Abstract. The Canadian Sea Ice and Snow Evolution Network (CanSISE) is a climate research network focused on developing and applying state of the art observational data to advance dynamical prediction, projections, and understanding of seasonal snow cover and sea ice in Canada and the circumpolar Arctic. Here, we present an assessment from the CanSISE network on trends in the historical record of snow cover (fraction, water equivalent) and sea ice (area, concentration, type, and thickness) across Canada. We also assess projected changes in snow cover and sea ice likely to occur by mid-century, as simulated by the Coupled Model Intercomparison Project Phase 5 (CMIP5) suite of earth system models. The historical datasets show that the fraction of Canadian land and marine areas covered by snow and ice is decreasing over time, with seasonal and regional variability in the trends consistent with regional differences in surface temperature trends. In particular, summer sea ice cover has decreased significantly across nearly all Canadian marine regions, and the rate of multi-year ice loss in the Beaufort Sea and Canadian Arctic Archipelago has nearly doubled over the last eight years. The multi-model consensus over the 2020-2050 period shows reductions in fall and spring snow cover fraction and sea ice concentration of 5-10% per decade (or 15-30% in total), with similar reductions in winter sea ice concentration in both Hudson Bay and eastern Canadian waters. Peak pre-melt terrestrial snow water equivalent reductions of up to 10% per decade (30% in total) are projected across southern Canada.

1 Introduction

Seasonal terrestrial snow and sea ice influence short term weather and longer term climate by altering the surface energy budget, modifying both the surface reflectivity and thermal conductivity (Serreze et al., 2007; Flanner et al., 2011; Gouttevin et al., 2012). Snow also influences freshwater storage through soil moisture recharge and surface runoff (Barnett et al., 2005). Understanding historical and projected future changes to snow and ice is essential both to assess the importance of physical changes to the climate system, and to thus assess their consequent impacts and risks. A previous assessment of the

Canadian cryosphere (snow, sea ice, freshwater ice, land ice, frozen ground) was compiled as part of the International Polar Year (IPY) in 2007-2008, and is described in Derksen et al. (2012). The current study updates the IPY analysis pertaining to terrestrial snow and sea ice by adding nearly a decade of data and including climate model projections of changes over the next 30 to 40 years. This work is a core contribution of the Canadian Sea Ice and Snow Evolution Network (CanSISE), a climate research network focused on developing and applying state of the art observational data to advance dynamical prediction, projections, and understanding of seasonal snow cover and sea ice. Recognizing the critical importance of the snow/sea ice component of the cryosphere to Canada's natural environment, ecosystems, and economy, this CanSISE study focused on Canadian territory, which is nearly completely covered by snow and ice for parts of each year and which features near-continuous coverage over high latitude and high elevation regions. While acknowledging the Canadian focus, much of the applied approach will be extended to other regions of interest through upcoming Coupled Model Intercomparison Project Phase 6 (CMIP6) experiments (i.e. van den Hurk et al., 2016).

Previous studies have shown that warming temperatures, which are amplified at higher latitudes as a natural response to increasing greenhouse gases (Serreze et al., 2009; Pithan and Mauritsen, 2014), reduce the spatial extent and mass of snow and ice (for example, see Derksen et al., 2012). In reality, the linkage between warming temperatures and snow/sea ice reduction is more nuanced due to:

- *regional and seasonal climate variability*: for example, surface temperature warming across Canadian land and ocean areas is not uniform in space and time, but contains regional and seasonal variability driven by natural climatic processes such as the El Niño Southern Oscillation (ENSO) and other oceanic teleconnections, and inter-seasonal and inter-annual changes in the preferred modes of atmospheric circulation (Vincent et al., 2015). The impact of warm temperature departures on the cryosphere vary with season: during spring they are directly linked to the timing and magnitude of melt onset; during fall warm temperatures can be associated with delayed snow cover onset and ice formation, the impacts of which may not become apparent for many months.
- *the selection of cryospheric variables*: the onset, accumulation/growth and melt of snow and sea ice are influenced by many factors and different metrics derived from these quantities that are relevant for different impacts on the environment and ecosystems do not always vary coherently with each other (Bokhorst et al., 2016). Changes in snow can be reflected in the timing of snow onset in the fall and melt in the spring, the peak seasonal accumulation of snow mass before melt, or the extent of snow covered area. For sea ice, not only are changes in the fractional ice cover important but also the type of sea ice present, specifically whether it is thin first-year ice or thicker multi-year ice (Maslanik et al., 2011).
- *other process drivers*: while surface temperature plays a major role in influencing snow and ice, there are other important drivers of change. For instance, increased precipitation in sufficiently cold regions may offset shorter snow seasons (Brown and Mote, 2009). Sea ice dynamics (driven by wind and ocean currents) can play a major role in regional sea ice conditions independent of surface temperature (Howell et al., 2013a).

- *snow/ice forcing of climate anomalies*: variations in snow and ice cover may also generate feedbacks to the atmosphere/ocean circulation that influence climate on seasonal to decadal scales (Cohen et al. 2007, Smith et al. 2010, Scaife et al. 2014), although there is no clear consensus on how changes in Arctic sea ice and snow cover influence midlatitude climate (Francis and Vavrus, 2012; 2015; Francis et al., 2017; Barnes, 2013; Screen et al., 2015).

