**Abstract.** Rapid retreat of Greenland's marine-terminating glaciers coincides with regional warming trends, which have broadly been used to explain these rapid changes. However, outlet glaciers within similar climate regimes experience widely contrasting retreat patterns, suggesting that the local fjord geometry could be an important additional factor. To assess the relative role of climate and fjord geometry, we use the retreat history of Jakobshavn Isbræ, West Greenland, since the Little Ice Age maximum in 1850 as a baseline for the parametrization of a width-depth integrated ice flow model. The impact of fjord geometry is isolated by using a linearly-increasing climate forcing and testing a range of simplified geometries.

We find that the total rate of retreat is determined by external factors—such as hydrofracturing, submarine melt and buttressing by sea ice—whereas the retreat pattern is governed by the fjord geometry. Narrow and shallow areas provide stabilization points and cause delayed but rapid retreat after decades of grounding line stabilization without additional climate warming. We suggest that these geometric pinning points may be used to locate potential sites for moraine formation and to predict the long term response of the glacier. As a consequence, to assess the impact of climate on the retreat history of a glacier, each system has to be analyzed with knowledge of its historic retreat and the local fjord geometry.

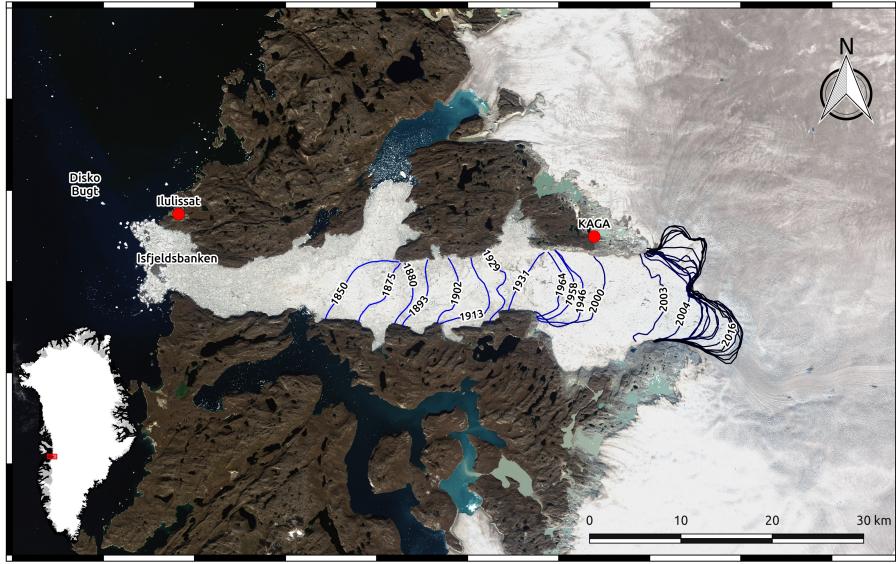

## 1 Introduction

Marine-terminating glaciers export ice from the interior of the Greenland Ice Sheet (GrIS) through deep valleys terminating in fjords (Joughin et al., 2017). Mass loss from the GrIS has increased significantly during the last two decades, contributing increasingly to sea-level rise (Rignot et al., 2011). The observed increase in mass loss has broadly been associated with large-scale atmospheric and oceanic warming (Holland et al., 2008a; Lloyd et al., 2011; Vieli and Nick, 2011; Carr et al., 2013; Straneo and Heimbach, 2013; Pollard et al., 2015). About half of the current mass loss from the GrIS is due to dynamic ice discharge (Khan et al., 2015), which is impacted by several processes partly linked to air and ocean temperatures. A warmer atmosphere enhances surface runoff, which may cause crevasses to penetrate deeper through hydrofracturing, which in turn, can promote iceberg calving (Benn et al., 2007; van der Veen, 2007; Cook et al., 2012, 2014; Pollard et al., 2015). A warmer ocean strengthens submarine melt below ice shelves and floating tongues (Holland et al., 2008a, b; Motyka et al., 2011), which can potentially destabilize the glacier via longitudinal dynamic coupling and upstream propagation of thinning (Nick

et al., 2009; Felikson et al., 2017). Increased air and fjord temperatures can additionally weaken sea ice and ice mélange in fjords, affecting calving through altering the stress balance at the glacier front (Amundson et al., 2010; Robel, 2017). Most of these processes are still poorly understood as well as heavily spatially and temporally undersampled (e.g. Straneo et al., 2013; Straneo and Cenedese, 2015).

5 Despite widespread acceleration and retreat around the GrIS, individual glaciers correlate poorly with regional trends (Warren, 1991; Moon et al., 2012; Csatho et al., 2014). For example, four glaciers alone have accounted for 50 % of the total dynamic mass loss since 2000; Jakobshavn Isbræ (JI) in West Greenland is the largest contributor (Enderlin et al., 2014). Even if exposed to the same climate, individual glaciers can respond differently, because inland mass loss can be regulated by individual glacier geometry (Felikson et al., 2017). It is well-known that grounding line stability and ice discharge is highly 10 dependent on trough geometry, with retrograde glacier beds potentially causing unstable, irreversible retreat (e.g. Schoof, 2007; Jamieson et al., 2012; Gudmundsson et al., 2012). The impact of glacier width, however, is less studied. Lateral buttressing (Gudmundsson et al., 2012; Schoof et al., 2017) and topographic bottlenecks (Jamieson et al., 2012; Enderlin et al., 2013b; Jamieson et al., 2014; Åkesson et al., 2018) have been suggested to stabilize grounding lines on reverse bedrock slopes. Despite 15 these studies showing the importance of geometry, limited knowledge still exists regarding the interplay between bedrock geometry, channel-width variations and external controls on glacier retreat. A poor understanding of the heterogeneous response of individual glaciers inhibits robust projections of sea-level rise due to mass loss from ice sheets. So far, there has been a strong emphasis on the role of ice-ocean interactions as a key control on the retreat of marine-terminating glaciers, disregarding the influence of trough geometry (e.g. Holland et al., 2008a; Joughin et al., 2012; Straneo and Heimbach, 2013; Fürst et al., 2015; Cook et al., 2016). Also, studies that focus on the control of geometry so far only model synthetic glaciers (e.g. Schoof, 2007; 20 Enderlin et al., 2013b), prohibiting validation and justification of model parameters. In this paper, we therefore use a real-world glacier geometry to study the geometric controls on glacier retreat.

Several attempts to model JI have been made to understand the dynamics behind the observed acceleration and retreat (Vieli and Nick, 2011; Joughin et al., 2012; Nick et al., 2013; Muresan et al., 2016; Bondzio et al., 2017). These studies focus on the time period past 1985 and partly into the future. However, our understanding and model capacity should span long 25 (centennial) timescales given the current exceptional rapid changes if we are to predict changes into the future. JI has a history of step-wise and non-linear retreat, that we aim to understand by comparing modeling results with observations since the LIA from 1850 into the present. Since the deglaciation of Disko Bugt between 10.5–10.0 thousand years before present (kyr BP) (Ingólfsson et al., 1990; Long et al., 2003), JI has experienced alternating periods of fast retreat and stabilization with the formation of large moraine systems (e.g. at Isfjeldsbanken, Fig. 1; Weidick and Bennike, 2007). Most observations exist after 30 the Little Ice Age (LIA) maximum in 1850 (Fig. 1), when the glacier started retreating again after a period of frontal advance. From 2001 until May 2003 it accelerated significantly after the disintegration of its 15 km long floating tongue (Thomas et al., 2003; Joughin et al., 2004; Luckman and Murray, 2005; Motyka et al., 2011). Today, it is the fastest glacier in Greenland (Rignot and Mouginot, 2012) with a maximum velocity of  $18 \text{ km yr}^{-1}$  (measured in summer 2012; Joughin et al., 2014) and ice discharge rates of about  $27\text{--}50 \text{ km}^3 \text{ yr}^{-1}$  (Joughin et al., 2004; Rignot and Kanagaratnam, 2006; Howat et al., 2011; 35 Cassotto et al., 2015). With a contribution of 4 % to global sea-level rise in the 20th century (IPCC, 2001), JI is the largest

**Figure 1.** Glacier front positions of JI from Khan et al. (2015) (1850–1985) and CCI products derived from ERS, Sentinel-1 and LADSAT data by ENVO (1990–2016). The background map is a LADSAT-8 image from 16 August 2016 (from the U.S. Geological Survey). Location names that occur in the text are marked. The inset shows the location of JI in Greenland.

contributor in Greenland (Enderlin et al., 2014). It is also one of the most vulnerable glaciers of the GrIS, with recent thinning potentially propagating as far inland as one third of the distance across the entire ice sheet (Felikson et al., 2017). Combining these centennial observations with dynamic flow modeling is crucial for putting the recent dramatic changes into a long-term perspective, but also for interpreting palaeo records and for future projections.

