11 **Abstract.** The horizontal-to-vertical spectral ratio (H/V) method implemented at single stations using seismic
12 ambient noise waveforms is a fast, noninvasive, efficient method to investigate the subsurface velocity
13 structures of the shallow crust. In this study, we report on a successful application of the H/V method to estimate
14 the Antarctic ice sheet thickness for the first time. Using three-component, five-day long, seismic ambient noise
15 records gathered from more than 60 temporary seismic stations located on the Antarctic ice sheet, the ice
16 thickness at each station was reliably measured. Preliminary analysis revealed that 60 out of 65 seismic stations
17 on the ice sheet obtained clear peak frequencies (f_0) related to the ice sheet thickness in the H/V spectrum. Thus,
18 assuming that the isotropic ice layer lies atop a high velocity half-space bedrock, the ice sheet thickness can be
19 calculated by a simple approximation formula. About half of the calculated ice sheet thickness were consistent
20 with the Bedmap2 ice thickness values. To further improve the reliability of ice thickness measurements,
21 two-type models were built to fit the observed H/V spectrum through non-linear inversion. The two-type models
22 represent the isotropic structures of single and two-layer ice sheet, and the latter depicts the non-uniform, layered
23 characteristics of the ice sheet widely distributed in Antarctica. The inversion results suggest that the ice
24 thicknesses derived from the two-layer ice models were highly consistent with the Bedmap2 ice thickness
25 database, and their ice thickness differences were within 300 m at almost all stations. Our results support
26 previous finding that the Antarctic ice sheet is stratified. Extensive data processing indicates that the time length
27 of seismic ambient noise records can be shortened to 1–2 hours for reliable ice sheet thickness estimation using
28 the H/V method. This study extends the application fields of the H/V method and provides a complementary and
29 independent way to measure ice sheet thickness in Antarctica.

30 1 Introduction

31 The Antarctic ice sheet is the largest on the Earth, covering over 98 % of Antarctic continent. As a fundamental
32 parameter of the Antarctic ice sheet, ice sheet thickness is significant for dynamic ice sheet modeling of mass

33 balance and global climate change (Budd et al., 1991; Gogineni et al., 2001; Bamber et al., 2001; Hanna et al.,
34 2013). Moreover, seismic waves become more complex when traveling through an ice sheet with thickness
35 ranging in hundreds to thousands of meters thick. Thus, accurate ice sheet thickness is a critical metric for
36 recognizing and denoising seismic multiples trapped inside the ice sheet when imaging crustal and mantle
37 structures below the ice sheet (Lawrence et al., 2006; Hansen et al., 2009, 2010). Therefore, better ice sheet
38 thickness and structures can also improve the study of the geological structure underneath the ice sheet in
39 Antarctica.

40 Given the importance of Antarctic ice sheet structures, many geophysical methods, such as gravity modeling,
41 radio echo sounding (RES), and active seismic approaches including reflection, refraction, and deep seismic
42 sounding, have been used in local or regional scale ice sheet thickness investigations since the 1950s (Bentley
43 and Ostenso, 1961; Bentley, 1964; Evans and Robin, 1966; Evans and Smith, 1969; Robin, 1972; Drewry et al.,
44 1982; Cui et al., 2016). By studying gravitational anomalies in the ice sheet, gravimetric measurements provide
45 an indirect way to infer the average ice thickness over a region. While active seismic and RES methods can
46 determine the ice thickness at a much smaller area by converting the echo time of seismic and electromagnetic
47 waves into an estimation of ice thickness. Among these methods, the active seismic and RES methods are the
48 most widely used techniques for ice thickness measurements due to their relatively high accuracy and better
49 spatial resolution. After compiling and gridding the data derived from these methods, the Bedmap1 at a
50 resolution of 5 km and Bedmap2 at a resolution of 1 km ice sheet thickness databases covering south of 60° S
51 were constructed (Lythe et al., 2001; Fretwell et al., 2013). However, traditional methods for estimating ice
52 thickness still have limitations. For example, the accuracy of the gravity method is relatively low because of its
53 intrinsically low sensitivity of a gravimeter to the gravitational anomalies related to the ice sheet-bedrock
54 interface and the approximated terrain correction assumptions necessary for data processing (Drewry, 1975). In
55 the case of the active seismic and RES methods, despite their high accuracy they require considerable economic
56 and logistical support, to collect the data. The RES method has a further limitation as the echo free zone (EFZ) in
57 areas of high temperature ice, possibly related to signal scattering or signal disappearance, making data
58 collection impossible in these areas (Drews et al., 2009). To enrich the ice thickness database in Antarctica and
59 make a complementary for the existing methods, more geophysical methods have to be explored for determining
60 ice sheet thickness reliably, accurately, and efficiently at low cost.

61 Passive seismic methods, such as the teleseismic P-wave receiver function (PRF), generally used to determine
62 crustal and mantle discontinuities is also sensitive to the ice-bedrock interface and the seismic properties of ice
63 sheets. Hansen (2010) successfully modeled ice sheet thickness beneath several stations in East Antarctica using
64 PRF. Wittlinger (2012, 2015) investigated the anisotropy of the polar ice sheet by modeling the P-to-S wave
65 conversion with the negative PRF amplitude. Yan (2017) confirmed that the ice thickness results derived from
66 PRF are consistent with the Bedmap2 ice thickness database. However, large numbers of teleseismic events are

67 needed to perform PRF; it usually takes at least a one-year period of data collection, thus greatly limiting the
68 application of the PRF method in harsh environments such as those found in Antarctica.

69 In order to improve the reliability, accuracy, and efficiency of ice thickness investigation, we selected the
70 horizontal-to-vertical spectral ratio (H/V) method to determine ice thickness. As a noninvasive and passive
71 seismic method, the H/V technique has been extensively used in seismic exploration as a tool to detect sediment
72 thickness, which suggests its powerful effectiveness in subsurface structure investigations (Konno and Ohmachi,
73 1998; Ibs-von Seht and Wohlenberg, 1999; Bonnefoy-Claudet et al., 2006; Bao et al., 2017). Considering that
74 the sediments and ice sheet layer are both low shear-wave velocity (V_s) layers atop the high velocity bedrock,
75 the H/V method should be suitable for determining ice sheet thickness.

