17 measurements. The  $r^2$  for both seasons is quite high at 0.97, similar to the accumulation period  
18 intercomparison at Sodankylä, but  $\beta$  is less (0.72 and 0.82) and  $\epsilon$  is much higher (91.7 and 79.0 mm w.e.) for  
19 both seasons (2013/2014 and 2014/2015). The outliers are obvious in Fig. 8 (bottom) when the manual SWE  
20 measurements are substantially higher than the sensor measurements. Unlike Sodankylä, these outliers mostly  
21 occur before maximum seasonal SWE, which is why we don't break the season down as we do with Sodankylä.  
22 They are, however, likely a result of sensor bridging which is discussed more in Section 4. There are also  
23 outliers that occur late in the ablation periods, where the sensor substantially overestimates SWE, and these  
24 are perhaps due to issues with the manual sampling of a complex (melting or melting/refreezing) snowpack.

1 When combining the two seasons, the resulting low MRB of 8% (for combined seasons) is somewhat surprising  
2 given the obvious outliers. Perhaps the low combined MRB is a reflection of errors in one season  
3 compensating the errors in the other season.

4

5 [3.3 CS725 vs. SSG1000](#)

6 The intercomparison with manual measurements for both the CS725 and the SSG1000 are suggesting that the  
7 agreements are the most favourable during accumulation rather than during ablation. Figure 7 shows the  
8 relationship between the CS725 and the SSG1000 for both seasons at Sodankylä with the 2014/2015 season  
9 shown in red circles and the 2013/2014 season shown in blue dots (changing to blue triangles at the  
10 approximate onset of ablation). The relationship for both years appears to be linear up to the time where  
11 maximum SWE is reached. At the onset of ablation, the relationship between the instruments (shown by the  
12 blue triangles) deviates substantially from linear. This is confirmed by Table 3 which shows a higher  $r^2$  when the  
13 2013/2014 ablation period is not included in the analysis. This analysis could only be completed for the  
14 2013/2014 season since the sensor data is missing for the 2014/2015 ablation period due to malfunction.

15

16 [3.4 Sensor Reliability](#)

17 Data quality control metrics for the CS725 sensors at each of the two SPICE sites demonstrated that the  
18 instruments performed at a high level of reliability, such that over 95 % of the sensor measurements were  
19 usable for intercomparison. No malfunctions were noted and no maintenance was required at any of the sites.

20

21 For the SSG1000, data quality control metrics show that the sensors performed reliably during the  
22 accumulation periods but malfunctioned at Sodankylä late in the spring of 2014 and again early spring of 2015.  
23 At Weissfluhjoch, 99% of the 1-minute data was usable for intercomparison. At Sodankylä, the malfunctions  
24 resulted in only 83 % and 67 % of the 1-minute data, for the 2013/2014 and 2014/2015 seasons respectively,

1 being available for intercomparison. The sensor malfunctions at Sodankylä were determined to be related to  
2 water damage to the electronics. Other than this, no other malfunctions were reported or maintenance  
3 required during the intercomparison.

4

## 5 4 Discussion

6 The regression analysis between the CS725 and the manual SWE measurements resulted in  $r^2$  values ranging  
7 from 0.55 to 0.99, depending on site and season. Combined season  $r^2$  values ranged from 0.90 to 0.92.  
8 Although generally lower than the correlations of 0.99 reported for intercomparisons with other instruments  
9 by Wright et al. (2011), our correlations (averaged by season) are similar to the  $r^2$  of 0.83 that they reported for  
10 snow tube measurements. The (combined season) bias shown here, which was between 30% and 35%, is  
11 substantially higher than the 18% reported by Choquette et al. (2008). The exception to this is the CS725 at  
12 Fortress Mountain which has a mean negative bias less than 5% when compared to the manual measurements.  
13 Besides the maximum SWE, the two major differences that Fortress Mountain has from Caribou Creek and  
14 Sodankylä are the soil and the topography. Soils at the Fortress Mountain site have higher clay and loam  
15 content, overlain with a layer of organics, and generally remain frozen and saturated for the duration of the  
16 winter. These, combined with the sloping terrain and faster meltwater runoff via drainage channels, likely  
17 minimizes the change in soil moisture during the transition seasons and thereby minimizes potential offsets in  
18 the CS725 measurements. Furthermore, the correlations for the CS725 for Caribou Creek are substantially  
19 lower than for Sodankylä and Fortress Mountain. This could be for several reasons. The spatial and seasonal  
20 variability are quite high at Caribou Creek and the sample size is low. This is especially the case for 2014/2015  
21 where sample size is small due to a shorter and more variable winter where melt and re-freeze occurred  
22 several times over the course of the season (Fig. 5 middle right). Melting and re-freezing generally makes the  
23 manual SWE measurements more difficult and prone to error, creates basal ice, and results in higher spatial

1 variability. Eliminating the ablation period improved the comparison statistics for 2013/2014 but made the  
2 statistics for 2014/2015 much worse due to the reduced sample size. Potential sources of error in the CS725  
3 intercomparison are discussed further in the following sections.