5 The aim of this study is to investigate the external, glaciological and geometric controls on JI in response to a linear forcing on a centennial timescale. We use a simple numerical ice flow model (e.g. Vieli and Payne, 2005; Nick et al., 2010) with a fully-dynamic treatment of the calving front to assess the relative impact of geometry and climate forcing on the retreat of JI from the LIA maximum to present-day. Geometric controls are isolated (a) using a linear forcing to avoid complex responses and (b) artificially straightening the trough width and depth. The study extends to a centennial timescale to account for internal glacier  
10 adjustment. The application of the model on a real glacier enables a comparison of model results with long-term observed velocities and front positions, but also ensures the use of realistic dimensions for the width-depth ratio, velocities, and model parameters.

15 In Sect. 2 of this paper, the numerical ice flow model is described, followed by Sect. 3 which describes the specific setup used for the simulations. In Sect. 4, the results of the forcing and geometry experiments are presented. Section 5 discusses the limitations of the model and stresses the importance of trough width versus depth as well as the implications for understanding the past.

## 2 Modelling approach

A simple width and depth integrated flowline model (Nick et al., 2010) is used for this study. Despite many assumptions made, it is well suited to study the general long-term (centennial) retreat pattern of an outlet glacier with high-basal motion (such as JI). It is based on continuity and a balance between driving stress, longitudinal stress gradient and basal and lateral drag. The 5 model benefits from a robust treatment of the grounding line (Pattyn et al., 2012) that is consistent with Schoof (2007) and a fully dynamic marine boundary (Nick et al., 2010). Also, it is more efficient than complex models (Muresan et al., 2016; Bondzio et al., 2016), which enables many model runs and the coverage of a centennial timescale. The used physical calving law has been successfully tested on several outlet glaciers against observations (Nick et al., 2013) and has the advantage of allowing for a dynamic and free migration of the glacier terminus given changes in climate forcing. The climate forcing is 10 implemented as a slow linear change in surface mass balance, crevasse water depth, submarine melt and buttressing by sea ice—model parameters that represent impacts by temperature. In this section, the physical approach, parameterizations and the implementation of climate forcing are described.

### 2.1 Numerical ice flow model

The width and depth integrated numerical ice flow model is constructed for marine-terminating glaciers (Vieli et al., 2001; 15 Vieli and Payne, 2005; Nick et al., 2009, 2010). Ice thickness variations with time are calculated from the along-flow ice flux and mass balance, using a width- and depth integrated continuity equation

$$\frac{\partial H}{\partial t} = -\frac{1}{W} \frac{\partial (HUW)}{\partial x} + \dot{B}. \quad (1)$$

$H$  is the ice thickness,  $W$  the width,  $U$  the velocity and  $x$  the along-flow component. The mass balance  $\dot{B}$  includes the surface mass balance (SMB) and submarine melt below the floating tongue described in Sect. 2.3.

20 The ice flux is controlled by a balance of lateral and basal resistance, along-flow longitudinal stress gradient and driving stress. Lateral resistance is parametrized using a width-integrated horizontal shear stress (van der Veen and Whillans, 1996) and we use a Weertman-type basal sliding law based on effective pressure (Fowler, 2010). The longitudinal stress gradient is dependent on the effective viscosity  $\nu$ , which is non-linearly dependent on the longitudinal strain rate  $\dot{\epsilon}_{xx}$  and the rate factor  $A$  (Nick et al., 2010). The stress balance is calculated as

$$25 \quad 2 \frac{\partial}{\partial x} \left( H \nu \frac{\partial U}{\partial x} \right) - A_s \left[ \left( H - \frac{\rho_s}{\rho_i} D \right) U \right]^{1/m} - \frac{2H}{W} \left( \frac{5U}{EAW} \right)^{1/n} = \rho_i g H \frac{\partial s}{\partial x}, \quad (2)$$

where  $s$  is the surface elevation,  $g$  the gravitational acceleration,  $D$  is the depth of the glacier below sea-level and  $\rho_i$  and  $\rho_s$  are the densities of ice and ocean water, respectively.  $n$  and  $m$  are the exponents for Glen's flow law and sliding relations, respectively. The lateral enhancement factor  $E$  for reducing lateral resistance and the basal sliding parameter  $A_s$  are model parameters that are adjusted to roughly match the observed flow and ice thickness for the present geometry. Both parameters 30 are constant along the flowline and in time. The dependency of the basal resistance on effective pressure is accounted for through the term  $H - \frac{\rho_s}{\rho_i} D$ .

The grounding line position is calculated with a flotation criterion based on hydrostatic balance (van der Veen, 1996). Its treatment relies on a moving grid that adjusts freely to the new glacier length at each time step, continuously keeping a node at the calving front (Vieli and Payne, 2005; Nick et al., 2009, 2010). This allows for a precise simulation of the glacier front and grounding line position using high grid resolution. The grid size is  $\Delta x = 302$  m initially and reduces to  $\Delta x = 292$  m at the 5 present day position due to the use of a stretched grid. At the marine terminus, a dynamic crevasse-depth calving criterion is used and further explained in Sect. 2.2.

## 2.2 Calving law

The here used fully-dynamic crevasse-depth criterion calculates calving where the sum of surface and basal crevasse depth ( $d_s$  and  $d_b$ , respectively) penetrate the whole glacier thickness (Nick et al., 2010). The depth of surface crevasses is given by

$$10 \quad d_s = \frac{R_{xx}}{\rho_i g} + \frac{\rho_w}{\rho_i} d_w, \text{ with } R_{xx} = 2 \left( \frac{\dot{\epsilon}_{xx}}{A} \right)^{1/n}. \quad (3)$$

as the sum of tensile deviatoric stresses  $R_{xx}$  and additional water pressure from melt water filling up the crevasses (Nye, 1957; Nick et al., 2010). Note that the water depth in crevasses  $d_w$  is not a physical quantity, but a forcing parameter within the calving model that links calving rates to climate.  $\rho_w$  is the density of freshwater. The tensile deviatoric stress is the difference between tensile stresses that pull a fracture open and the ice overburden pressure. It is calculated via Glen's flow law from the 15 longitudinal stretching rate  $\dot{\epsilon}_{xx}$ , which is responsible for the opening of crevasses by

$$\dot{\epsilon}_{xx} = \frac{\partial U}{\partial x} = f_i A \left[ \frac{\rho_i g}{4} \left( H - \frac{\rho_s}{\rho_i} \frac{D^2}{H} \right) \right]^n \quad (4)$$

in dependency of a sea ice factor  $f_i$ , which accounts for reduced buttressing due to weakening of ice mélange. The depth of basal crevasses is calculated from tensile deviatoric stresses and the height above buoyancy (Nick et al., 2010).

$$d_b = \frac{\rho_i}{\rho_s - \rho_i} \left( \frac{R_{xx}}{\rho_i g} - \left( H - \frac{\rho_s}{\rho_i} D \right) \right) \quad (5)$$

20 Water in crevasses and sea ice buttressing are both model parameters that impact the glacier response by changing the calving rate. Because the parameters are linked to different processes, they are kept separate in the model to enable a distinct forcing.