76 Jean-Jacques (2010) applied the H/V method to four stations in the Dome C region of Antarctica for inferring
77 the uppermost snow layer thickness and its corresponding ice properties a few meters depth. Picotti (2017)
78 recently adopted the H/V method to detect glacial ice thickness ranging from a few tens of meters to ~ 800 m in
79 Italy, Switzerland, and West Antarctica. The H/V method has been validated for its reliability to measure glacial
80 thickness comparing with the radio-echo sounding, geoelectric, and active seismic methods implemented at or
81 near the same study sites. The great advantage of the H/V method over other approaches is that there is no need
82 to record earthquakes or active sources, since it utilizes seismic ambient noise. Moreover, the H/V method
83 requires only a few tens of minutes of seismic ambient noise recordings at single portable three-component
84 seismometers. This greatly enhances efficiency and reduces cost and logistical support requirements.

85 Since the shear-wave velocity of an ice sheet is ~ 1900 m s⁻¹, and generally much higher than a snow layer
86 (~ 700 m s⁻¹), therefore the velocity contrast of the ice sheet-bedrock half-space is not as high as that of the
87 snow-ice sheet layer. Moreover, the H/V spectrum may be more complicated than that of a glacier or snow layer
88 given the complex subglacial environment since there might be subglacial lakes and sedimentary layers. In
89 addition, the internal ice structure might affect the H/V spectrum given the variations in seismic velocities
90 induced by changes in density, and temperature, as well as the ice crystal size and orientation of an ice sheet.
91 Whether the H/V method can be used to estimate the ice sheet thickness or not remains an open question.
92 Although the H/V method has been successfully applied to study snow and shallow glacial thickness
93 (Jean-Jacques et al., 2010; Picotti et al., 2017), to our knowledge, the H/V method has not been performed to
94 estimate Antarctic ice sheet thickness yet. In this study, we present estimated ice thickness results from 65
95 stations with a typical coverage deployed on the Antarctic ice sheet to verify the feasibility of using the H/V
96 method as an effective complementary way to existing methods for measuring ice thickness.

97 2 Data and methods

98 2.1 Data

99 Over the past two decades, several temporary seismic arrays have been deployed in Antarctica, including the
100 Transantarctic Mountains Seismic Experiment (TAMSEIS, 2000—2003) (Lawrence et al., 2006), the
101 Gamburtsev Antarctic Mountains Seismic Experiment (GAMSEIS, 2007—2012) (Hansen et al., 2010), and the
102 Polar Earth Observing Network/Antarctic Network (POLENET/ANET, 2007—2016) (Chaput et al., 2014).
103 Despite their relatively sparse distribution, these three arrays together effectively cover East, and West
104 Antarctica as well as the Transantarctic Mountain region (Fig. 1). In these three arrays, all stations are equipped
105 with the Guralp CMG-3T or Nanometrics T-240 broadband sensors with a sampling rate of 25 Hz or 40 Hz.
106 Most stations are buried 1—2 meters below the surface snow to guarantee data quality (Anthony et al., 2015).
107 Equipped with solar panels and rechargeable batteries, the GAMSEIS and POLENET/ANET stations work
108 continuously year round except the TAMSEIS, and provide abundant seismic ambient noise waveforms for the
109 H/V processing. To investigate the effectiveness of the H/V method for ice thickness measurements and the
110 proper time length for H/V processing, we selected seismic ambient noise records lasting about five days, which
111 is much longer than that used in usual H/V data processing (only a few minutes' records for sedimentary
112 investigations with tens to hundreds of meters thick). In total, 65 stations deployed on the Antarctic ice sheet
113 were used in this study.

114 2.2 Methods

115 The single-station H/V method, extensively used in sediment structure detection, acquires reliable sediment
116 thickness and shear-wave velocities (Nogoshi and Igarashi, 1971; Nakamura, 1989). In this method, seismic
117 ambient noise data are collected by a three component seismometer and the ratio between the horizontal (H) and
118 vertical (V) Fourier spectra are calculated. The principle of the technique can be understood by assuming a low
119 velocity sedimentary layer overlying a high velocity bedrock half-space. Due to the sharp impedance contrast at
120 the interface between the two layers, the shear-wave energy within the sedimentary layer produces a prominent
121 peak that can be observed in the H/V spectrum.

122 Extensive field experiments and numerical simulations have been carried out to verify the reliability of the
123 H/V spectrum as derived from the H/V method. Although the amplitude value of the H/V spectrum peak
124 frequency is not that robust since the contributing factors are complicated, the H/V spectrum peak frequency is
125 commonly accepted as a proxy of the resonance frequency of a particular layer (Field and Jacob, 1993; Lachel
126 and Bard., 1994; Javier and Chávez-García, 1994; Delgado et al., 2000; Fäh et al., 2001; Lunedei and
127 Malischewsky, 2015; Picotti et al., 2017). To calculate the H/V spectrum, a specialized GEOPSY program was
128 developed by the European SESAME team, and widely used to investigate the sediment structures (Bard and

129 SESAME team, 2005). Then an approximation equation or H/V spectrum inversion approach can be used to
130 derive the sedimentary layer thickness with the H/V spectrum.

131 Under the assumption of one-dimensional velocity subsurface conditions, in cases of homogenous and
132 isotropic sedimentary layers over a homogenous half-space, the observed peak frequency equals the
133 fundamental resonant frequency of the sedimentary layer. Thus, the resonance frequency of the low velocity
134 layer is closely related to its thickness h through the following relationship (Ibs-von Seht and Wohlenberg, 1999;
135 Parolai et al., 2002; Picotti et al., 2017; Civico et al., 2017):

$$136 \quad h = \frac{V_S}{4f_0} \quad (1)$$

137 Where V_S is the average shear-wave velocity of the sedimentary layer, and f_0 is the observed peak frequency.
138 Provided that a correct estimate of the average shear-wave velocity of the sedimentary layer is available, its
139 thickness can be roughly estimated.

140 Complicated sedimentary internal structures, including anisotropy and low velocity layers beneath stations,
141 will affect the H/V spectrum and consequently violate the assumptions of Eq. (1). Therefore, when inferring
142 complex subsurface structures, an inversion of the full H/V spectrum can be used to explain more accurately the
143 observed H/V spectrum. Based on different assumptions for the interpretation of ambient noise wavefield
144 composition, several inversion approaches have been proposed and successfully applied to study sedimentary
145 structures (Fäh et al., 2003; Arai and Tokimatsu, 2004; Herak, 2008; Lunedei and Albarello, 2009;
146 Sánchez-Sesma et al., 2011).