70

The first objective of this paper is to provide an overview of observed changes to seasonal terrestrial snow and sea ice across Canadian territory using the longest available time series of validated gridded datasets. We use a multi-data set approach, averaging multiple estimates of terrestrial snow together for a more robust trend and using an integrated, multi-source dataset for analysis of sea ice change. The second objective is to compare these recent historical changes to projected changes of snow and sea ice over a similar length of time from the near future out to the middle of the 21st century (2020-2050). We use simulations from state of the art climate models with confidence levels that account for uncertainty in the regional temperature response (note that the focus of this study is not model evaluation – that analysis is described in Kushner et al., 2017). Results are presented in two sub-sections, separated by the observational analysis period (Section 3.1) and the future projections (Section 3.2). Details on the datasets and methodology are provided in Section 2. We summarize our key findings in Section 4 and present remaining points of discussion in Section 5.

80

2 Data

2.1 Historical Datasets

2.1.1 Terrestrial Snow Data

85 Following Mudryk et al. (2015), we took a multi-dataset approach to analyze observed snow cover change in order to account for observational uncertainty. We calculated monthly snow cover fraction (SCF) and seasonal maximum snow water equivalent (SWE) using daily SWE data taken from the following four sources over the 35 year period from 1981-2015. 1) The Modern-Era Retrospective Analysis for Research and Applications version 2 (MERRA-2), (Reichle et al., 2017, updated from Rienecker et al. 2011), is a National Aeronautics and Space Administration (NASA) atmospheric reanalysis product generated with the Goddard Earth Observing System Model, version 5.2.0 (GEOS-5) atmospheric general circulation model and atmospheric data assimilation system (ADAS). 2) The temperature index model described by Brown et al. (2003) reconstructs daily SWE using 6-hourly temperature field and 12-hourly precipitation field inputs from ERA-interim reanalysis. This simplified index model includes most of the temperature dependent processes included in the snow component of numerical land surface schemes (e.g., partitioning of precipitation into solid and liquid fractions, melt from rain-on-snow events, specification of new snowfall density, snow aging, and snowmelt). 3) The physical snowpack model Crocus simulates daily SWE using meteorology from ERA-Interim (Brun et al. 2013). 4) The European Space Agency

90

100 GlobSnow product (version 2; www.globsnow.info) is a gridded product derived through a combination of satellite passive microwave data, forward snow emission model simulations, and climate station observations for non-alpine regions of the northern hemisphere (Takala et al. 2011). Because the GlobSnow product is masked over complex topography, we replaced such cells with a blend of the GlobSnow data and the mean value from the other three data sources. The weighting for the blend was determined by the fraction of the grid cell area containing complex topography. For grid cells with no complex topography, unaltered GlobSnow data are used. As the fraction of complex topography increases, the weight applied to the GlobSnow data is linearly reduced, reaching zero for grid cells only containing complex topography.

105 For a given dataset of daily SWE, we interpolated the data to a regular 0.25 degree grid over Canada and applied a 4 mm threshold to produce a daily binary snow cover extent. We averaged this daily field over each month to produce a monthly snow cover fraction. Seasonal maximum SWE fields were calculated as the maximum value of daily SWE attained at each grid location over a given snow season. For both SCF and maximum SWE, we computed trends separately for each of the four datasets and then averaged these together into a final trend representing the mean across the observational ensemble.

110 2.1.2 Sea Ice Data

We extracted total and multi-year ice (MYI) area within Canadian Arctic waters from the Canadian Ice Service Digital Archive (CISDA), which is an integration of a variety of data sets including: satellite observations, surface observations, airborne and ship reports, operational model results and the expertise of ice analysts (see Canadian Ice Service, 2007 and Tivy et al., 2011a for complete details). We selected the CISDA record instead of satellite passive microwave data because i) 115 the CISDA was found to be more accurate in the shoulder seasons during which passive microwave retrievals can underestimate sea ice concentration by as much as 44% (Agnew and Howell, 2003) and ii) the CISDA sea ice record provides homogeneous data back to 1968 for regions of the Canadian Arctic (Tivy et al., 2011a), almost 10 years earlier than coverage by satellite passive microwave observations. The CISDA data was analyzed over two historical periods, the 1981-2015 period consistent with available snow data and a longer 1968-2016 period.

120

We also used the Canadian Ice Service record of in situ landfast ice thickness measurements, made regularly at coastal Arctic stations since the early 1950's (Howell et al. 2016b). In general, thickness measurements are available at weekly frequency, starting after freeze-up when the ice is safe to walk on and continuing until breakup or when the ice becomes unsafe. Details of this dataset are provided by Brown and Cote (1992) and are available on the Canadian Ice Service Web 125 site at <http://iceglaces.ec.gc.ca>.