## 2.3 Atmospheric and ocean forcing

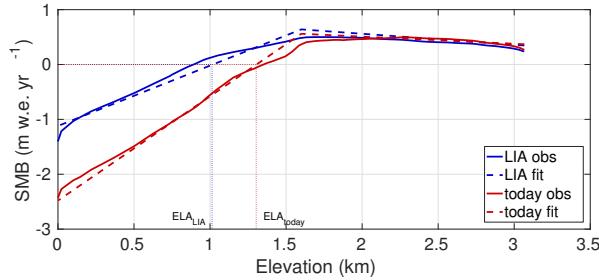

The model SMB,  $a$ , is derived from observed monthly mean SMB data at JI (Box, 2013) which are based on a combination of meteorological station records, ice cores, regional climate model output and a positive-degree day model. Its implementation 25 in our model consists of a piecewise linear function of surface elevation separated by a transition height  $s_0$ : the steep lower part where the SMB increases with elevation and the flat upper part of low precipitation where the SMB decreases with elevation (Eq. 6).

$$a(x) = \left( a_0 - \frac{da}{dx} \cdot s_0 \right) + \frac{da}{dx} \cdot s(x); \text{ with } \frac{da}{dx} = \begin{cases} G_l & \text{for } s(x) \leq s_0 \\ G_u & \text{for } s(x) > s_0 \end{cases} \quad (6)$$

**Table 1.** List of variables, physical parameters and constants used in the model. The forcing parameters with their initial (LIA) values are given in the lower part. Parameter values used for the glacier retreat experiments are listed in Table 2.

Symbol	Definition	Value	Unit
$H$	glacier thickness		m
$t$	time		yr
$W$	glacier width		m
$x$	along-glacier coordinate		m
$U$	velocity		$\text{m yr}^{-1}$
$B$	mass balance		$\text{m yr}^{-1}$
$\nu$	viscosity		$\text{Pa yr}$
$D$	depth below sea-level		m
$s$	surface elevation		m
$d_b$	depth of basal crevasses		m
$d_s$	depth of surface crevasses		m
$R_{xx}$	tensile deviatoric stress		Pa
$\dot{\epsilon}_{xx}$	longitudinal strain rate		$\text{m yr}^{-2}$
$Q_L$	lateral ice flux		$\text{m yr}^{-1}$
$a$	surface mass balance (SMB)		$\text{m yr}^{-1}$
$s_0$	transition height for SMB	1600	m
$g$	gravitational acceleration	9.8	$\text{m yr}^{-1}$
$\rho_i$	ice density	900	$\text{kg m}^{-3}$
$\rho_s$	ocean water density	1028	$\text{kg m}^{-3}$
$\rho_w$	fresh water density	1000	$\text{kg m}^{-3}$
$m$	sliding exponent	3	
$n$	Glen's flow law exponent	3	
$A$	rate factor taken from Cuffey and Paterson (2010)	$A(-20^\circ\text{C}) - A(-5^\circ\text{C})$	$\text{yr}^{-1} \text{Pa}^{-3}$
$A_s$	basal resistance parameter	120	$\text{Pa m}^{-2/\text{m}} \text{s}^{-1/\text{m}}$
$E$	lateral enhancement	10	
$dx$	grid size	250–300	m
$dt$	time step	0.005	yr
<i>Perturbation parameters with their initial LIA values</i>			
$m$	submarine melt rate	175	$\text{m yr}^{-1}$
$d_w$	crevasse water depth	160	m
$G_l$	lower SMB gradient	0.0011	$\text{m yr}^{-1}$
$G_u$	upper SMB gradient	-0.002	$\text{m yr}^{-1}$
$a_0$	maximal SMB	0.64	$\text{m w.e. yr}^{-1}$
$f_i$	sea ice buttressing factor	1	

Figure 2 shows the observed and linearly approached SMB profiles for the LIA period (1840–1850 average) and for present-day. The corresponding values for the vertical gradients  $G_l$  and  $G_u$  as well as the SMB  $a_0$  at the height  $s_0$  are given in Tables 1 and 2.

**Figure 2.** SMB profiles along JI's main flowline at the LIA (1840–1850 average) and present-day (2002–2012 average) from observations by Box (2013) and the linear fit used in the model. Thin dotted lines show position of the equilibrium line altitude (ELA) for the present day and LIA fit.

Submarine melt is implemented in the model as a vertical melt rate that decreases the glacier thickness seaward of the grounding line and is assumed to be spatially uniform. The thereby induced artificial step decrease in ice thickness is smoothed out in the model by a grounding line flux an order of magnitude larger than the submarine melt rates and a sufficiently small time step. Sensitivity analysis with along-flow variations (Motypka et al., 2011) in submarine melt show similar results as long as the constant value is comparable with the along-flow averaged submarine melt rate.

#### 2.4 Lateral ice flow

The model domain covers the full drainage basin towards the ice divide at about 520 km upstream of the present-day position. For the lowermost 77 km, we restrict the model width to the pronounced narrow channel seen in bed topography data to realistically account for lateral and basal stresses. Lateral ice flow into this narrow channel from the surrounding ice sheet and tributary glaciers is here implemented as an additional SMB similar to previous studies (Nick et al., 2013; Jamieson et al., 2014; Lea et al., 2014) to get a realistic mass flux into the lower channel. This lateral influx  $Q_{L,0}$  is initially calculated as the sum of the northern and southern lateral fluxes given by observed velocity  $U_{L,0}$  and thickness  $H_{L,0}$  (Rignot and Mouginot, 2012; Morlighem et al., 2014) at each grid point along the lateral boundary of the narrow main channel divided by the width of the main trough  $W_{JI}$  (Eq. 7). The strength of the initial influx is indicated by the arrows in Fig. 3 and locally accounts to about 100 times the SMB, with a maximum of  $120 \text{ m yr}^{-1}$ .

We assume that the relative contribution of the lateral flux to the overall flux is constant in time; therefore, we scale it with the change in the overall flux with time (Eq. 8).

$$Q_{L,0}(x) = \frac{U_{L,0}(x) \cdot H_{L,0}(x)}{W_{JI}(x)} \quad (7)$$

$$Q_{L,t}(x) = Q_{L,0}(x) \cdot \frac{Q_{JI,t}(x)}{Q_{JI,0}(x)} \quad (8)$$

$Q_{JI,0}$  and  $Q_{JI,t}$  are thereby the initial overall flux through the main trunk and the flux after time  $t$ , respectively. Note that the constant relative contribution by side fluxes is a rough approximation, because a thinning of the main trunk could initiate a speed up in the tributary glaciers due to the increased surface slope.

### 3 Model setup

5 Despite the general focus of this study on the external versus geometric controls on glacier retreat, we apply the model to JI—a real glacier. The intention is to use a realistic along-glacier geometry to compare modeled thickness, length and velocity with observations. Observations of velocities, calving front positions, ice thickness, and ice discharge (Joughin et al., 2004, 2014; Howat et al., 2014; Khan et al., 2015) are used to tune model parameters. In the following, we distinguish between constant parameters (basal sliding parameter, rate factor and lateral enhancement factor) and climate-related perturbation parameters  
10 (SMB, submarine melt rate, crevasse water depth and sea ice buttressing). For the model experiments, the perturbation parameters are changed linearly from their LIA values to simulate generally increasing temperatures. Importantly, the calving front and grounding line evolve freely during retreat. Only those combinations of forcing parameters, that simulate a total retreat rate matching the observed retreat of about 43 km from the LIA to 2015, are considered. In the following, the choice of tuning parameters and the perturbations are elucidated together with related observations.

15 **3.1 Model glacier geometry**

JI expands 520 km inland towards the ice divide and is mainly distinct from the surrounding ice sheet by its high velocities along the deep trough. The geometry of the model glacier consists of a narrow (in average about 5.4 km wide) and deep (1.3 km at the deepest) trough; further upstream, it widens gradually with a relatively flat and shallow bottom. The fjord width in the today's ice free area is obtained from satellite images (Fig. 1) and the channel width in the fast flowing part (77 km upstream  
20 of the 2015 position) is defined as the trough width at the present-day sea-level from topography data by Morlighem et al. (2014). Further upstream, where the catchment widens gradually, the width is defined following Nick et al. (2013). For the one-dimensional glacier depth in the deep trough and fjord, we use the along-flow bed topography profile as it is presented in Boghosian et al. (2015). The fjord bathymetry is therein obtained from Operation IceBridge gravity data and the subglacial  
25 trough profile from high-sensitivity radar data by Gogineni et al. (2014). For the bed in the wider catchment area, 150 m resolution data by Morlighem et al. (2014) are averaged over the glacier width.