4

5 The SSG1000 was quite highly correlated with the manual SWE measurements at both Sodankylä and  
6 Weissfluhjoch with  $r^2$  values as high as 0.99 at Sodankylä (when excluding the ablation period) and 0.97 at  
7 Weissfluhjoch. However, when the ablation period is included in the intercomparison for 2013/2014 at  
8 Sodankylä (it is not present in 2014/2015 at Sodankylä due to sensor malfunction), the  $r^2$  drops to 0.84. The  
9 more significant result at Sodankylä is the smaller MRB as compared to the CS725, which is -2% to -15%  
10 (depending on the exclusion of ablation). The magnitude of the MRB is similar at Weissfluhjoch but the bias  
11 here is a positive 8%. This is surprising considering the many occurrences of negative sensor bias (as seen in  
12 Figure 8 bottom) but these negative outliers are balanced by some large (albeit inconspicuous) positive outliers  
13 at the end of the ablation periods. The outliers for Sodankylä in Fig. 7 (top) occur during the ablation period in  
14 late April to May 2014 but it is difficult to ascertain if the errors are related to the instrument or to the manual  
15 measurement. The most likely explanation is that these are related to the occurrence of bridging. Bridging is  
16 also suspected as the cause of the pre-ablation outliers at Weissfluhjoch since the sensor seems to agree quite  
17 well with the manual measurements up to mid-March and early-April for both seasons. An intercomparison  
18 with a collocated snow pillow (not shown here) suggests a similar albeit smaller negative bias during the same  
19 period. Errors associated with bridging are discussed further in this section.

20

21 The CS725 and SSG1000 measurements at Sodankylä correlate very well with each other showing correlations  
22 as high a 0.99 when excluding the ablation periods. The key result here, as shown in Fig. 9, is the deviation from  
23 this linear correlation at the onset of melt in the 2013/2014 season. Although some of this deviation can be  
24 blamed on differential melting at the site, we attribute a large portion of the deviation to the different

1 measurement principles of the sensors. At the onset of melt and the ripening of the snowpack, meltwater  
2 drains out of the snowpack towards the ground surface. Once reaching the surface, the meltwater can pool  
3 and re-freeze (potentially forming a basal layer of ice), runoff from the measurement area, or infiltrate into the  
4 soil. Due to the flat measurement area and the sandy soil at Sodankylä, runoff is unlikely; therefore the  
5 meltwater is either infiltrating into the sandy soil or re-freezing at the surface. Either way, the same meltwater  
6 is likely draining through and away from the measurement plate of the SSG1000 and therefore no longer being  
7 measured as SWE in the snowpack. However, this meltwater, whether infiltrated into the top layer of the sandy  
8 soil or pooling at the surface, is still being registered by the CS725 as SWE. This contributes to the  
9 overestimation of SWE by the CS725 as compared to the SSG1000 and to the non-linearity of the  
10 intercomparison shown in Fig. 9 after ablation. Also, this meltwater is either difficult or impossible to include in  
11 a snow tube sample, increasing the bias between the CS725 and the manual measurements.

12

#### 13 4.1 Sources of error

14 There are several possible sources of error that affect both the automated and manual SWE measurements.  
15 They are discussed and analyzed for each instrument/method in this section.