2.1.3 Surface Temperature

In light of documented differences in gridded temperature datasets over Canada (Rapaic et al., 2015), surface temperature trends were derived from a blend of six reanalysis products: the European Centre for Mid-Range Weather Forecasting

(ECMWF) Reanalysis (ERA-Interim, Dee et al., 2011), the Japanese 55-year and 25-year Reanalyses (JRA-55, Kobayashi et al., 2015; JRA-25, Onogi et al, 2007), the Modern-Era Retrospective analysis for Research and Applications version 1 and 2 (MERRA-1, Reinecker et al., 2011; MERRA-2, Reinecker et al., 2017), and the Climate Forecast System Reanalysis (CFSR, Saha et al., 2010). The average trend was determined by first computing the average of JRA-55 and JRA-25 (resulting in a single JRA trend), and the average of MERRA-1 and MERRA-2 (resulting in a single MERRA trend). The multi-reanalysis mean trend was computed by averaging (ERA-Interim, CFSR, JRA, and MERRA). Reanalysis was used instead of point station data in order to produce spatially continuous trends over both terrestrial and marine areas.

2.2 Model Simulations

2.2.1 Terrestrial Snow

We used monthly mean output from the suite of historical and future simulations from the CMIP5 archive (Taylor et al. 2012; <http://cmip-pcmdi.llnl.gov/cmip5/>) to evaluate snow cover fraction (variable ‘SNC’) and snow water equivalent (variable ‘SNW’). The models utilized for snow analysis are listed in **Table 1**; note that no model selection was performed – all models with archived snow data were utilized. Future snow projections were selected from the Representative Concentration Pathway (RCP) 8.5 projected forcing scenario because it most closely resembles the observed emissions pathway over the past decade (Peters et al. 2013). We then computed individual trends for each realization and then took the inter-realization average across each model to calculate individual model ensemble means. These values were averaged to determine the CMIP5 multi-model mean values. If only a single realization was available, that was used directly as input to the multi-model mean calculation. SWE and SCF output were also taken from a large initial condition ensemble (50 realizations) of the Second Generation Canadian Earth System Model (CanESM2; Arora et al., 2011), a global earth system model from the Canadian Centre for Climate Modelling and Analysis. The realizations of this ensemble branch off from five different historical simulations of CanESM2 in 1950, evolving under combined historical and RCP8.5 forcing scenarios in accordance with CMIP5 (see Thackeray et al., 2016 for more details). This ensemble was used to characterize the role of internal climate variability on projected snow cover changes over Canada.

2.2.2 Sea Ice

Monthly mean sea ice concentration (variable ‘SIC’) and the land-sea mask (variable ‘SFTLOF’) were also retrieved as available from CMIP5 output resulting in a sea ice ensemble that comprises 42 models and a combined total of 91 simulations (Table 2). The sea ice concentration was projected to an EASE grid using the exact same procedure as in Laliberte et al. (2016). For projections of sea ice-free conditions over the four Canadian marine subregions (Baffin Bay, Beaufort Sea, Canadian Arctic Archipelago, and Hudson Bay), we excluded models that do not capture at least 75% of the region’s observed ocean area (resulting in about half of the models rejected in the Canadian Arctic Archipelago) and compute sea ice extent (SIE), as in Laliberte et al. (2016).

160 2.3 Evaluation of Trend Significance

In order to make comparable significance calculations for the observed and projected trends, we use a Monte Carlo method following Swart et al. (2015) and applied in Howell et al. (2016). The method ensures that spread due to internal variability is comparable for all CMIP5 models, even those that only include a single realization in their archived output. This is achieved by adding simulated noise representing internal variability to those models with only a single realization. The added noise is calculated from the collection of models with multiple realizations under the assumption that the spread due to internal variability is the same across all models. A trend is significantly different from zero if it is distinguishable from the combined spread due to interannual variability (using a t-distribution for each simulation), internal variability (with noise added as described), and model spread.

170 We use an analogous approach to compute significance for the various observation-based dataset trends. We assume that differences in the trends arise from differences in retrieval performance and reanalysis methodologies but not from sampling of internal variability. Thus, a trend is significantly different from zero if it is distinguishable from the combined spread due to interannual variability (using a t-distribution for the dataset mean) and the added spread due to differences in the trends among the different data sets.

175 3 Results

3.1 Observed Trends in Terrestrial Snow and Sea Ice

Seasonally averaged trends in terrestrial snow cover fraction (SCF) and sea ice concentration (SIC) over the 1981-2015 time period are shown in **Figure 1** (the dashed line denotes limit of Canadian marine territory). Positive trends in SCF (more snow cover) are evident over a small region of the southern prairies in winter (January/February/March, JFM) and more extensively over western Canada in spring (April/May/June, AMJ). Trends in all remaining regions and seasons are negative, notably over eastern Canada in spring and most of the Canadian land area in the fall (October/November/December, OND). The predominantly negative trends in snow cover are consistent with previous studies (Brown and Braaten, 1998; Vincent et al. 2015) but with evidence of a shift to stronger snow cover reductions in the snow onset period over eastern Canada in response to enhanced OND warming shown in **Figure 2 (discussed below)**. The observed rates of snow cover change are also consistent with the recent Snow, Water, Ice, Permafrost in the Arctic (SWIPA) assessment (Brown et al. 2017) that documented annual SCD changes over Arctic land areas of -2 to 4 days/decade (~ -1 to -2% per decade assuming 250 days mean snow cover). Other studies focused on Arctic snow cover (i.e. Derksen and Brown, 2012; Derksen et al., 2016) have identified spring snow cover losses that are stronger than those in **Figure 1**. This difference may stem from stronger spring trends in the NOAA snow chart data record (the NOAA dataset was not used in this study due to known deficiencies in the