### 3.2 Constant parameters

Most observations only exist for present-day. Parameters that are constant in time (basal resistance parameter, lateral enhancement factor and rate factor) are therefore tuned with those observations to obtain a steady-state glacier that corresponds to the observed present-day glacier geometry. Climate-related perturbation parameters are set to values corresponding to present-day.  
30 After tuning the constant parameters, the climate-related perturbation parameters are reduced to colder temperatures to achieve a steady-state at observed LIA front position that is used as initial setup. For the LIA steady-state, the only constraints are given

by the LIA front position (Khan et al., 2015) and the height of the LIA trimline found at the Global Positioning System (GPS) station KAGA (Fig. 1; Jeffries, 2014) by Csatho et al. (2008).

Basal sliding—as implemented in the model— influences ice flow and hence the surface slope and thickness. The basal sliding parameter  $A_s = 120 \text{ Pa m}^{-2/3} \text{ s}^{-1/\text{m}}$  is chosen to achieve an observed present-day thickness of 3065 m at the ice divide (Howat et al., 2014); the present-day thickness in the interior is also valid for the LIA initialization because the ice sheet is assumed to be in steady-state above 2000 m of elevation within this time period (Krabill, 2000). We keep the basal sliding parameter constant in time, because the impact of increased melt on basal sliding on interannual timescales is still unclear (Sole et al., 2011; Tedstone et al., 2015). Also, the model takes into account the dependency of basal sliding on the effective pressure, which is calculated explicitly. The actual degree of basal resistance at the bed of JI is highly debated with some studies explaining high surface velocities as reflecting a slippery bed (Lüthi et al., 2002; Shapero et al., 2016), whereas other studies use weakened shear margins as main explanation for high velocities (e.g. van der Veen et al., 2011) or an interplay of both processes (Bondzio et al., 2017).

The surface profile and velocity are in addition determined by the lateral resistance and the rate factor. A uniform lateral enhancement factor is applied along the whole glacier and controls the strength of the transmission of lateral drag to the sides. A value of  $E = 10$  achieves best a present-day surface corresponding to observations (Howat et al., 2014). The rate factor for Glen’s flow law is in a first approximation a function of ice temperature and here set to values corresponding to temperatures of  $-20^\circ\text{C}$  at the ice divide linearly increasing to  $-5^\circ\text{C}$  at the terminus (Cuffey and Paterson, 2010), which provides present day glacier surface and velocities closest to observations (Howat et al., 2014; Joughin et al., 2014). The rate factor is here kept constant in time.

### 20 3.3 Forcing experiments and perturbation parameters

The climate-related perturbation parameters are tuned for the LIA steady-state to simulate the observed glacier length and velocities or ice discharge. A retreat of the initial LIA glacier is then forced with simultaneous linear changes in SMB, crevasse water depth, submarine melt rate and sea ice buttressing. The parameter perturbations are combined to force a total retreat of 43 km from 1850 to 2015, corresponding to the observed retreat. Nine different combinations that satisfy the observations and cover a wide range of perturbations are presented here. Table 2 shows the values that each parameter reaches in 2015 for the nine different model runs.

SMB is the only purely physical and well known parameter both for LIA and today (Box, 2013). The piecewise-linear function presented in Section 2.3 is a good approximation to the observed profiles (Figure 2) and is therefore used here. All model experiments use the same gradual changes of the SMB gradients and maximal SMB from the LIA values to present day values (Table 2).

Submarine melt is influenced by ocean temperatures, which have increased from about  $1.5^\circ\text{C}$  in 1980 to  $3^\circ\text{C}$  in 2010 in Disko Bugt (Lloyd et al., 2011) with a  $1^\circ\text{C}$  warming in 1997 (Holland et al., 2008a; Hansen et al., 2012). Jenkins (2011) estimates about a doubling of melt rates underneath the tongue of JI (depending on initial conditions and the way in which melting is applied), when considering a  $1^\circ\text{C}$  warming and steepening of the glacier front. Submarine melt rates may additionally be

enhanced by increased subglacial ice discharge (Jenkins, 2011; Xu et al., 2012, 2013; Sciascia et al., 2013), although this may be a local effect and negligible when with-averaged (Cowton et al., 2015). Observations of submarine melt rates beneath JI's floating tongue suggest an annual melt rate of  $228 \pm 49 \text{ m yr}^{-1}$  between 1984 and 1985 (Motyka et al., 2011) and  $2.98 \text{ m d}^{-1}$  ( $1087 \text{ m yr}^{-1}$ ) averaged over the melt seasons in 2002 and 2003 (Enderlin and Howat, 2013). Since submarine melt rate is 5 otherwise poorly constrained, especially further back in time, we conduct a large range of linear forcing, from no increase, to a two-fold increase of the LIA value of  $175 \text{ m yr}^{-1}$  to  $340 \text{ m yr}^{-1}$  in 2015. Note that the model neglects submarine melt at the vertical calving front.

The crevasse-water depth has not been measured and is here a non-physical model parameter that regulates discharge fluxes. It is therefore likely exaggerated to account for the lack of submarine melt at the vertical glacier front in the model. For the 10 LIA steady-state, the crevasse water depth is set to 160 m, which produces the observed glacier length and a calving rate of  $34 \text{ km}^3 \text{ yr}^{-1}$  in 1985, which is in the same order of magnitude as the observed calving rate of  $26.5 \text{ km}^3 \text{ yr}^{-1}$  in 1985 (Joughin et al., 2004) and more recent values obtained from other studies ( $24\text{--}50 \text{ km}^3 \text{ yr}^{-1}$ ; Rignot and Kanagaratnam, 2006; Howat et al., 2011; Cassotto et al., 2015). The increase in crevasse water depth with time is unknown, but may be related to the 15 increase in runoff, which has increased by 63 % since the LIA (Box, 2013). To account for such a large range, we increase the crevasse water depth from its LIA value depths to values between 185 m and 395 m in 2015. It is thereby tuned depending on the combination of sea ice buttressing and submarine melt rate to reach the observed retreat (Table 2).

Ice mélange in the fjord can apply a buttressing stress to the calving front of about 30-60 kPa or one tenth of the driving stress (Walter et al., 2012). With increasing air and ocean temperatures, ice mélange can weaken or break-up, largely influencing iceberg calving (e.g. Sohn et al., 1998; Reeh et al., 2001). However, the correlation is poorly known and break-up of ice 20 mélange is thought to impact frontal migration on a daily to seasonal timescale, leaving annual fluxes unaffected (Amundson et al., 2010; Walter et al., 2012; Todd and Christoffersen, 2014; Cassotto et al., 2015; Todd et al., 2018). We conduct experiments with unchanged sea ice buttressing ( $f_s = 1$ ; also used for the LIA steady-state) as well as decreased buttressing by a factor two and three compared to the LIA value in 2015.

In order to reach the observed retreat position in 2015 in all combinations presented in Table 2, the 2015-values for each 25 parameter depend on the values for the other parameters. This means e.g. that a low submarine melt rate is needed in case of reduced sea ice buttressing and a small crevasse water depth or that the crevasse water depth has to be large when sea ice buttressing is not reduced and the submarine melt rate small.

In addition to experiments with linearly increased parameters, we also conduct one experiment with a step increase in the four parameters after the LIA maximum. The values for sea ice buttressing, submarine melt rate, water depth in crevasses and 30 SMB applied in 1850 for the step increase are comparable to those reached in year 2015 in run 5, with slightly different values to reach the right front position in 2015. All experiments shown in Table 2 are run until 2100 to expand the temporal and spatial dimensions to show the importance of the geometry.