16

##### 17 4.1.1 Soil moisture (CS725)

18 A potential source of error for the CS725 can arise from a poor pre-snowpack soil moisture calibration or a  
19 large post-calibration change in soil moisture prior to the freezing of the ground surface. Overwinter soil  
20 moisture changes (Gray et al., 1985) or infiltration of snowmelt water into soils (Gray et al., 2001) could also  
21 result in deviation between the manual and CS725 SWE measurements. Since the CS725 calculation of SWE is  
22 based on gamma ray counts during wet and dry periods with no snow cover, incorrect measurements or faulty  
23 assumptions with respect to the soil moisture calibrations could result in a sensor offset. Furthermore, if soil  
24 moisture levels change significantly prior to freeze-up, during winter, or during ablation, then the SWE

1 estimates derived from the sensor are less reliable. The approximate error associated with an inaccurate  
2 gravimetric soil moisture calibration, as provided by the manufacturer, is roughly 10 mm w.e. of SWE for a 0.10  
3 change in GWC. Figure 6 shows an increase in soil moisture at Caribou Creek up to a VWC of 0.18 (GWC of 0.13)  
4 prior to freeze-up in the fall of 2014, an increase of 0.03 GWC and approximately 3 mm w.e. The resulting  
5 calibration offset could explain up to 30 % of the early season difference between the instrument and the  
6 manual measurement shown in Fig. 4 (middle right) and Fig. 5 (middle right). This calibration issue would then  
7 perpetuate through the winter period and grow with any additional infiltration into the soil beneath the  
8 snowpack. It is unfortunate that this same soil moisture and soil temperature data are not available for  
9 Sodankylä or for the first season at Caribou Creek as this would have provided some verification for the  
10 calibration offset.

11

12 From Fig. 6, there appears to be a coinciding jump in the CS725 bias and the jump in soil moisture (due to  
13 above freezing soil temperatures and infiltration) in the spring of 2015 at Caribou Creek. Although the bias is  
14 not as large as that seen in mid-winter, it is a significant increase of approximately 10 mm w.e. for each of the  
15 final two intercomparison points in mid-March and early-April. Much of this 20 mm w.e. increase could be  
16 explained by a corresponding increase in soil moisture from 0.18 VWC (0.13 GWC; estimated at freeze up) to  
17 0.45 VWC (0.32 GWC; spike at thaw) or approximately 19 mm w.e., assuming that the CS725 is interpreting this  
18 near surface soil moisture as SWE.

19

20 There is some ambiguity in the soil moisture results because the soil moisture sensors are incapable of  
21 measuring moisture content below 0° C and because this is not the only source of error. However, we think  
22 that these soil measurements are useful for explaining at least some of the offsets seen between the sensor  
23 and the manual SWE measurements, especially during the transition periods. More work is needed on these  
24 linkages before a reliable sensor adjustment can be derived.

1

2    4.1.2    Ice bridging (SSG1000)

3    Ice bridging is a known issue affecting SWE measurements that are made by weight, such as snow pillows or  
4    the snow scale (e.g. Engeset et al., 2000). Bridging typically occurs when air temperature reaches 0 °C and then  
5    cools creating a melt-refreeze crust layer on the snow surface. This layer is very hard and supports the weight  
6    of the snow, thus causing an underestimate of measured SWE with further accumulation on the surface.  
7    Probable bridging situations can be seen in Fig. 7 both at Sodankylä and at Weissfluhjoch. At Sodankylä, in  
8    December 2013, March 2014 and February-March 2015, the SWE values measured by the SSG1000 do not  
9    increase as quickly as the manual measurements. At the same time, air temperature first goes above 0 °C and  
10   then cools to as low as -30 °C creating perfect conditions for ice bridging. At Weissfluhjoch, the cause of  
11   potential ice bridging is not so obvious, but it is difficult to explain the differences between manual and  
12   SSG1000 measurements otherwise. The snowpack was homogeneous (verified with terrestrial laser scans) and  
13   even though a co-located snow pillow (not shown here) showed some underestimation compared to the  
14   manual measurements, the underestimation was much smaller than by the SSG1000. However, snow pillows  
15   have been found to be less prone to ice bridging issues due to their larger surface area (Beaumont, 1966;  
16   Tollar, 1970). A more comprehensive description of the physical processes that cause measurement errors in  
17   SWE pressure sensors can be found in Johnson (2004).