190 fall period; Brown and Derksen, 2013) compared to other snow products (Mudryk et al., 2017), and stronger trends across
the Eurasian Arctic compared to North America (Derksen et al., 2016).

SIC trends over Canadian waters for this period are almost exclusively negative in all seasons. Regions with the strongest
SIC declines are eastern Canadian waters in winter and spring, and the Canadian Arctic Archipelago and Hudson Bay in
195 summer and fall consistent with the warming patterns shown in Figure 2. The SCF and SIC trends can be viewed collectively
as changes in the timing and extent to which highly reflective snow and ice cover the Earth's surface, with important
implications for the surface energy budget. There are no sharp boundaries in trends across adjacent land and ocean regions.
This provides confidence in the consistency of the snow and ice datasets, as well as evidence of a coherent response of snow
and ice to temperature forcing across terrestrial and marine regions.

200

Figure 2 shows seasonal surface air temperature (TAS) trends over the 1981-2015 period computed from a blend of six
atmospheric reanalysis datasets (see Section 2.1.3). TAS trends are generally positive, although no trends are seen
throughout the northwestern portion of the country during winter and spring, and there is significant cooling over the
Canadian prairies in spring. Land areas with cooling trends are co-located with positive SCF trends in **Figure 1**, although the
205 region with positive SCF trends is slightly more extensive. The reduced warming and cooling over northwestern Canada is
consistent with the influence of North Pacific oceanic variability over the last 35 years as analyzed in Mudryk et al., 2014.
The reanalysis TAS trends are also seasonally and spatially consistent with the analysis of Rapaic et al. (2015, Fig. 13) based
on blended data from both homogenized station observations and multiple reanalyses. In both reanalysis and in situ data,
Arctic trends are strongest in the fall and winter, with an increase in the magnitude of warming from the southwest to
210 northeast regions of the country apparent in all seasons.

To examine the role of air temperature trends in driving the observed snow and ice cover trends, spatial correlations
(centered and uncentered) were calculated to quantify the pattern relationship between SCF, SIC, and TAS trends (**Figure 3**).
The centered (uncentered) statistic measures the similarity of the two patterns after (without) removal of the domain mean. A
215 large negative uncentered correlation indicates that the correlation between the two fields is negative on average, but does
not require that the field patterns are congruent. A large negative centered correlation does require spatial similarity in the
field patterns. Both SCF and SIC trend show large uncentered correlations for all seasons indicative of the general
relationship between increasing temperatures and decreasing SCF and SIC. During JFM and AMJ, the large centered
correlations between SCF and TAS indicate that the spatial patterns are also similar, and hence there is a strong association
220 between SCF and TAS trends at the local scale during these seasons, with reduced connections during JAS and OND
(consistent with Mudryk et al, 2017). SIC trend patterns are more closely associated with warming patterns during ice
onset/growth (OND and JFM), however overall there is less co-variability of SIC trends with TAS trends than for SCF
trends. This difference may stem from the fact that ice (especially MYI) is more difficult to melt than snow, and the

225 additional influence of dynamical effects (such as wind-driven redistribution of sea ice) weakens the thermodynamically driven spatial association between SIC and TAS trends.

Trends in pre-melt seasonal maximum snow water equivalent (SWE_{max}), which indicates water resource and streamflow potential just before spring melt, are shown in **Figure 4**. The figure represents averages from the same datasets used to generate the SCF trends in **Figure 1**. Trends are negative over much of Canada, indicating a reduction over time in SWE_{max} at the onset of the melt season each spring. This is consistent with observed in situ snow depth trends (Brown and Braaten 1998; Vincent et al., 2015) and other observational studies (for example Mudryk et al., 2015). There is evidence of SWE_{max} increases in the western Canadian Arctic Archipelago (CAA) but these are modest in strength and regionally limited. As will be discussed further in Section 4 in the context of future projections, the varying influence of temperature and precipitation changes need to be disentangled in order to understand the driving mechanisms behind trends in SWE_{max} (Raisanen, 2008; Brown and Mote, 2009).