Despite a relatively high number of frontal observations since the LIA (Fig. 1), only the observed calving front positions in 1850 and 2015 are used here to tune the parameters; in between, the forcing parameters increase linearly and the glacier 35 length evolves freely. We present the time evolution of the simulated front positions together with observations. To obtain one-

**Table 2.** Nine combinations of the perturbation parameters used in this study. Values shown here are those reached in 2015 after a linear perturbation from their LIA value shown in Table 1. Values for the SMB are perturbed to the same 2015-values for all model runs:  $G_l = 0.0019 \text{ yr}^{-1}$ ,  $G_u = -0.00013 \text{ yr}^{-1}$ ,  $a_0 = 0.64 \text{ m w.e. yr}^{-1}$ . Run 5 (in bold) is presented in more detail in the paper.

dimensional observed front positions, we assume the trough to be approximately east-west oriented. We calculate the mean latitudinal coordinate of each observed calving front (Fig. 1) with the corresponding longitudinal position at that latitude. The positions of the resulting one-dimensional front positions lie approximately in the center of the trough. The uncertainty of the front positions is calculated as the maximal spread of each front in cross-trough direction.

### 5 3.4 Geometric experiments

In addition to the effect of forcing, we also try to investigate the effect of fjord geometry and the relative importance of bed topography versus channel width. We design experiments with a smoothed width and depth in the deep and narrow trough. Four different geometry combinations are constructed and shown in Fig. 3.

**a** Original geometry: Observed width and depth of the trough as described in Sect. 3.1.

10 **b** Straight width: The width until 80 km inland of today's front is set to a constant value of 5.4 km. Only at the LIA front position, a wide section is kept in order to reach a steady-state with the same parameters. The depth is kept as in **a**.

**Figure 3.** Different model geometries used to investigate the impact of topography on ice dynamics. (a) Original geometry, (b) straight width, (c) straight bed and (d) straight width and bed. Arrows indicate the tributary ice flux, with their length representative for the influx volume.

**c** Straight bed: The bed of the deep trough to 120 km inland of today's front is smoothed to get an almost straight bed, linearly rising inland. The width is kept as in a.

**d** Straight width and bed: Both, the width and the bed are straightened here.

The runs with simplified geometry start from steady-state at the LIA front position with the same parameters and forcing  
5 as for the original model setup (Table 2). Due to the changed topographies, the glacier surfaces and velocities differ from the original geometry and the LIA front position is slightly changed.

## 4 Results

In this section, we present the steady-state glacier at the LIA maximum extent and the glacier retreat simulated with run 5 (Table 2) as an example. In addition, the response to different forcing parameter combinations, more simplified geometries and  
10 a step forcing is presented.

#### 4.1 Jakobshavn Isbræ at the LIA maximum

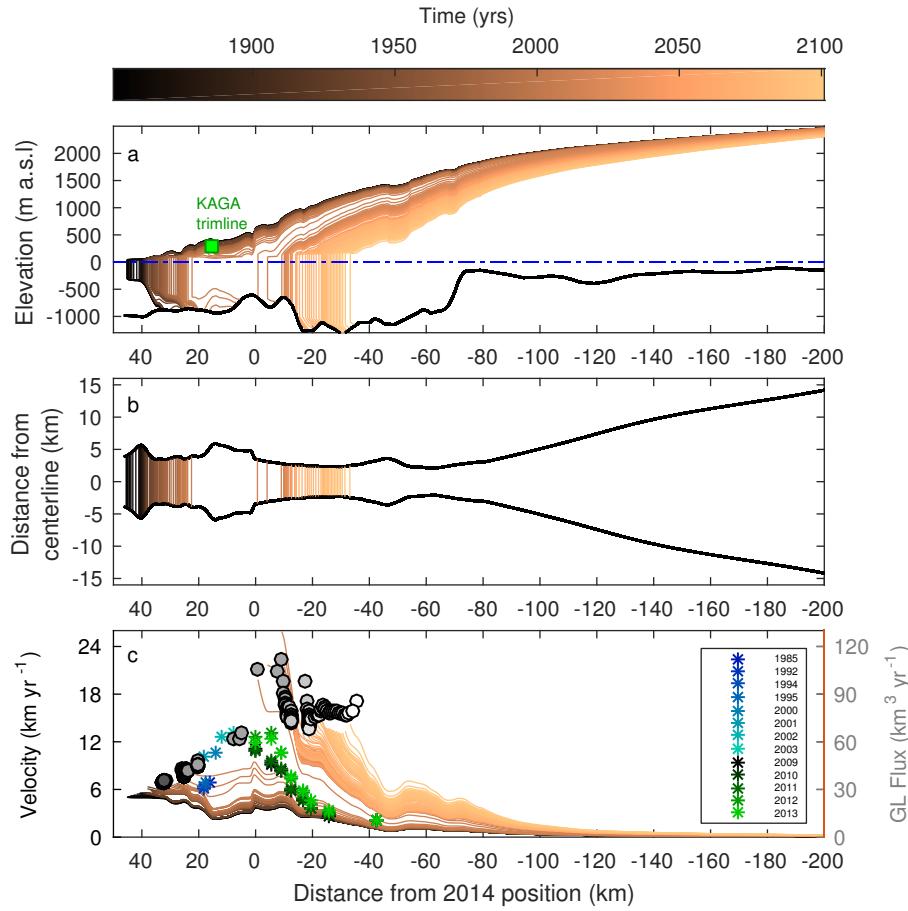

The initial steady-state glacier as shown in Fig. 3a and 5a is reached with the parameters in Table 2. It has an uneven surface that reflects the trough geometry, which is common for fast flowing ice streams (Gudmundsson, 2003). At the position of KAGA, the surface elevation reaches about 400 m compared to the 300 m of the LIA-trimline height (Figure 4a; Csatho et al., 2008);

5 however, the side margins are expected to be lower than the centerline and the model glacier has a—probably overestimated—surface bump at that position. The LIA glacier terminates with a 9 km-long floating tongue, where it has a velocity of  $5 \text{ km yr}^{-1}$  and a grounding line flux of  $35 \text{ km yr}^{-1}$ . The modeled width-averaged basal shear stress for the LIA is about 128 kPa at 40 km inland of the present-day front position and the driving stress is 290 kPa at that location, when applying a 3 km moving average to smooth the surface bumps. In comparison, other modeling studies obtain lower basal resistance (Joughin et al., 10 2012; Habermann et al., 2013) and data assimilation methods imply basal stresses at the bed of the deep trough of about 65 kPa at 50 km upstream of the calving front, equivalent to only 20 % of the driving stress (Shapero et al., 2016). However, these estimates are from present day and it is unknown how much the relative contribution of the stresses have changed over the time period. During the speed up, the basal shear stress might have reduced in the lowermost 7 km and not changed further upstream (Habermann et al., 2013). Note also that the stresses provided by the model are width-averaged.

#### 15 4.2 Non-linear glacier response to linear forcing

Figures 4 a,b show that the modelled front position retreats non-linearly in response to the linear external forcing (shown here is run 5 in Table 2). It retreats 21 km during the first 163 years, after which a 16 km long floating tongue forms. During the break-off of the tongue in 2013 to 2014, the front retreats a further 23 km. Throughout the retreat, the glacier terminus configuration alternates between a floating tongue and a grounded front. The front velocities (Fig. 4c) only increase by  $3 \text{ km yr}^{-1}$  during the 20 first 163 years and more than double from  $8 \text{ km yr}^{-1}$  to  $19 \text{ km yr}^{-1}$  when the floating tongue breaks off. This acceleration is overestimated, as the simulated tongue breaks off faster than observed. However, velocity observations Joughin et al. (2004, 2014), shown in Fig. 4c, are smaller than the simulated in the early 1990s, but are in-between the simulated velocities before and 25 after the break-off. The model simulations show that the acceleration continues until the retreat of the front slows down. The grounding line flux, calculated as the grounding line velocity times the grounding line gate area, increases from  $35 \text{ km}^3 \text{ yr}^{-1}$  to  $65 \text{ km}^3 \text{ yr}^{-1}$  from the LIA until 2015 compared to observed values of about  $32\text{--}50 \text{ km}^3 \text{ yr}^{-1}$  between 2005 and 2012 (Rignot and Kanagaratnam, 2006; Howat et al., 2011; Cassotto et al., 2015). Beyond 2015 it increases to  $100 \text{ km}^3 \text{ yr}^{-1}$  and finally stagnates with  $77 \text{ km}^3 \text{ yr}^{-1}$ .