147 The H/V method has been successfully applied in studies of sedimentary structures, such as studies of
148 thickness and shear-wave velocities (Ibs-von Seht and Wohlenberg, 1999; Langston and Horton, 2014; Civico
149 et al., 2017; Bao et al., 2017). However, applications in ice environments are rare. Jean-Jacques (2010) studied
150 the snow layer thickness and the ice properties beneath four stations in Dome C region of Antarctica using the
151 H/V method. Picotti (2017) measured ice thickness ranging from tens of meters to 800 m of six glaciers in Italy,
152 Switzerland and West Antarctica. However, the impedance contrast between the ice sheet layer and the
153 overlying bedrock is not as high as that of sedimentary-bedrock and snow-ice layers. Moreover, the complex
154 subglacial environment and internal ice structure create other technical obstacles. Thus, there have been no
155 investigations of ice sheet thickness incorporating the H/V method for measurements or estimations.

156 In this study, the H/V spectra of 65 stations deployed on ice were processed by using the GEOPSY software,
157 which has been used for sedimentary structure investigations in many regions. Under the general assumption
158 that the seismic properties are stable throughout the whole ice column, we calculated the ice thickness using Eq.
159 (1) as in most seismological applications to approximate the ice sheet as a homogeneous layer. Meanwhile, a
160 non-linear H/V spectrum inversion method developed by García-Jerez (2016) was adopted to constrain the
161 observed H/V spectrum to infer the ice structure, comprised of shear-wave velocity and thickness.

162 During H/V spectrum acquisition using the Geopsy software, we remove the transient signals (earthquakes)
163 from noise records with the STA/LTA technique and divide the records into 600 s length windows with an
164 overlap of 5 %. Time series were tapered with a 5 % cosine function, and the FFT was calculated for each
165 component. The spectra were smoothed with a Hanning window in a bandwidth of 0.1—2 Hz on a logarithmic
166 frequency scale. The spectra of the two horizontal components (NS and EW) were merged to one horizontal
167 component spectrum by calculating their geometric mean. The spectral ratios and corresponding standard
168 deviation estimates between the horizontal component and the vertical component were calculated.

169 Having acquired the resonance frequency of the ice sheet, we adopted Eq. (1) with a uniform average
170 shear-wave velocity—1900 m s⁻¹ of the ice layer to calculate the ice thickness. This velocity used here is
171 reasonable given that it is in the general range of ice Vs determined by seismic experiments (Kim et al., 2010).
172 Moreover, this velocity has also been widely used in previous studies (Hansen et al., 2010; Wittlinger and Farra,
173 2012; Ramirez et al., 2016). Keeping the velocities set, the ice thickness at each station was calculated using Eq.
174 (1).

175 In the H/V spectrum inversion procedures, Bedmap2 ice thicknesses were used as references to build the
176 initial models, as along with the related seismic elastic parameters (Fig. 2, Wittlinger and Farra, 2012; Ramirez
177 et al., 2016). We adopted two different models assuming the ice sheet is homogenous and inner ice stratified;
178 respectively, as shown in Fig. 2 to perform H/V spectrum inversion. Model A is a simple homogeneous and
179 isotropic ice structure with an ice layer overlying the half-space. In this model, the ice thickness varies from 0.7
180 to 1.3 times the Bedmap2 ice thickness for each station. Model B is constructed following Wittlinger (2012,
181 2015) as a two-layer ice structure in which a low shear-wave velocity lies in the lower ice layer. In this model,
182 the thickness of the upper ice layer and the lower ice layer were set to occupy 60—75 and 25—40 percent of the
183 Bedmap2 thickness, respectively. Using the non-linear Monte Carlo method (García-Jerez et al., 2016), we
184 retrieved the optimum solutions for model A and B. These two solutions were best fitted to the observed H/V
185 spectrum.

186 It usually takes a few minutes to about half an hour to collect seismic ambient noise waveforms in the
187 investigations of sedimentary layers with thickness ranging from several tens to hundreds of meters. However,
188 there is no experiences for the time length of recording seismic ambient noise in the Antarctic ice sheet with
189 several kilometers thick. It is necessary to apply the H/V method with a much shorter recording time for seismic
190 ambient noise, considering the harsh environment and logistical support difficulties in Antarctica. Therefore, we
191 investigated the feasibility and reliability of H/V method by testing a range of noise record lengths; eight hour,
192 four hour, two hour, and one hour intervals were tested. The processing strategies remained the same as in H/V
193 spectrum acquisition except the window length was changed to 200 s when calculating the H/V spectrum using
194 different length noise records.

3 Results

In this study, the H/V spectra of 65 stations were obtained. Figure 3 displays the H/V spectra of nine stations selected from three arrays. These examples are representative of all the results, and the remaining spectra are presented in the supplementary Fig. S1. It is clearly shown that in almost all H/V spectra there were two or three clear peaks in the frequency band. Generally, the largest amplitude appears at the first peak located around 0.2 Hz or below, and the second and the third peaks with lower amplitudes are located at ~ 0.5 and ~ 0.8 Hz, respectively. Following the general interpretation principles for H/V spectra (Bard and SESAME team, 2005), the peak frequency denoting the largest amplitude should be the resonance frequency of the ice sheet layer, while the peaks appearing with lower amplitudes at higher frequencies may indicate the shallower impedance contrast layers. The reasonableness of considering the first peak frequency with the largest amplitude as the resonance frequency of the ice sheet layer was verified through rough estimation based on Eq. (1), i.e., for station E012, the Bedmap2 ice thickness at that location is 1050 m, so the resonance frequency according to Eq. (1) should be 0.452 (the given V_s is 1900 m s^{-1}), and as expected was observed in the H/V spectrum. However, there are exceptions such as station N148 displayed in Fig.2 whose first peak amplitude is slightly lower than that of the following peak observed at higher frequency. At this station however, the location of the first peak correlates with the resonance frequencies through rough estimation. In addition, there are some stations that have no peak frequencies correlating with the ice sheet thickness, despite the existence of peak frequency with strong amplitude in the frequency band. Station ST07 seen in Fig. 3 is such a case, whose fundamental resonance frequency as calculated by Eq. (1) should be 0.191 (its Bedmap2 ice thickness is 2490 m). Nevertheless, no clear peak around this expected frequency is observed in the H/V spectrum. We therefore can group the results into three categories:

- 1) 42 stations with first peaks denoting the largest amplitude in the observed spectrum related to the ice sheet resonance frequency, like the E012, E018, GM02, N148, P071, ST01, ST02 stations in Fig. 3.
- 2) 18 stations with first peaks with slightly lower amplitude but also related to the ice sheet resonance frequency such as station N108.
- 3) Five stations without peaks correlating to the resonance frequency, such as station ST07.