The longer period of consistent summer sea ice information in Canadian waters from the CISDA allows consideration of additional years not covered by the 1981-2015 trends in **Figure 1**. To be consistent with Tivy et al. (2011a) and Derksen et al., (2012) the summer ice season is defined as average sea ice area from June 25 to October 15 for the Beaufort Sea, CAA, and Baffin Bay regions and from June 18 to November 19 for Hudson Bay, Hudson Strait, Davis Strait and Labrador Sea. Between 1968 and 2016, sea ice area averaged over the summer period has experienced significant decreases in almost every region of the Canadian Arctic, up to 20% per decade in some regions (e.g. the Hudson Strait and Labrador Sea; **Figure 5**). Compared to previous trends reported by Tivy et al. (2011a) over the period of 1968-2008 and Derksen et al., (2012) for 1968-2010, more regions are now experiencing significant decreases and the rate of decline is stronger in all regions except Hudson Bay (**Figure 6e**). For MYI, there are more regions across the Canadian Arctic, particularly in the western CAA, that are now experiencing significant declines compared to previous studies (e.g. Tivy et al., 2011a; Derksen et al., 2012; **Figure 5**). The largest declines in MYI occurred in the CAA and Beaufort Sea, both of which almost doubled their rate of decline for 1968-2016 when compared to the trend for 1968-2008 (**Figure 6e**).

250 A stepwise reduction in Hudson Bay sea ice area occurred in the mid-1990s (**Figure 6d**; Tivy et al., 2011b; Hochheim and Barber, 2014) and Baffin Bay has experienced consistently low sea ice area since 1999 (**Figure 6c**); whereas, considerably more interannual variability is apparent in the Beaufort Sea and CAA (**Figures 6a and b**). Of note, the Beaufort Sea experienced a record low sea ice area in 2012, becoming virtually ice-free near the end of the melt season (Babb et al., 2016). This was nearly repeated in 2016. As previously reported, the CAA eclipsed the previous and long standing record low ice year of 1998 in both 2011 and 2012 (Howell et al., 2013b). A contributing factor to the decline of sea ice across the Canadian Arctic is increasing spring air temperature (see **Figure 2**) coupled with longer melt seasons resulting in the

absorption of more solar radiation and increased ice melt (Howell et al., 2009; Tivy et al., 2011a; Stroeve et al., 2014; Parkinson, 2014).

260 Arctic sea ice thickness has declined in recent years (e.g. Kwok and Rothrock, 2009; Haas et al., 2010; Laxon et al., 2013; Richter-Menge and Farrell, 2013; Kwok and Cunningham, 2015; Tilling et al., 2015). These studies indicate thickness declines are greater in the Beaufort Sea compared to the north facing coast of the CAA, which still contains some of the thickest sea ice in the world. Unfortunately, the spaceborne sensors used to obtain sea ice thickness information are not of sufficient spatial resolution to provide reasonable thickness estimates within the CAA. However, the Canadian Ice Service
265 record of in situ landfast ice thickness measurements represents one of the longest datasets in the Arctic, and spans over 5 decades (Howell et al., 2016b). However, the seasonal behaviour of landfast ice thickness can provide useful information for understanding the interannual variability because ice growth is almost entirely due to thermodynamic forcing. Significant declines in maximum ice thickness have occurred at 3 sites in the CAA (Cambridge Bay, Eureka, and Alert) with decreases ranging between -3.6 to -5.1 cm per decade over the period from the late 1950s to 2016 (**Figure 7**). No significant trend was
270 found at Resolute (**Figure 7b**) but an early study from Brown and Cote (1992) reported a significant increase in maximum ice thickness at Resolute over the period from 1950-1989.

Although systematic measurements at other regions within the CAA are unavailable or contain too much uncertainty, surveys in 2011 and 2014 of ice thickness from airborne electromagnetic induction (AEM) described by Haas and Howell
275 (2015) indicated the ice is still thick, with a modal thickness of 1.8-2.0 m (not shown). Ice between 3-4 m in mean thickness was found in the MYI regions throughout the CAA.

3.2 Projected Changes in Terrestrial Snow and Sea Ice

Projected trends in snow cover fraction (SCF) and sea ice concentration (SIC) for the 2020-2050 time period across Canadian territory are shown in **Figure 8**. These projections are the multi-model mean from the ensemble of CMIP-5 climate
280 models, using the RCP8.5 forcing scenario (which assumes 'business as usual' continued growth of greenhouse gas emissions through the 21st century). While other scenarios exist, projections to the mid-century are primarily dependent on natural variability and model dependent uncertainties rather than the choice of forcing scenario (Hodson et al., 2012). The multi-model projected mean changes in surface temperature are positive in all seasons, hence in the ensemble mean only reductions in SCF and SIC are evident in **Figure 8**. Seasonal differences and varying sensitivity of snow and ice to
285 temperature forcing drives the spatial variability in **Figure 8**. During winter, projected snow cover reductions are greatest along the southern margins of Canada, where temperature increases directly result in less snow. Temperatures remain sufficiently cold at higher latitudes (despite projected warming) so there is no projected response in this region in JFM SCF. During spring, the region of snow sensitivity to temperature forcing shifts north, across the boreal forest, subarctic, and Arctic tundra, which leads to the negative SCF trends projected across these regions during AMJ. Ensemble-mean reductions

290 projected for SIC are very strong and focused on the ice melt (summer) and ice formation (fall) seasons, with the exception
of Hudson Bay and eastern Canadian waters which also have projected winter season loss of sea ice cover.