18

19    4.1.3    Snow spatial variability

20    Another potential source of error in this analysis is due to the spatial variability at the intercomparison sites  
21   impacting the relative SWE between the sensor and manual measurement locations. At Sodankylä, the  
22   maximum distance between the sensors and the manual SWE measurements was 12 m for the CS725 (6 m  
23   after the move prior to the 2014/2015 season) and 25 m (16 m in 2013/2014) for the SSG1000. Unfortunately,  
24   only one SWE measurement is made at the intercomparison site, but generally the spatial variability is low with

1 snow depth exhibiting a coefficient of variation (COV) under 6 % (with a maximum snow depth of just over 80  
2 cm). Therefore, the impact of spatial variability in SWE, even with a 25 m separation, is likely quite small for  
3 most of the season. However, both webcam photos and snow depth measurements provide evidence that  
4 snow melt rates during ablation vary across the site, largely dependent on exposure. Manual snow depth  
5 measurements suggest that spatial differences in the area around the SWE measurements are small and are  
6 perhaps as high as 4 cm in mid-April of 2014 and less in mid-April of 2015. These differences obviously account  
7 for very little of the late season SWE deviation shown in Fig. 5 (top). This also suggests that the CS725 move  
8 prior to the 2014/2015 season had a low impact on sensor bias from one season to the next.

9

10 Caribou Creek, with maximum snow depths of 56 cm and 41 cm for the two consecutive seasons, exhibits a  
11 much higher spatial variability. Here, COV is about 15 % (19 %) at peak snow depth but increases to 30 % (90 %)  
12 during ablation for 2013/2014 (2014/2015). With a full 5 point snow course performed here, mean SWE  
13 maximum is approximately 125 mm w.e. in 2013/2014 and 75 mm w.e. in 2014/2015 with COV very similar to  
14 those shown for snow depth. The manual measurement used in the intercomparison is made just inside the  
15 measurement area of the sensor, approximately 5 m from the centre. Although relatively close, the higher  
16 spatial variability could result in a spatial bias, especially during ablation. For example, in 2013/2014, we  
17 estimate SWE to increase across the sensor measurement area by approximately 10 mm w.e. in late April due  
18 to differential melting as a result of exposure. With the manual measurement closer to the lower SWE estimate  
19 in the sensor measurement area, up to 25 % of the difference in SWE between the sensor and the manual  
20 measurement (as shown in Fig. 5 middle left) could be explained.

21

22 The spatial variability is not assessed for Fortress Mountain or Weissfluhjoch.

23

1      4.1.4    Experiment design

2      Some aspects of the design of the SWE intercomparison are less than ideal and often were a result of

3      compromise amongst the overall SPICE objectives, site host resources, and nationally accepted practices. These

4      compromises potentially contribute to some ambiguity of the study results and this commentary could form

5      the basis for recommendations on the design of future SWE sensor intercomparisons.

6

7      Ideally, the manual reference at each site should have been identical using the same sampling equipment at a

8      prescribed offset distance from each SWE sensor. Rather, each site host used their nationally accepted method

9      of sampling SWE (as described in Section 2.3). Distances between the manual SWE measurement and the

10     sensor varied from 5 m to 25 m, depending on site, but perhaps more significantly, the variation within the

11     sensor measurement area (especially for the CS725) was not properly assessed. This could certainly have been

12     a factor at Caribou Creek but the intense sampling within the measurement area of the sensor would have

13     caused too much disturbance and impacted sensor measurements. Also, increased frequency (i.e. weekly) of

14     manual measurements is desirable especially after significant changes in the snowpack, albeit at the risk of

15     disturbance. In the future, manual observers should pay special attention to the existence of basal ice layers

16     which may have an impact on the overall accuracy of the manual SWE estimate.

17

18     Another ideal situation would have been the co-location of both SWE sensor types at each site. This, in

19     combination with soil moisture and temperature sensors within the measurement area of the CS725 sensors,

20     would have provided additional information for the assessment of sensor bias. Another good addition would

21     be the automated and high frequency measurement of snow depth within the sensor measurement areas to

22     provide an indicator of snow density and melt rates and perhaps an indicator of snow bridging on the weighing

23     SWE sensors.

24

1 4.1.5 Manual SWE measurements

2 As noted above, the manual SWE measurements differed by site, the exception being Caribou Creek and  
3 Fortress Mountain that both used the ESC-30 snow tube and bagged and weighed the sample. We won't  
4 comment further on possible bias associated with different samplers (Farnes et al., 1983; Goodison et al.,  
5 1987), as these are generally small as compared to the differences in the measurements shown in these  
6 results. We do, however, want to address possible errors associated with the manual measurement of a  
7 complex snowpack (i.e. a snowpack with ice layers or during melt), especially with a snow tube.