Figure 4 shows the H/V spectra of stations along four profiles, together with the ice sheet and bedrock elevation extracted from Bedmap2 database for each station. As shown in Fig. 4, although the neighboring stations are 80 km apart for profile AA', 100 km for profile BB' and DD', and 20 km for profile CC', the shape of the spectra are similar along each profile. Also, along each profile, the peaks associated with the ice thickness are clear and the locations of the peaks shift towards lower or higher frequencies cohering with the variation of the corresponding ice thickness. There are four stations (N060, ST04, ST06, ST07) along the four profiles without peak frequencies related to their corresponding ice thicknesses. This may be caused by the bad coupling of the seismometer with the ice surface or possibly a complicated subglacial environment, for example clear evidence indicates the existence of sedimentary layer beneath station N060.

230 Having identified resonance frequency of the ice sheet, we calculated the ice thickness using Eq. (1) with the
231 average shear-wave velocity—1900 m s⁻¹. The results are listed in Table 1. We projected the calculated ice
232 thickness and the reference Bedmap2 ice thickness for stations along the four profiles in the upper elevation
233 panels in Fig. 4. It is clear that the calculated ice thickness for some stations along the four profiles are close to
234 the reference ice thickness like the E012, P071, and ST01 stations, while there are large deviations at some
235 stations such as E018, N148, and ST02.

236 The optimum shear-wave velocity models derived from H/V spectrum inversion are presented in Fig. 5 and
237 supplementary Fig. S2. The observed H/V spectrum together with the synthetic H/V spectra using the two
238 optimum shear-wave velocity models are plotted in Fig. 6 and shown in supplementary Fig. S3. As Fig. 6 and the
239 supplementary Fig. S3 shows, the synthetic H/V spectra of the optimum inversion results for model A and model
240 B at almost all stations, both fit the observed H/V spectra in peak frequency and spectrum shape. However, the
241 inversion ice thickness from model A deviates substantially from the Bedmap2 thickness at most stations (such
242 as N108, N148, GM02 and ST02 in Fig. 5), and the difference extends 1 km for some stations (Fig. 7). By
243 contrast, the inversion thickness from model B is consistent with the Bedmap2 thickness as the differences
244 between them are mostly within 200 m. The overall inversion ice thicknesses from model B are listed in Table 1.
245 We also projected the inversion thickness for stations along the four profiles in the elevation panels seen in Fig.
246 4, which depicts a high level consistency between the inversion and the reference ice thickness at these stations.

247 The results of four different length seismic ambient noise records (1 h, 2 h, 4 h, 8 h) used to obtain H/V
248 spectrum are displayed in Fig. 8 (and in supplementary Fig. S4). These plots show that the shape of the spectra of
249 the four tested record lengths are similar to the shape determined using a record five days long. The peak
250 frequencies of the four different length records are all within the margin of error for the peak frequency as
251 determined with the record five days long. We found that the longer the ambient noise record, the more stable the
252 peak frequency is as there are slight shifts in the peak frequency when determined with 1 h and 2 h records; such
253 as those from stations E018 (Fig. 8), E020, and E024 (shown in supplementary Fig. S4). Despite variation in ice
254 thickness from 600 m to about 4 km at the study sites, the length for recording seismic ambient noise suited for
255 H/V methods can be as short as 1—2 hours, in terms of stability and efficiency.

256 4 Discussion

257 Bedmap2 ice thickness were used as reference to verify the ice thickness derived from Eq. (1) and H/V spectrum
258 inversion since we lacked actual ice thickness as obtained from the more direct and accurate ice-core drilling,
259 RES and active seismic methods at or near each study site. Because of various factors contributing to the
260 uncertainty in the Bedmap2 database such as data coverage, basal roughness, and ice thickness measurement and
261 gridding error, however, the Bedmap2 ice thickness is not exactly accurate with uncertainty varying from site to
262 site. We obtained the uncertainty of the Bedmap2 ice thickness at each station from the grids of ice thickness
263 uncertainty (Fretwell et al., 2013, also, the uncertainty at our study sites can be roughly seen in supplementary

264 Fig. S5). A close examination of the uncertainty of the Bedmap2 ice thickness reveals that the uncertainty at 52
265 stations ranges from 59 m to about 200 m, and the uncertainty at 57 stations is below 300 m. As the accuracy of
266 the H/V method is at the same scale with the uncertainty of the Bedmap2 ice thickness at the 57 stations, the
267 Bedmap2 ice thicknesses are adequate to verify the results derived from the H/V method. The remaining three
268 stations including ST09, ST13, and ST14 are excluded for validation as the uncertainty of the reference ice
269 thickness at these stations reaches 1000 m.

270 A comparison of the inversion ice thickness from Model B and Bedmap2 database reveals that the differences
271 in ice thickness at all the 57 stations are less than 400 m; there are 33 stations whose differences are within 200 m
272 and 47 stations within 300 m; the maximum difference was 370 m at station ST03. Given that uncertainty of the
273 Bedmap2 database can reach 300 m in some study sites (Fretwell et al., 2013), it is certain that the inversion ice
274 thicknesses are adequately constrained at over 47 stations.

275 Based on the homogenous ice sheet layer assumption, most of the ice thickness estimations derived from Eq.
276 (1) are not compatible with Bedmap2 ice thickness (Fig. 4 and Fig. 7), as the differences at 26 stations can extend
277 400 m and at 10 stations are over 600 m; the maximum difference reaches 910 m at station N036. Moreover,
278 most of the inversion ice thickness results based on the homogenous ice structure of model A also largely
279 deviated from the reference Bedmap2 thickness (Fig. 7 and supplementary Fig. S2). These large deviations
280 cannot be attributed to the uncertainty in the reference Bedmap2 ice thickness since they made minor
281 contributions to the large differences.

282 The inversion ice thickness from model B, however were highly consistent with the Bedmap2 database. A
283 close examination of the inversion thickness from model B shows that it refined the rough estimation results at
284 47 stations as calculated with Eq. (1) to varying degrees. As at stations E012 and N036, the calculated ice
285 thicknesses using Eq. (1) deviate from Bedmap2 at 90 m and 910 m, while the inversion ice thickness from
286 model B refines the gaps to 20 m and 320 m.