While natural decadal-scale climate variability resulted in cooling trends (and hence positive SCF and SWEmax trends) for
some regions and seasons during the 1981-2015 period (see **Figures 1, 2 and 4**), over the longer 1948-2012 period observed
295 surface temperature trends over Canada are almost exclusively positive (Vincent et al., 2015). Similarly, we expect there
could be short term, localized fluctuations in trend direction and magnitude from the projections shown in **Figure 8**. These
localized fluctuations exist in individual realizations of the model projections (not shown) and act to increase the spread in
the TAS, SCF, and SIC responses. This spread reduces the significance of the ensemble-mean response for a given
confidence level; for this reason only the coastal regions in British Columbia show significant SCF decreases at the 90%
300 confidence level, whereas projections show widespread reductions in SIC at the 90% confidence level. The differences
between SCF and SIC in the significance of their projected responses may result from varying sensitivity to temperature
forcing if SCF depends more strongly on the local temperature response than SIC.

Figure 9 shows trends in SWEmax also derived from the CMIP-5 multi-model ensemble. The ensemble mean shows that
305 peak SWEmax loss will be extensive (5-10% per decade through 2050, or a cumulative 15-30% reduction over the entire
2020-2050 period) over much of Alberta and British Columbia, and similarly in Southern Ontario and the Maritime
provinces (note that the greatest near-future loss in the CMIP5 ensemble occurs just south of the Canadian border, not shown
in **Figure 9**). While positive Arctic SWEmax trends start to emerge by mid-century in the Eurasian Arctic (not shown; see
Brown et al., 2017) minimal change is projected across high latitude land areas of Canada because increasing temperature
310 (which shortens the snow accumulation season) balances projected increases in snowfall.

Month by month projected changes in Canadian snow extent and snow mass for the CMIP5 multi-model ensemble, and the
large initial condition ensemble from the second generation Canadian Earth System Model (CanESM2) are shown in **Figure**
10. The two ensembles agree that the greatest near-future snow loss (as a percentage of climatological snow) is projected to
315 occur in the shoulder seasons (Oct-Nov, May-Jun). During mid-winter there is minimal percentage change in snow cover
extent projections because winter temperatures over northern regions of Canada will remain cold enough to sustain snow
cover and there is greater climatological snow extent in winter, which results in smaller percentage changes reflected in
Figure 10. The projected trends from CMIP5 are similar in magnitude to the rate of change during the historical period
considered in this study, while trends from CanESM2 are slightly stronger due to greater warming in CanESM2 compared to
320 the CMIP5 multi-model mean (Thackeray et al., 2016). Because the CMIP5 ensemble includes many different models, there
is a greater spread in most months than the CanESM2-LE, which represents multiple climate realizations generated from a
single model. Nonetheless, it's striking that the interquartile range of the CanESM Large Ensemble is quite comparable to

that of the CMIP model ensemble. This likely indicates that a large portion of the inter-model spread is associated with internal variability.

325

Sospedra-Alfonso and Merryfield (2017) showed that the interannual variability in monthly SWE between January and April can be skillfully estimated with a multiple linear regression model based on precipitation and temperature predictors. This statistical model suggests coherent relationships that provide context to the character of the changes to terrestrial snow cover that are being considered here. **Figure 11** shows present-day (1981-2016) and projected (2015-2050) seasonal near-surface air temperature (T_s) defined following Sospedra-Alfonso and Merryfield (2017) and given roughly by the average temperature over the consecutive months from snow onset up to March. Results are obtained from five ensemble members of historical (1951-2005) + RCP8.5 (2005-2100) simulation runs in CanESM2 downscaled with CanRCM4. The seasonal temperature threshold, T_{th} , divides March snow cover into two regions characterized by their sensitivity to precipitation and temperature variability; the region where $T_s < T_{th}$ has snowpack variability driven mainly by precipitation, whereas the region where $T_s > T_{th}$ has temperature-driven snowpack variability. The temperature threshold is temporally varying but is generally found between $T_{th} = -5 \pm 1^\circ\text{C}$ for historical and projected simulations. This range is in agreement with Sospedra-Alfonso and Merryfield (2017) who showed that T_{th} in CanESM2 is largely independent of time and emission scenario.

330

335

In 1981-2016, regions with temperature-dominated March snowpack ($T_s \lesssim -5^\circ\text{C}$) include coastal British Columbia, southern Alberta, southwest Saskatchewan, southern margins of the St. Lawrence River and the Great Lakes, the Maritime provinces and Newfoundland. Because of the projected warming, the seasonal isotherms shift northward and toward higher elevations extending the portion of the snow cover that is more sensitive to temperature variations. By 2015–2050, regions with temperature-driven snowpack also include most of southern Canada, the interior of British Columbia, and more extensive portions of the Prairies provinces, Ontario and Quebec. In these regions, March SWE is expected to decrease during anomalously warm years. The portion of the snow cover with $T_s < -20^\circ\text{C}$, which is largely unaffected by temperature variability (Sospedra-Alfonso and Merryfield, 2017) and encompasses areas of the Northwest Territories and most of Nunavut in present-day climate, is projected to recede to the Canadian Archipelago by mid-century.