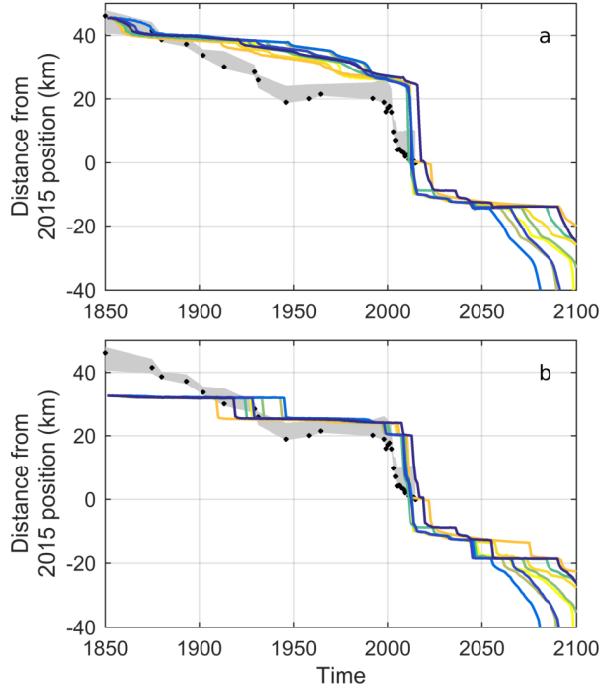

Various parameter combinations presented in Table 2—and many more that are in-between those presented here—force the 30 observed total retreat since the LIA. Figure 5 shows the retreat of the glacier front and grounding line with time for the applied nine parameter combinations. The simulated temporal retreat pattern of the frontal retreat—despite the linear forcing (Fig. 5a). The response to the different forcing experiments differs mainly in the timing of the phases of rapid retreat, especially the final retreat just after 2050. All model runs show a very abrupt retreat of at least 23 km within a few years, which corresponds to the observed retreat of 19 km after

**Figure 4.** Modeled retreat of JI in response to a gradual change of the forcing parameters (run 5 in Table 2). Yearly profiles are shown for (a) the along-flow glacier profile and the elevation of the KAGA LIA trimline (Csatho et al., 2008) in green, (b) the front positions in a top-view and (c) the along-glacier annual velocities including the yearly grounding line (GL) flux (grey circles from dark to light with time). Observed yearly velocities are plotted at the calving front from 1985 to 2003 (Joughin et al., 2004) and at seven different points upstream from the glacier front from 2009 to 2013 (Joughin et al., 2014).

year 2000. The simulated frontal positions differ from those observed, which is expected due to the strong simplification of the forcing. The aim is here to study the geometric controls on rapid retreat rather than tuning the model until the simulated retreat fits the observations. The reasons for the deviation of the simulations from the observations is discussed in Sect. 5.

The grounding line retreats more step-wise (Fig. 5b) compared to the glacier front. Before 2015, it stabilizes at distances of 32 km, 25 km and 20 km from the 2015 frontal position for all experiments. It retreats more gradually beyond 2015 with short stabilizations at 8 km, 12 km and 18 km upstream of the present-day position. The forcing parameter combination thereby determine the timing of the grounding line displacement.

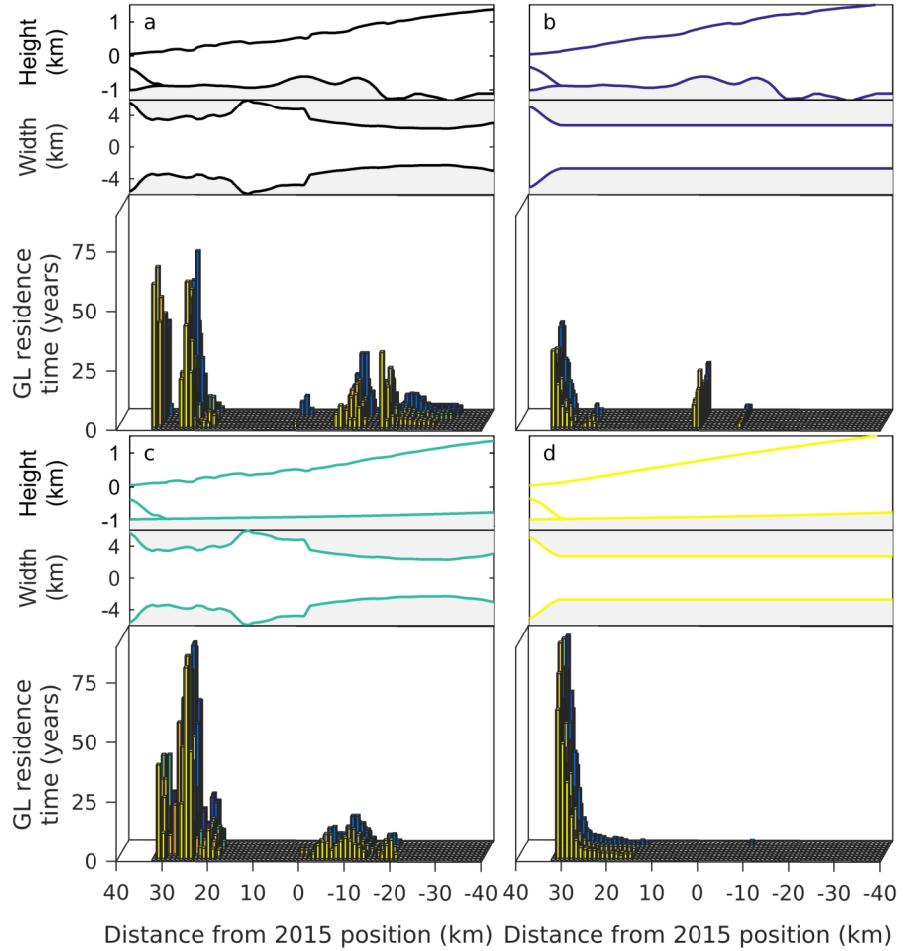

**Figure 5.** Simulated position of (a) the front and (b) the grounding line for nine different gradual forcing combinations presented in Table 2. The colors for the different model runs are random. Black dots show the observed front positions at the centreline with a spread (grey shading) corresponding to the across-fjord variation of each front position (Fig. 1).

#### 4.3 Control of fjord geometry on front and grounding line retreat

The residence time of the grounding line is analyzed here for the different geometries introduced in Fig. 3. Residence time is thereby quantified by the amount of time that the grounding line rests within a distance of 1 km. Figure 6a shows the original geometry with the most pronounced pinning points at distances of 32 km, 25 km, -10 km and -13 km from the 2015 position.

5 Only the length of grounding line still-stand thereby varies among the nine different model runs (Table 2), whereas the pinning point locations coincide (also seen in Fig. 5b). Artificially straightening the width removes the pinning points at 25 km and those beyond the 2015 position (Fig. 6b). Instead, the glacier rests at the present-day position. The geometry with the straightened bed causes a similar response to the linear forcing as with the original geometry, only with a wider spread of pinning points (Fig. 6c). Straightening the bed and the width removes all pinning points (Fig. 6d) and leads to a linear retreat. Note that all  
10 geometries have an initial pinning point at the LIA position to allow a steady-state at the LIA position. Generally, a reduction in the complexity of the fjord geometry, e.g. straightening the bed and/or width reduces the number of pinning points.

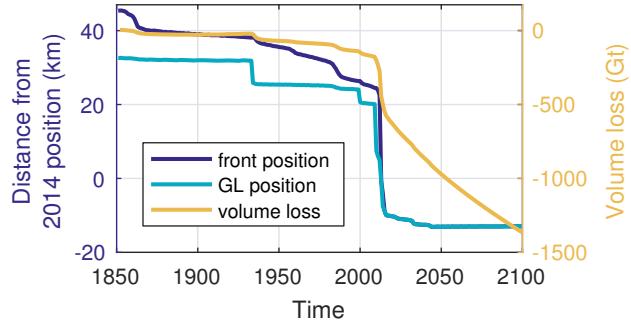

**Figure 6.** Residence time of the grounding line (GL) for the different geometries presented in Sect. 3.4: (a) the original geometry, (b) straightened width, (c) straightened bed and (d) straightened width and bed. The bars represent the time that the grounding line rests within 1 km (in years), and the colours correspond to the model runs in Table 2. Only residence times of more than two years are included.