287 We compared our results with those found in Wittlinger (2012). Using the PRF method and a grid search
288 stacking technique, he found that the Antarctic ice is stratified, possibly due to the preferred orientation of ice
289 crystals and fine layering of soft and hard ice layers under pressure. In Fig.9, we present the ice thickness results
290 for 12 stations common to both studies. It is clear that the interface separating the upper and the lower ice sheet
291 layers determined using the H/V method and the PRF method, is consistent for almost all stations.

292 The agreement of two-layer ice sheet thickness with the Bedmap2 database, and the consistency of our results
293 to Wittlinger's results, as well as the large deviation of ice thickness estimated using Eq. (1) and model A jointly
294 support the thesis that the two-layered ice sheet models are more reasonable than an homogeneous ice sheet layer
295 assumption. Moreover, the ice thickness of 28 stations derived from Eq. (1) were close to the reference Bedmap2
296 database. This consistency, however, does not strongly support the homogenous ice sheet layer assumption as it
297 can be attributed to the fact that the Vs values adopted in rough estimation was coincidental with the average
298 velocity of the two-layer Vs models.

299 The examples presented in this work clearly show that the H/V method with seismic ambient noise can be
300 effectively to measure ice sheet thickness. However, there are also some limitations that may affect the results.
301 Shear-wave velocity (V_s), as the key parameter for H/V spectrum inversion and rough estimation using Eq. (1),
302 will significantly affect the effectiveness and uncertainty of the H/V method. We can see from Fig. 6 that the
303 synthetic H/V spectra from the optimum V_s profiles of model A and model B for the N108, GM02 and N148
304 stations (Fig. 5), match the observed H/V spectrum. The inversion ice thickness from model A and model B at
305 these stations however, are remarkably different as the results from model B are more closely match the
306 reference Bedmap2 ice thickness than those from model A (Fig. 5). Also evident in these results is a directly
307 proportional relationship between ice thickness and the V_s as expected from Eq. (1) in rough estimation. Given a
308 ~5 percent variation in the average shear-wave speed of the ice layer, then ice sheet thickness estimation will
309 result in a similar variation such as 150 m for a station with 3 km thickness. Accurate known V_s profiles are
310 therefore prerequisites when obtaining reliable H/V spectrum inversion results, as well as for rough estimations
311 using Eq. (1).

312 It is evident that the longer the noise record, the more stable the observed peak frequency is as the sources of
313 the seismic ambient noise are more evenly distributed, spatially and temporally. This is significant for stations
314 with thin ice primarily due to the fact that thin ice sheet layers are excited by high-frequency waves such as
315 winds and other sources (Picotti et al., 2017). Thus, a longer ambient noise record can improve the stability of
316 the H/V spectrum. In our study, we found that the quality of the H/V spectrum are generally better for thick ice
317 sheet layers than for thin ice sheet such as stations BENN, E012, E018, E024, E026, and E028 with relatively
318 smaller ice thicknesses than other stations. The H/V spectra for these stations exhibited less stability when the
319 lengths of noise records decreased (Fig. 8 and supplementary Fig. S4). Also, the peak frequency obtained from a
320 one hour long record slightly deviates from the peak frequency determined with a five day record. These
321 deviations consequently could lead to uncertainties in ice thickness estimation. The efficiency and the cost of
322 noise record acquisition in Antarctica however, are equally important. In this sense, the proper record length in
323 H/V method application is 1—2 hours.

324 5 Conclusions

325 Given the vital role that ice sheet thickness plays in ice mass balance and global climate studies, many methods
326 have been used to estimate ice sheet thickness, obtaining abundant results. However, new methods must be
327 explored to enrich the database considering the vast area of the Antarctic ice sheet and the limitations of the
328 existing methods.

329 In this study, the H/V method is proposed as a reliable, efficient method to investigate the Antarctic ice sheet
330 thickness. The H/V method is effective for identifying the fundamental resonant frequency correlating with the
331 ice sheet thickness. In this approach, the ambient noise recording length can be as short as 1—2 hours, reducing
332 costs and increasing efficiency. Equation (1) can retrieve a fast and rough estimation of the ice thickness but

333 should be used with care since the shear-wave velocity varies at different sites. H/V spectrum inversion,
334 however, unlike estimation with Eq. (1), is robust and can obtain reliable ice thickness results with given seismic
335 properties. Moreover, the H/V spectrum inversion ice sheet thickness results are consistent with the reference
336 Bedmap2 database. Our results also support the argument that the Antarctic ice sheet has a two-layer structure.
337 The H/V method is an excellent complementary approach to the most commonly used RES and active seismic
338 methods for ice sheet thickness measurements in terms of its effectiveness. What makes this new approach most
339 attractive are the ease and economy of seismic ambient noise waveforms collection when deploying a single
340 seismometer for short time intervals. Finally, we hope that specific seismic experiments can obtain more
341 accurate shear-wave velocity profiles in the ice sheet, thus making better constraints for H/V method results.

501

502

Figure 2. Sketches of the two ice layer models used for H/V spectrum inversion. Model A comprises a single ice layer, while model B is a two-layer ice structure with low shear-wave velocity in the lower ice layer. The parameters used in the two models are referred to Wittlinger (2012).