340

345

Turning to projected changes in sea ice, **Figure 12** shows the observed record of sea ice extent (sea ice concentration $>15\%$) across Canadian marine regions, compared to the CMIP-5 multi-model ensemble. While the observed and simulated trends are similar, only those years with strong observed negative departures from the long term trend (e.g. 1998 and 2012) reach the mean simulated ice extent. During the historical record, the models have a large spread (gray histogram, right side of **Figure 12**), with most models within the range of observations. After 2050, the large spread persists, but most models are $\sim 10\%$ below the historical sea ice extent (yellow histogram, right side of **Figure 12**).

350

355

The probability of sea ice free conditions by 2050 for regions of the Canadian Arctic calculated from the CMIP-5 multi-model ensemble are shown in **Figure 13** (see Laliberté et al., 2016, for a full description of the sea ice free probability methodology). Use of two ice area thresholds, 5% and 30%, applied to each grid cell, indicates the sensitivity in timing to the definition of minimum ice area. Under a 5% ice area scenario, there is a greater than 50% probability that all Canadian regions will be sea ice free in September. Ice free probabilities are similar for August, but lower for October and November. Hudson Bay, which is already largely ice free in August and September, has a high probability of being ice free for 4 consecutive months. With a more relaxed threshold of 30% ice area, probabilities are (by definition) greater for all regions and months. Baffin Bay is projected to be ice free for August through October, and 2 months of ice free conditions in the Beaufort Sea and the CAA are a possibility.

365 4 Key Findings

This assessment of observed historical changes in terrestrial snow cover and sea ice over Canada, together with projected changes to the middle of the 21st century, has produced the following key findings:

Historical datasets show the fraction of Canadian land and marine areas covered by snow and ice is decreasing.

370 Observations show decreased SIC in all seasons and decreased terrestrial SCF in fall (delayed snow cover onset) and spring (earlier snow melt). There is regional and seasonal variability in the direction and strength of the trends (for example, some increases in spring snow cover across boreal western Canada) due to seasonal and spatial variability in surface temperature trends resulting from natural climate variability. There is evidence of decreasing pre-melt SWE (reflective of shallower snow depth) consistent with the study of Mudryk et al. (2015) and trends of annual maximum snow depth reported in Vincent et al. (2015). There is only regional evidence (western CAA) of increasing winter season snow accumulation and hence higher SWE across Arctic Canada. Summer season total ice cover is decreasing significantly across nearly all Canadian marine regions. MYI ice losses are greatest in the Beaufort Sea and the western CAA. In just 8 years, the rate of MYI loss nearly doubled over the 1968-2016 period, compared to a previous assessment over 1968-2008. 60 year long records of in situ landfast ice thickness show evidence of thinning ice in the CAA that was not evident in an earlier study by Brown and Cote (1992), which covered the late 1950s to 1989.

Canadians should anticipate further reductions in snow and sea ice cover by the middle of the 21st century.

Averaging projections across many climate model simulations provides evidence that SCF, pre-melt peak SWE, and SIC will continue to decrease across Canadian land and marine areas through the middle of the 21st century. However, this decrease need not be spatially uniform and regions of negligible decrease or even increase are possible in the near future due to climate variability competing with anthropogenic forcing at the decadal and multi-decadal time scale. For the highly populated regions of southern Canada, there is evidence of a shift in the primary control on inter-annual variability in snow

cover from precipitation availability to surface temperature. While the thickest sea ice in the world will continue to be present in the CAA and along its northern coast, climate models suggest that Canadian Arctic marine regions which are currently ice covered could be sea ice-free in the summer by 2050.

5 Discussion

Snow cover is a defining characteristic of the Canadian landscape for a few months each winter along the southern margins of the country and up to 9 or 10 months each year in the high Arctic, evolving from nearly complete snow cover over the entire country in the winter to a near total loss of snow cover by the summer. Highly reflective snow cover acts to cool the climate system, effectively insulates the underlying soil, and stores and redistributes water in solid form through the accumulation season before spring melt. Sea ice insulates the ocean from the atmosphere; provides an essential habitat for northern mammals, influences navigation and access to the north, and is of high importance to the traditional lifestyle of northern communities. This assessment of observed and projected changes in seasonal terrestrial snow and sea ice is focused on Canadian territory, but a number of cross-cutting issues with broader implications for understanding interactions between the cryosphere and climate system were identified through this analysis:

1. The majority of previous assessments of snow cover trends (i.e. Derksen and Brown, 2012; Hernandez-Henriquez et al., 2015; Derksen et al., 2016; Kunkel et al., 2016) were based on the NOAA snow chart climate data record (NOAA-CDR; Estilow et al., 2015) selected on the basis of the longest available record. The reliance on individual datasets such as the NOAA-CDR, however, makes trends prone to uncertainty due to the inherent uncertainties in an individual dataset (for instance, see Brown and Derksen, 2013 and Mudryk et al., 2017 for issues related to the NOAA-CDR). It is clear that consideration of multiple datasets either as a means of showing the range of trends from individual datasets (Mudryk et al., 2017), for calculating confidence intervals around an individual dataset (Brown and Robinson, 2011), or to benchmark other datasets (Brown et al., 2010; Hori et al., 2017) is a more robust approach. However, in this case, we acknowledge that the availability and use of multiple datasets came at the sacrifice of time series length (the NOAA record extends back to 1967, whereas passive microwave satellite data and reanalyses such as ERA-interim only begin in 1979).