#### 4.4 Delayed abrupt glacier response

In addition to the linear increase in climate forcing, the response to a step forcing (Table 2) is presented in Fig. 7. With the step forcing, the glacier front remains at a distance of 22 km for 60 years, before it retreats rapidly to its new pinning point. This unprovoked rapid retreat—after centuries of constant forcing—demonstrates the long response time of the glacier (Nye,

5 1960; Jóhannesson et al., 1989; Bamber et al., 2007; Enderlin et al., 2013b). The long response time is caused by a slow adjustment of the glacier volume to external changes. The corresponding accumulated volume loss also shown in Fig. 7 adjusts steadily to the initial changes in forcing, despite the constant grounding line position. During the rapid frontal retreat, the volume decreases by 300 Gt and continues even after the grounding line reaches a still-stand. This emphasizes that a constant

**Figure 7.** Simulated front and grounding line (GL) positions with accumulated volume loss for the step forcing (Table 2).

grounding line position does not imply a steady-state. Similarly, an observed rapid retreat of a marine-terminating glacier might be the delayed response to previous temperature changes.

## 5 Discussion

For the example of JI, our results show the importance of lateral and basal topography and their implications for the evolution of 5 glacier retreat in fjords. This knowledge can be used for a better understanding of the recent observed retreat history; however, it is hard to isolate the relative impact of changes in ocean forcing, SMB and internal factors including the fjord geometry. Here, we discuss the impact of fjord geometry on glacier front retreat and compare the simulated glacier response to the recorded long term glacier retreat history. In addition, we explore the implications of our results for the future response of JI to changes in climate.

10 We argue that fjord geometry and fjord width in particular to a large degree control the retreat pattern history of marine-terminating glaciers. Nevertheless, changes to the external forcing of the glacier are important because their magnitude controls the onset and overall rate of the retreat (Fig. 5).

### 5.1 Geometric control on glacier stability

Our simulations show that once a glacier retreat is triggered through changes at the marine boundary or at the glacier surface, 15 a non-linear response unfolds due to variations in the fjord geometry with a complexity given by the bed topography and the trough width. For a retrograde bed, an increasing water depth as the glacier retreats increases ice discharge, leading to further unstable glacial retreat in the case of non-changing lateral stresses (Weertman, 1974; Schoof, 2007). Previous studies show that changes in the width of a glaciated fjord impact the lateral resistance as well as the ice flow, thereby stabilizing the glacier where narrow sections occur (Gudmundsson et al., 2012; Jamieson et al., 2012, 2014; Enderlin et al., 2013b; Morlighem et al., 20 2016; Åkesson et al., 2018). These findings are corroborated in our study. However, most of these studies use synthetic glaciers that do not allow for a validation of the model, shorter time periods that disregards long term adjustments or a realistic forcing that makes the role of the geometry nontransparent. Figure 7 shows that the timescale of glacier adjustment can be several

decades. However, in reality temperature changes are likely smaller and less abrupt than we have imposed. Nevertheless, our study highlights that observed recent retreat can have been triggered and sustained by a warming event further back in time. This finding is consistent with Jamieson et al. (2014), who studied Antarctic ice stream retreat on millennial timescales. Depending on the local geometry of the underlying bed, individual glaciers have different response times and spacial extensions of dynamic thinning (Felikson et al., 2017).

The geometry experiments in Figure 6 assess the relative role of glacier width versus glacier length on JI. The width seems to be the leading factor for grounding line still-stand as artificially straightening the lateral boundaries removes most of the pinning points that cause slow-down in grounding line retreat. Straightening the bed topography is less efficient in linearizing the grounding line retreat compared to straightening the lateral boundaries. It has to be considered that the glacier trough is an order of magnitude wider than it is deep with larger variations in the width compared to the bed, resulting in a larger importance of the glacier width. Future studies will add further detail to these findings.

## 5.2 Relative role of forcing parameters

Only certain parameter combinations simulate the observed total retreat of JI since the LIA (Table 2). If the submarine melt rate is increased, the crevasse water depth has to be reduced and/or the sea ice buttressing increased. Similarly, if the sea ice buttressing is reduced, the crevasse water depth and submarine melt rate have to be smaller (Table 2). Importantly, none of the forcing parameters can trigger the retreat alone, unless they are changed unreasonably much relative to their LIA values. Only changed individually, the submarine melt rate would have to reach  $650 \text{ m.yr}^{-1}$  in 2015—an increase by 370 % from the LIA, the crevasse water depth has to increase to 400 m (250 % larger than the LIA value), and the sea ice buttressing factor has to be more than quadrupled (value 4.2 relative to LIA factor of 1) in 2015 to force a strong enough retreat. Absolute values for the parameters have to be taken with caution, because they do not necessarily correspond to physical variables. For example, to reach the observed grounding line flux, the value for the crevasse water depth is likely too high in our study. This is because it is a model parameter for calving that has to balance the neglected submarine melt along the calving front in the model. The change in parameters required to trigger the retreat is also dependent on the initial parameter choices and what forcing is needed to unpin the grounding line from the initial pinning point. As shown by Enderlin et al. (2013a), non-unique parameter combinations can exist for the same front positions. This implies that real-world observations are vital to reduce uncertainty in transient model simulations.

Note that the SMB contributed insignificantly to the frontal retreat, even if the lower SMB gradient  $G_l$  is doubled and the SMB curve is lowered by 50 %, which together gives a SMB of  $-6 \text{ m w.e. yr}^{-1}$  at the terminus compared to  $-1.1 \text{ m w.e. yr}^{-1}$  during LIA (cf. Fig. 2). In our model of JI, variations in air temperatures contribute mainly through runoff and the filling of crevasses with water, rather than directly through surface ablation. For the specific geometry of JI, that the influx of ice at the lateral boundaries is a factor 100 larger than the local SMB could be important for the sensitivity of the glacier to changes in climate forcing. However, the lateral influx is an order of magnitude smaller than the flux through the main trough and a sensitivity study shows that the lateral flux has a minor impact on the retreat pattern (not shown here). If all other parameters are kept fixed, the lateral influx has to be decreased by nearly 70 % from its LIA profile to simulate the observed overall retreat.

### 5.3 Model limitations and comparison to observations

In order to isolate the effect of geometry on glacier retreat, a relatively simple—but physically based—model is forced here with a linearly changing external forcing. Notwithstanding a number of assumptions, the model used is well suited as it is computationally inexpensive and allows for a large range of ensemble simulations starting from the LIA in 1850. The use 5 of this long time period is vital in order to capture internal glacier adjustment to changes in external forcing beyond the last few decades. Unfortunately, few observations exist for such a long time period to validate the model with, which supports our chosen idealized model setup. The model parameters are calibrated with the few observations that exist and the modeled retreat of JI is compared to the observed retreat.

Both modeled and observed calving front positions show a highly non-linear retreat and the rapid disintegration of a several 10 km long floating tongue (Fig. 5). The model results show a robust dependency of this non-linear retreat on the trough geometry, especially the trough width. However, the modeled glacier front retreats more slowly in general (deviation to up to 13 km from the observations) and exaggerates the break-off of the floating tongue. For the dynamic interpretation of the non-linear retreat, a perfect agreement is not essential, especially given the one-dimensionality of the model and the uncertainties in the width averaged observed front positions.

15 For the interpretation of the model results, the assumptions made in the model have to be considered. The most obvious assumption is the one-dimensionality that does not account for across and vertical variation in geometry. The residence time of the grounding line at pinning points may be partly overestimated due to this width- and depth integration. Local bedrock highs that have been observed to ground the floating tongue (Thomas et al., 2003) are not properly represented in a width-averaged setting and the width is regarded as symmetric around the central flowline. In reality, one lateral margin might narrow down and 20 pin the grounding line while the other lateral margin widens up, causing an asymmetric calving front retreat (see Fig. 1). Here, we only focus on the large-scale dynamics; lateral and vertical variations in the ice flow are seen as second order processes considering the high basal motion and high velocities in the deep and narrow channel at the lowermost 100 km of the model domain. As the glacier retreats further upstream "into" the ice sheet, the lateral ice flux becomes more significant so that the whole drainage area should explicitly be modeled, suggesting the use of a three dimensional model for future projections.