503

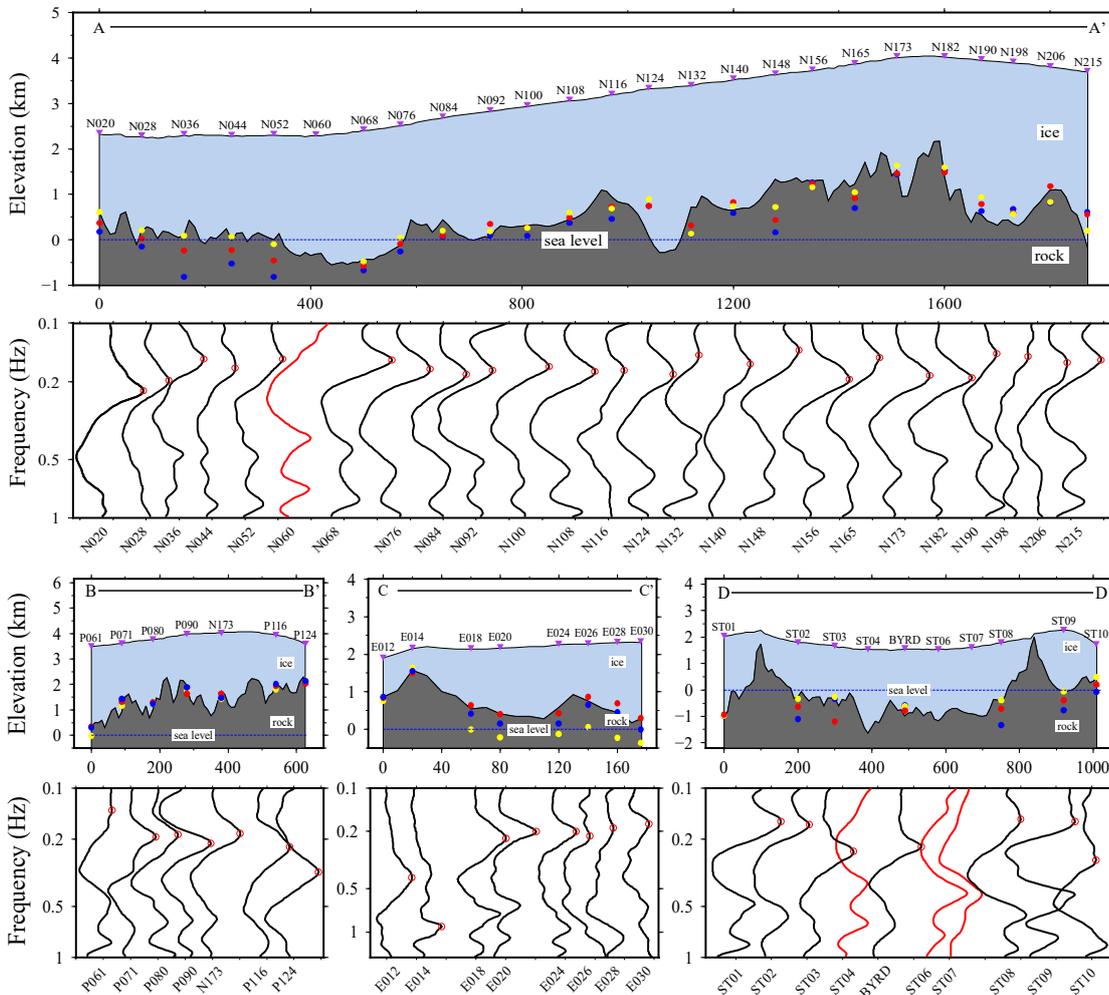

504

505 **Figure 3.** H/V spectra of nine stations shown as representative of all results in this study. The H/V spectra were calculated
506 using five-day long ambient noise record. The spectra of the E012, E018, GM01, N148, P071, ST01 and ST02 stations
507 represent 42 stations whose clear first peaks with the largest amplitudes are in agreement with the resonance frequency of
508 the ice sheet layer. Station N108 is representative of 18 stations whose first peaks are related to the ice sheet resonance
509 frequency but with slightly lower amplitude than peaks in higher frequencies. ST07 is the example that no peak frequency
510 correlating to the ice thickness appears as expected in the observed H/V spectrum.
511