8

9 During the intercomparison, both Caribou Creek and Sodankylä experienced several freeze and thaw cycles  
10 over the course of the winter (as seen in Fig. 5 top and middle) but one was especially pronounced at Caribou  
11 Creek during mid- to late-January 2015 (Fig. 5 middle right). The result of freeze/thaw is usually a "crusty"  
12 snowpack with several ice layers. In general, these characteristics make a snowpack difficult to sample with a  
13 snow tube as the tube cutters need to cut through multiple ice layers without snow escaping from the bottom  
14 of the tube (Powell, 1987; Sturm et al., 2010). It is anticipated that even an expert user will have difficulties  
15 obtaining an accurate sample in these conditions, exacerbated even more by the shallow pack found at Caribou  
16 Creek in 2014/2015. It is difficult even at the time of the sample to estimate measurement error, but it could  
17 easily result in a 5 to 10 % underestimate of SWE. Sturm et al. (2010) reported an average underestimate from  
18 a snow tube of 7.1% as compared to layer-integrated snow pit measurements. Although this may explain some  
19 of the bias in the CS725 measurements, especially at Caribou Creek, it is countered by the relatively good  
20 agreement between the manual and SSG1000 measurements for Sodankylä. However, mid-winter melting  
21 could also result in basal ice as the meltwater percolates through the snow and refreezes at the surface  
22 (providing that the surface is below 0 °C) or in the top layer of the sandy substrate. Not only would this ice  
23 layer be difficult to measure with a snow tube (which is difficult to cut through and often results in an  
24 underestimate), the meltwater may drain off of the SSG1000 measurement surface and be underestimated by

1 that measurement as well. This may partially explain the often (but sometimes inconsistent) increase in sensor  
2 bias shown by manual SWE measurements following mid-winter freeze/thaw cycles in Fig. 5 (top and middle).  
3 Unfortunately, the observer's notes did not indicate when a basal ice layer was observed so much of this is  
4 speculation.

5

6 During ablation, measures were taken to sample the snowpack before it ripened but this could not always be  
7 accomplished due to travel time to the site (especially for Caribou Creek). Because the sample was bagged and  
8 weighed rather than weighed in the tube, a wet sample would experience some errors because of the bagging  
9 process (liquid water or sticky snow left in the tube) and result in an underestimate of SWE (perhaps 5 % as a  
10 rough estimate).

11

## 12 5 Summary and Conclusions

13 Two automated SWE sensors were tested at three WMO-SPICE sites (Sodankylä, Weissfluhjoch and Caribou  
14 Creek) and at one additional Canadian site (Fortress Mountain) during the WMO-SPICE intercomparison  
15 (Northern Hemisphere) winters of 2013/2014 and 2014/2015. Instrument measurements were compared to  
16 periodic manual measurements of SWE at the sites and cross referenced with ancillary measurements of air  
17 temperature and soil moisture and soil temperature (at Caribou Creek) to try to determine causality for some  
18 of the bias seen in the intercomparison. The objective was not necessarily to determine which instrument  
19 makes the most accurate measurement, but to inform users of potential measurement issues that may  
20 influence their data interpretation.

21

22 Intercomparison results for the CS725 show that it overestimates SWE on average by 30 % and 35 % at  
23 Sodankylä and Caribou Creek respectively with combined season correlations ( $r^2$ ) of 0.92 at Sodankylä and 0.90

1 at Caribou Creek. Interseasonal variability in both the MRB and the correlations were higher at Caribou Creek,  
2 the differences attributed to smaller sample sizes, higher spatial variability of SWE, and ice layers in the  
3 snowpack. Offsets were generally higher at Caribou Creek which could be indicative of an inaccurate soil  
4 moisture calibration of the instrument, a change in soil moisture relative to the calibration prior to or after the  
5 soil freezing, or sampling errors in the manual SWE measurement due to a more complex snowpack.

6 Correlations at Fortress Mountain are also quite high over the single intercomparison season ( $r^2=0.92$ ) with a  
7 mean negative bias of approximately 5 %, which is more comparable to the results of Wright et al. (2011) in  
8 similar conditions. At the two sandy SPICE sites, the agreement between the CS725 and the manual SWE  
9 measurements are generally better prior to the start of seasonal ablation. We believe this occurs largely  
10 because of early spring melt percolating through the snowpack and either forming a basal ice layer or  
11 infiltrating into the sandy substrate. Either way, this water is difficult or impossible to measure with a snow  
12 tube. However, because this water continues to attenuate the gamma radiation signal detected by the CS725,  
13 the sensor still interprets this water as SWE and therefore appears to overestimate as compared to the manual  
14 measurements. Seasonal ablation has no significant impact on the agreement at Fortress Mountain due to  
15 saturated frozen soils that restrict infiltration and a mild slope that promotes runoff of meltwater from the site.