25 The depth and width integration also applies to internal glacier properties; ice temperatures are in reality high at the bottom (Lüthi et al., 2002), so that most deformation happens there, whereas the model assumes a vertically constant shearing and a constant rate factor. Along the margins of a real glacier, ice viscosity drops significantly in response to acceleration and calving front migration (Bondzio et al., 2017) and marginal crevasses can form, which are here disregarded. However, lateral drag and weakened margins mostly affect the timing but not the style of retreat, which has been tested in an idealized setting with the 30 same model (Åkesson et al., 2018). Ice viscosity is rather a response to dynamic changes rather an a cause and is therefore not expected to change the retreat pattern significantly, although it may alter the timing and residence time of the grounding line slightly.

Several parameterizations of physical processes are used in the model, such as submarine melt and buttressing by ice mélange. This complicates direct model validation with observed values. However, these processes are still crudely imple-

mented, if at all represented. For example, many models prescribe the position of calving front (e.g. Bondzio et al., 2017) or only focus on grounding line migration, whereas our model uses a physical calving law. Also, few observations exist on submarine melt rate, calving rates and basal sliding, especially over the long time period studied here. The impact of plume dynamics on submarine melt could be implemented in our model (Jenkins, 2011) or an along-flow variation in submarine melt rates (Motyka et al., 2003); however, the number of observations on ocean temperatures is sparse and the model results are similar when using along-flow variations in submarine melt compared to a constant value along the floating part (not shown here). Also an interannual variability of calving rates due to submarine melt, runoff and ice mélange is neglected here and not considered as important when looking at centennial timescales. Although many of the model parameters are only indirectly linked to observations, existing observations such as velocities, ice discharge and thickness are used to tune the parameters and to reproduce the glacier behavior as close as possible. Note that the needed change in forcing parameters to dislodge the grounding line from its stable LIA position might be overestimated due to strong variations in bed topography and width. Also, many parameter combinations can simulate the same stable position but lead to different glacier retreat (Enderlin et al., 2013a). We therefore include a large range of parameter perturbations, which lead to different residence times for the grounding line, but do not influence the importance of the geometry in defining locations of intermittent slow down in the overall grounding line retreat.

The choice of the model is dependent on the questions raised; if the objective is to accurately predict or reconstruct the time evolution of glacier retreat (e.g. Nick et al., 2013; Muresan et al., 2016), a more sophisticated model has to be used. Note that also the observations contain uncertainties. The front position can vary by several kilometers seasonally (e.g. Amundson et al., 2010) and this position varies by several kilometers across the trough (Fig. 1). For the calculation of the one-dimensional front position, we assume a west-east orientation of the trough, which gives an offset at the most recent calving fronts; however, the deviation is only a few km and within the spread of the across variation of the calving front. Most importantly, the bed topography—especially in the densely ice covered fjord and a sediment rich subglacial bed (Boghosian et al., 2015)—is challenging to obtain. Due to the strong control of the fjord geometry on the glacier retreat, small uncertainties in the trough geometry cause a highly different retreat pattern. This highlights the importance of detailed knowledge on the underlying bed topography (e.g. Durand et al., 2011).

#### 5.4 Glacier front reconstructions based on trough width

Figure 6 illustrates the potential in using the model simulations in a geomorphological context. Marine-terminating glaciers continuously erode their beds and deposit sediments, forming submarine landforms such as moraines. The rate of sediment deposition and resulting proglacial landforms are functions of climatic, geological and glaciological variables, though these functions remain poorly quantified due to sparse observational constraints. Proglacial transverse ridges tend to form during gradual grounded calving front retreat, whereas more pronounced grounding zone wedges are associated with episodic grounding line retreat (Dowdeswell et al., 2016).

The abundance of ice mélange in front of JI renders studies of submarine geomorphology difficult. Studies of this kind are lacking in the fjord, though evidence of the style of deglacial ice sheet retreat in Disko Bugt do exist (Streuff et al.,

2017). Our study raises generic questions about the links between trough geometry and moraine positions. We suggest that likely locations for moraine formation can be predicted from the glacier width, which here largely determines the position of grounding line stabilization. The finding of very robust influence of width on the retreat patterns (Fig. 6) means that looking at fjord geometry allows us to locate positions of expected slow-downs or step changes (Åkesson et al., 2018; Small et al., 5 2018). This is extremely useful for reconstructions and interpreting paleo-records, for example from adjacent land-records e.g. moraines and reconstructions based on proglacial lake sediments.

To this end, our study clearly highlights the potential of combining long-term modelling studies with geomorphological and sedimentary evidence to understand the non-linear response of marine ice sheet margins. This needs to be considered when inferring climate information based on glacier retreat reconstructions.

## 10 6 Conclusions

The rapid retreat of many of Greenland's outlet glaciers during the last decades has been related with increased oceanic and atmospheric temperatures, though glaciers display diverse behavior. As an example of a rapidly retreating glacier, we study the retreat of JI from its Little Ice Age maximum to its present-day position. The numerical model is forced with a linear increase in SMB, submarine melt rate, crevasse water depth and reduction in sea ice buttressing to isolate the importance of geometry 15 for temporary grounding line stability. The following conclusions can be drawn:

- The glacier response to a linear climate forcing is highly non-linear due to its characteristic trough geometry. The importance of the trough geometry is a robust feature in our study and the modeled non-linear frontal retreat is consistent with longterm (century scale) observations.
- External changes at the glacier terminus determine the degree and the timing of the glacier retreat: calving and submarine melt act together to trigger the observed total retreat of JI. SMB plays a negligible role in forcing the glacier retreat.
- The fjord geometry, and in particular trough width, determines where the grounding line retreat slows down during the overall retreat. Artificially straightening the trough geometry in the model reduces the non-linearity of the glacier retreat.
- Grounding line stabilization on pinning points can cause delayed rapid retreat due to a long dynamic adjustment to past changes in external forcing. We show this for the case of JI which might be transferable to similar marine-terminating 20 25 glaciers in Greenland and other regions with glaciated fjord landscapes.

Our findings suggest that the retreat history of Jakobshavn Isbræ since the LIA has largely been controlled by variations in trough width and bedrock bathymetry and that future retreat will be governed by similar factors. Since grounding line stability is fundamentally controlled by the geometry, we also postulate that geometry—notably trough width—is a vital source of information for when interpreting paleo-records of marine-terminating glaciers.

*Code and data availability.* The model code is available through Faezeh M. Nick (faezeh.nick@gmail.com). The model output and other datasets can be obtained upon request from the corresponding author.

*Author contributions.* Nadine Steiger, Kerim H. Nisancioglu and Henning Åkesson designed the research, Nadine Steiger performed the model runs and created the figures with significant input from Kerim H. Nisancioglu, Henning Åkesson and Basile de Fleurian. Faezeh Nick  
5 provided the model and technical support. Nadine Steiger wrote the paper, with substantial contributions from all authors.

*Competing interests.* The authors declare that they have no conflict of interest.

*Acknowledgements.* This research was funded by the Fast Track Initiative from Bjerknes Centre for Climate Research and the European Research Council under the European Community's Seventh Framework Programme (FP7/2007-2013)/ERC grant agreement 610055 as part of the ice2ice project. Henning Åkesson was supported by the Research Council of Norway (project no. 229788/E10), as part of the  
10 research project Eurasian Ice Sheet and Climate Interactions (EISCLIM). Front positions of JI since 1990 are obtained from ENVO at <http://products.esa-icesheets-cci.org/>. We want to thank Mahé Perrette (<https://github.com/perrette/webglacier1d>) for providing a python-javascript project to produce a 1-D profile of bed topography and glacier surface. Thanks to Jason Box for providing SMB data for the GrIS. We also thank Martin Lüthi, Johannes Bondzio, Andreas Vieli and Ellyn Enderlin for constructive reviews that improved the manuscript greatly. Thanks to Anna Hughes for proofreading the manuscript.