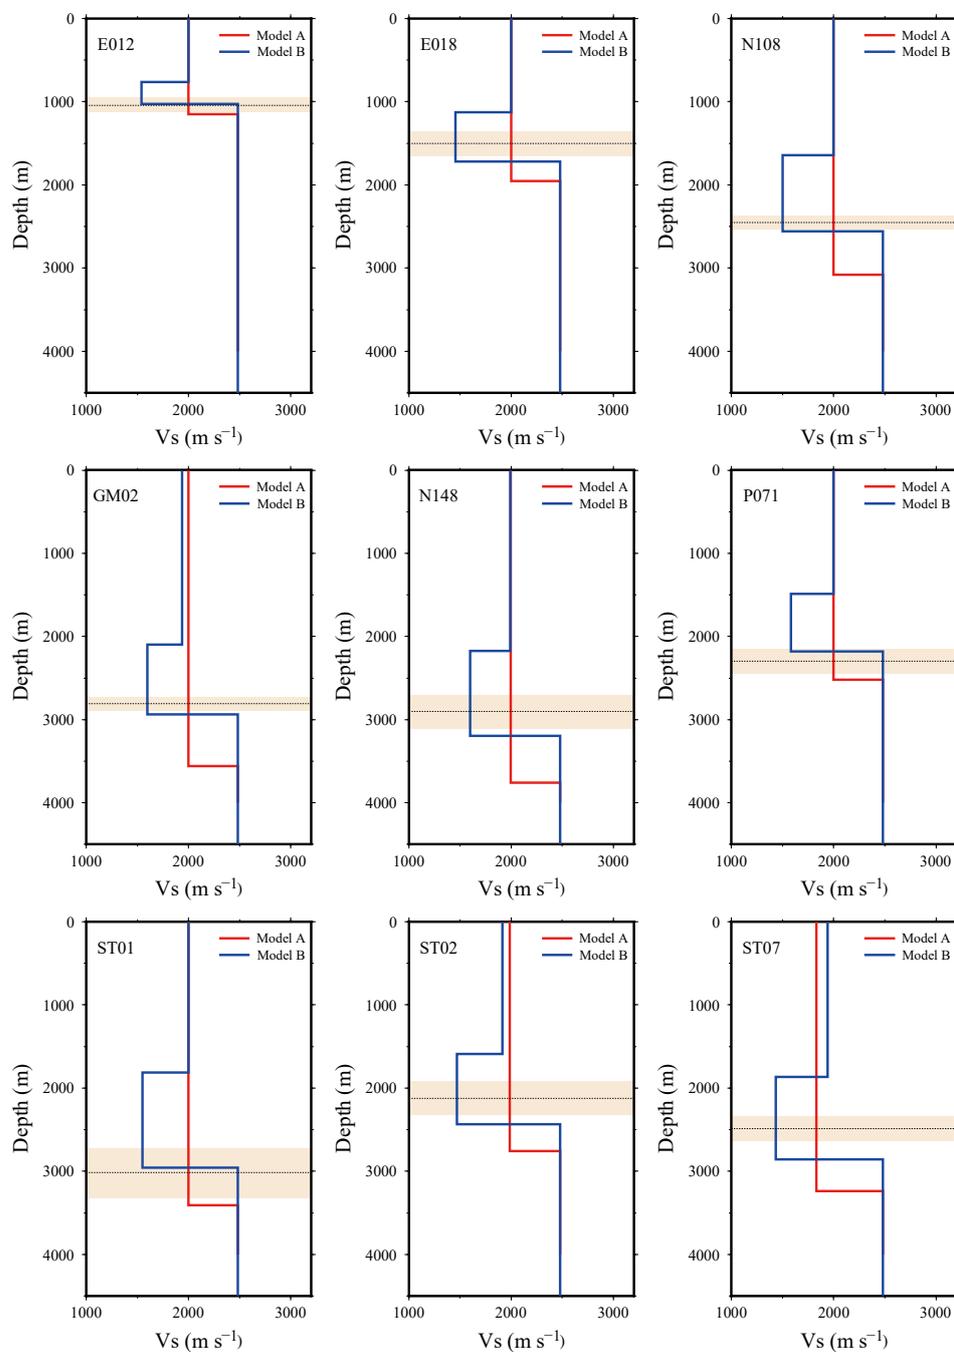

512

513

514 **Figure 4.** Cross section showing H/V spectra and the ice sheet thickness obtained from the H/V method at stations along
 515 the four profiles (Fig. 1). In the below H/V spectra cross section panels, the red circles denote the resonance frequencies
 516 correlating to the ice thickness for each station, and the spectra of the four stations without clear peaks are plotted with red
 517 lines. The upper panels show the variation of the bedrock and ice surface elevation along each profile obtained from
 518 Bedmap2 database. In these plots, the red dots indicate the reference Bedmap2 ice thickness, while the yellow and the blue
 519 dots represent the calculated ice thickness using Eq. (1) and the inversion ice thickness from model B, respectively.
 520

524

525

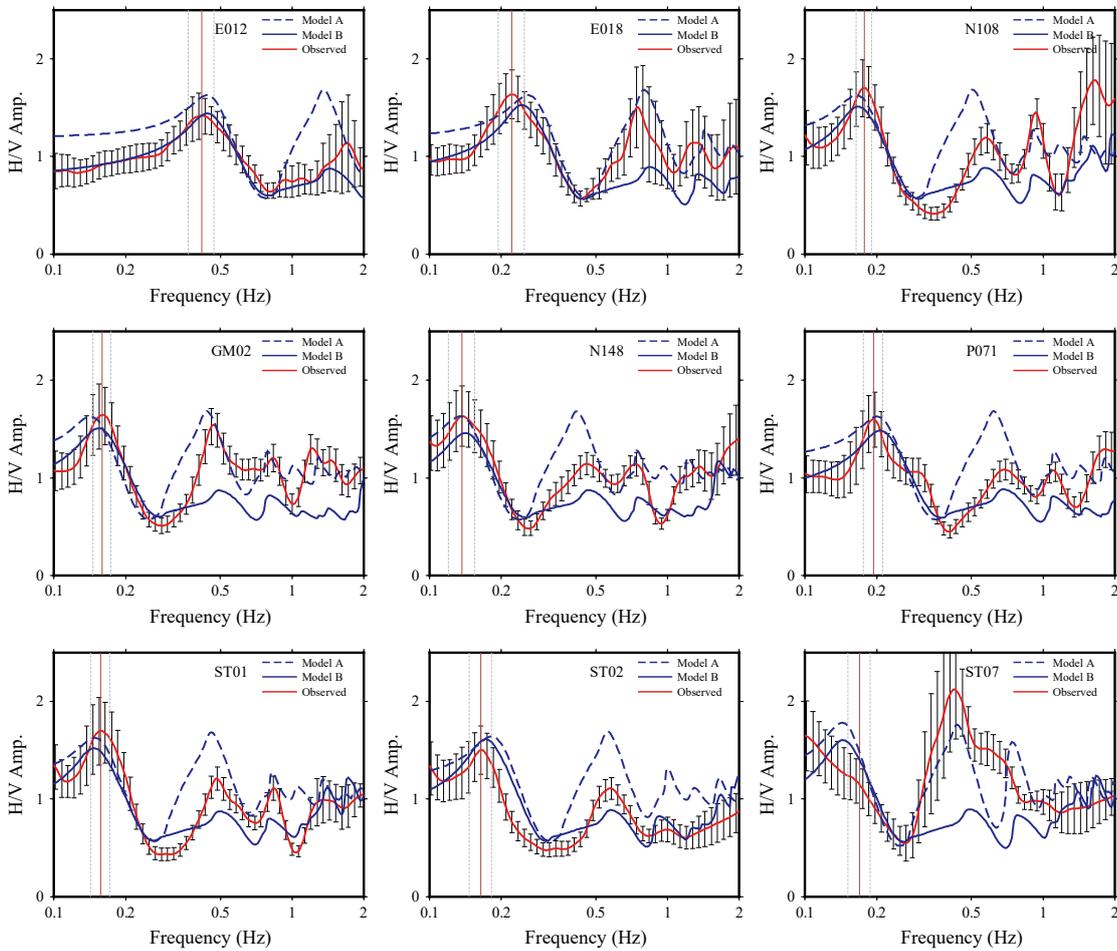

526

527

Figure 5. The optimum inversion shear-wave velocity models for the nine stations. The horizontal dashed line in each plot indicates the reference Bedmap2 ice thickness, and the shaded area shows the uncertainty of the Bedmap2 ice thickness. Apparently, the inversion ice thickness results derived from the two-layer structure (model B) are much closer to the Bedmap2 thickness than those determined using the single ice layer (model A).