16

17 The SSG1000 at both Sodankylä and Weissfluhjoch, compared quite well to the manual SWE measurements  
18 showing mean biases of -11 % and 8% at the respective sites. It did, however, experience some technical issues  
19 at Sodankylä early in the 2014/2015 snowmelt period which limited the intercomparison for that season. The  
20 correlations were quite high with the combined season  $r^2$  ranging from 0.88 at Sodankylä to 0.96 at  
21 Weissfluhjoch. Many of the outliers in the SSG1000 intercomparisons are most likely due to bridging of the  
22 snowpack on the weighing plate but we also have to consider errors related to the manual measurements and  
23 other processes going on at the snow-soil-sensor interface (as outlined in Johnson, 2004). At Weissfluhjoch,  
24 these outlier events occurred prior to maximum seasonal SWE while at Sodankylä they occurred during

1 ablation. Removing the ablation period in the 2013/2014 Sodankylä data resulted in a substantial increase in  $r^2$   
2 from 0.84 to 0.97.

3

4 The SSG1000 correlated very well with the CS725 at Sodankylä during the accumulation period. Although the  
5 overestimation of SWE by the CS725 is quite apparent when compared against the SSG1000, the accumulation  
6 period  $r^2$  was 0.98 and 0.99 for the two respective seasons. Intercomparison of the two sensors clearly shows  
7 how the overestimation of SWE by the CS725 increases at the onset of ablation in March/April of the  
8 2013/2014 season. Independent of the manual measurements, this indicates that the deviation of the CS725  
9 from manual SWE during ablation is most likely instrument related and a result of the CS725 misinterpreting  
10 the melt water infiltrated into the sandy soils as SWE.

11

12 When comparing SWE instruments to a manual reference, there are several considerations that must be made  
13 that ultimately impact the interpretation of the results. We know that the manual measurements of SWE are  
14 not free of error. Experience proves that making a snow tube bulk density sample in a snowpack containing ice  
15 layers or during melt is difficult and inherently prone to errors. We also have to consider the spatial variability  
16 of the snow that we are sampling as the CS725 (and the SSG1000 to a lesser degree) have a much larger  
17 measurement area than the manual point sample. Taking this and the technical capabilities of the instruments  
18 into consideration, both sensors have high correlations (generally higher than 0.90, Caribou Creek being the  
19 exception) with the manual reference measurements. We have identified that the SSG1000 has had some  
20 technical issues during snowmelt but are satisfied that these issues can be overcome with some installation  
21 modifications. The SSG1000 may also underestimate SWE on occasion due to bridging so users need to be  
22 aware of this potential error. We have identified the potential for the CS725 measurements to be  
23 misinterpreted, especially when deployed over sandy soils and during melting conditions. Although more  
24 verification work is required on the impact of soil moisture change on the CS725 bias, aggregating sub-surface

1 moisture in the SWE estimate could potentially be useful from a hydrological perspective as it ultimately  
2 impacts the amount of water available for runoff. Nevertheless, it is recommended to co-locate the CS725 with  
3 ancillary measurements of soil moisture, soil temperature, and snow depth to guide the user in interpreting  
4 the data.

## 5 Acknowledgements and Disclaimers

6 Many of the results presented in this work were obtained as part of the Solid Precipitation Intercomparison  
7 Experiment (SPICE) conducted on behalf of the World Meteorological Organization (WMO) Commission for  
8 Instruments and Methods of Observation (CIMO). The analysis and views described herein are those of the  
9 authors at this time, and do not necessarily represent the official outcome of WMO-SPICE. Mention of  
10 commercial companies or products is solely for the purposes of information and assessment within the scope  
11 of the present work, and does not constitute a commercial endorsement of any instrument or instrument  
12 manufacturer by the authors or the WMO. We wish to thank the WSL Institute for Snow and Avalanche  
13 Research SLF for kindly providing the SSG1000 and manual SWE measurements from Weissfluhjoch as well as  
14 the countless other contributors to SPICE who helped to make the project a success. We would like to express  
15 our appreciation for the effort that the reviewers and the special issue editor provided to help us improve this  
16 manuscript with a special thanks to Dr. Charles Fierz (WSL-SLF, Davos) who provided a very thorough review  
17 with substantial and helpful feedback.