530

531

532

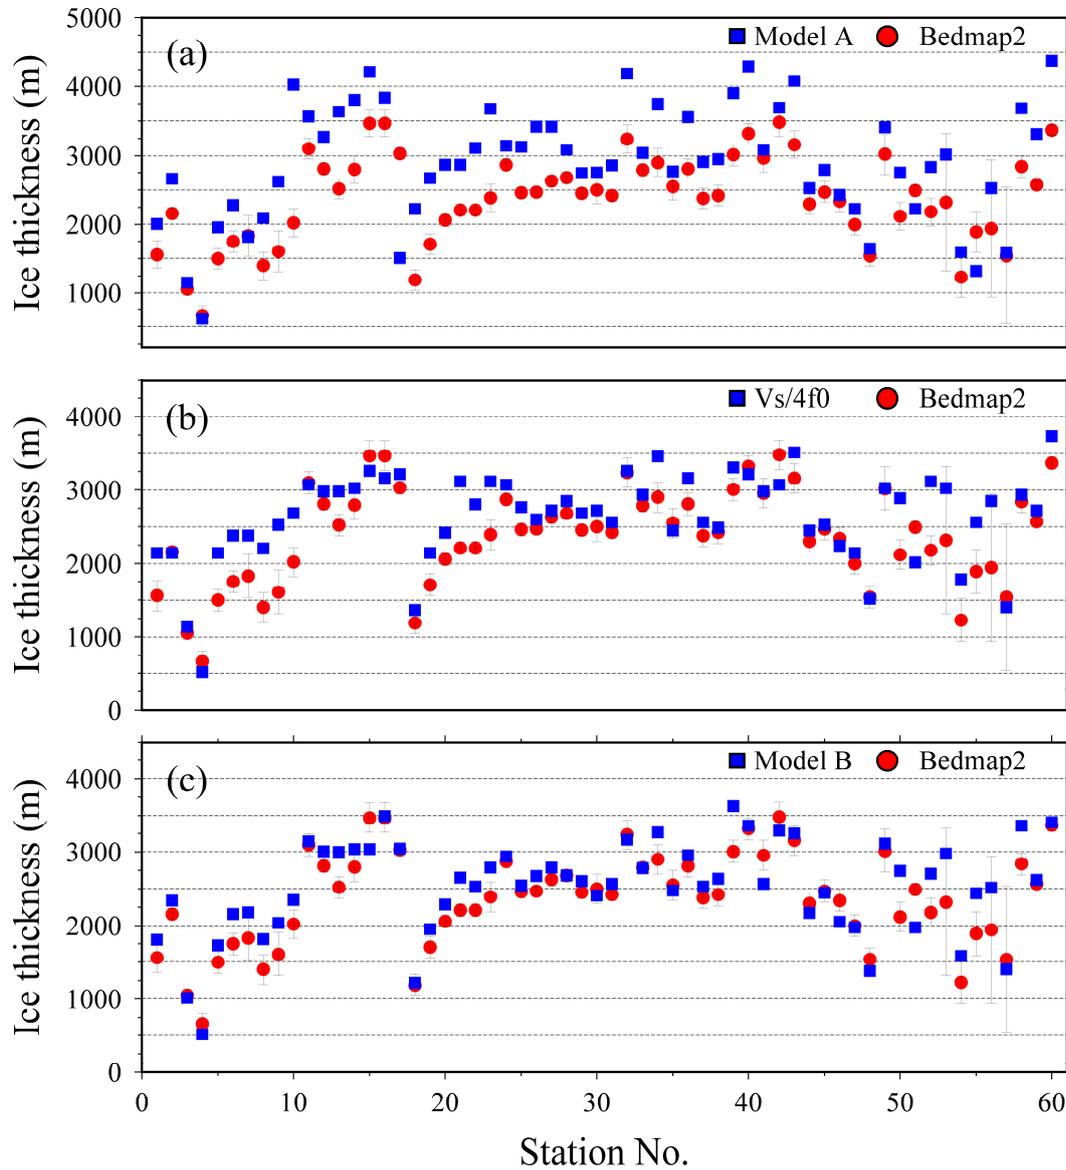

533

534

Figure 6. The synthetic H/V spectra and the observed H/V spectrum for the nine stations. The synthetic H/V spectra are modelled using the optimum inversion shear-wave velocity profiles for model A and model B. The two synthetic H/V spectra are both in good agreement with the observed H/V spectrum. Note that the amplitudes of the synthetic H/V spectra are normalized by dividing 2 in the whole frequency band.

540

541

Figure 7. Ice thickness derived from the H/V method versus the reference Bedmap2 ice thickness. The blue squares in panel (a), (b), and (c) represent ice thickness estimations from model A, Eq. (1), and model B, respectively. The red circles in each panel denote the Bedmap2 ice thickness and each Bedmap2 value is marked with its corresponding error bar obtained from the uncertainty grids (Fretwell et al., 2013).

542

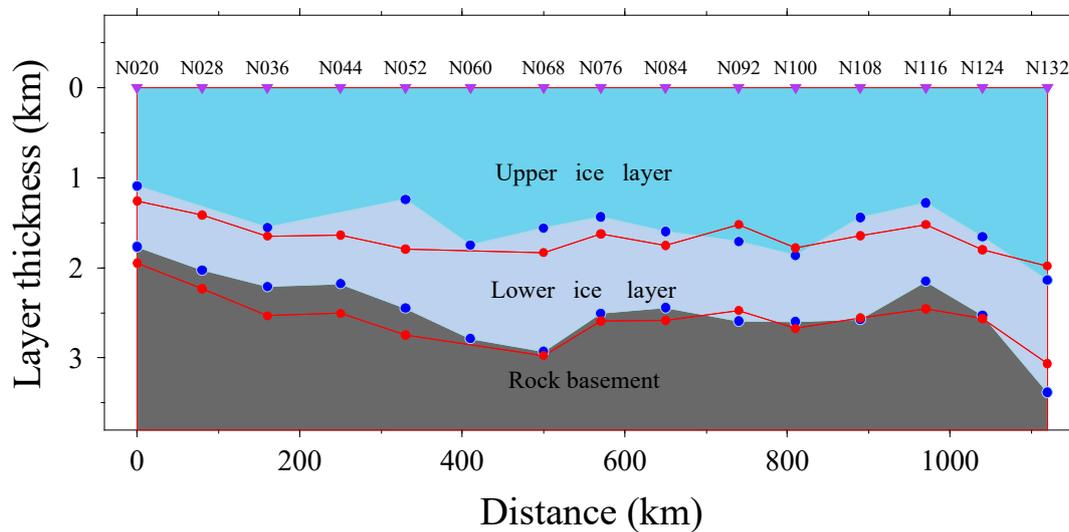

543

544 **Figure 8.** H/V spectra calculated using different lengths of ambient noise records. There is a good consistence between
545 H/V spectra determined with different tesing length of noise records (1 h, 2 h, 4 h and 8 h) and the spectrum with record
546 five-day long, both in locations of peak frequencies and the spectra shape. However, the peak frequency obtained from 1 h
547 record slightly deviates the peak frequency determined using 5 d record for the E012 station.
548

549

550

552 the ice thickness derived from H/V spectrum inversion in our study, and the blue dots indicate the ice thickness determined
553 with the PRF method and a grid search stacking technique (Wittlinger and Farra, 2012, Table1).