2. Alpine snow poses a unique challenge to trend analysis because the coarse spatial resolution of gridded products used for climate analysis cannot resolve the high degree of spatial variability (driven by land cover variability and steep topographic gradients) in alpine regions. It is imperative that we address and improve our ability to characterize variability and change in alpine snow because it is these regions that are both extremely sensitive to climate induced changes in snow accumulation (i.e. elevation dependent changes in rainfall versus snowfall ratios) and impactful with respect to water resources (Fyfe et al., 2017; Berg and Hall, 2017; Sospedra-Alfonso et al., 2015; Scalzitti et al., 2016).

420 3. Changes in sea ice are driven by warming temperatures, but also by changes in atmospheric circulation. The Beaufort Sea
was once a region where ice would thicken and age before being transported to the Chukchi Sea and re-circulated in the
Arctic (Tucker et al., 2001; Rigor et al., 2002) but now the region has become a considerable contributor to the Arctic's MYI
loss (Kwok and Cunningham, 2010; Maslanik et al., 2011; Krishfield et al., 2014; Galley et al., 2016). Ice is still being
sequestered from the Canadian Basin and transported through the Beaufort Sea during the summer months but the ice is now
425 younger and thinner and unable survive the melt season en route to the Chukchi Sea (Howell et al., 2016a). The CAA was
also a region with historically heavy MYI conditions present throughout the melt season but ice conditions have become
lighter in recent years (see **Figure 6b**). The replenishment of CAA MYI via FYI aging and MYI inflow from the Arctic
Ocean has decreased in recent years because of increased temperature and changes in atmospheric circulation (Howell et al.,
2015).

430
4. There is a strong association between the magnitude of warming and snow and ice loss both in observational datasets and
climate model simulations, with projected declines in snow and sea ice cover proportional to the amount of future warming
(Thackeray et al., 2016; Mudryk et al., 2017; Notz and Stroeve, 2016). The multi-model mean projections indicate
decreasing snow and ice cover because the multi-model mean projects a warmer climate by mid-century. Within this multi-
435 model mean, however, individual climate model realizations contain regions and seasons with cooling trends (see Mudryk et
al., 2014). It is important to remember, therefore, that we live in a single climate realization, while models produce dozens of
potential realizations of a future climate. The multi-model mean warming trend (with associated reductions in snow and ice
cover) is indicative of a high likelihood of a warmer future, but there will be decadal-scale natural variability, particularly at
regional scales, projected onto this overall trend.

440
The objective of this report was to provide a physical climate assessment of observed and projected changes in snow and ice
across Canada. While not the focus of this study, these changes will have profound impacts on terrestrial and marine
ecosystems, and many sectors of the Canadian economy. This includes risks related to freshwater supply from snow (Sturm
et al, 2017) and other impacts of changing snow on the Canadian landscape and economy (Sturm et al., 2016). Resolving the
445 dates of summer sea ice-free conditions for Canadian regions (Laliberté et al. (2016) has important implication for climate
studies, but also for determining impact and mitigation strategies. The decreases in MYI within the Beaufort Sea and the
CAA illustrated in **Figure 5** were found to be statistically linked to an increase in shipping activity, pointing out the potential
implications of continued sea ice declines in these regions (Pizzolato et al., 2016).

inmcm4	1	NorESM1-ME	1
IPSL-CM5A-LR	4	HadGEM2-AO	1
IPSL-CM5A-MR	1	GFDL-CM3	1
IPSL-CM5B-LR	1	GFDL-ESM2G	1
FGOALS-g2	1	GFDL-ESM2M	1
FGOALS-s2	1	CESM1(BGC)	1
MIROC-ESM	1	CESM1(CAM5)	3
MIROC-ESM-CHEM	1	CESM1-CAM5-1-FV2	1

665 **Figure 1: Terrestrial snow cover fraction and sea ice concentration trends for 1981-2015. Datasets are described in Section 2.1. Single hatching (\) indicates pointwise significance at the 90th percentile. Crossed hatching (X) means False Discovery Rate (FDR) significance at the 90th percentile (Wilks 2006, after excluding regions with non-varying cover). A pointwise significant location is always FDR significant. Dashed line denotes limit of Canadian marine territory.**

670 **Figure 2: Trends in surface temperature, 1981-2015, from a blend of ERA-Interim, JRA-55, JRA-25, MERRA1, MERRA2, and CFSR reanalysis products. See Figure 1 for explanation of hatching.**

675 **Figure 3:** Centered (dark) or uncentered (light) pattern correlation between seasonal TAS trends and seasonal SCF (black) or SIC (blue) trends.

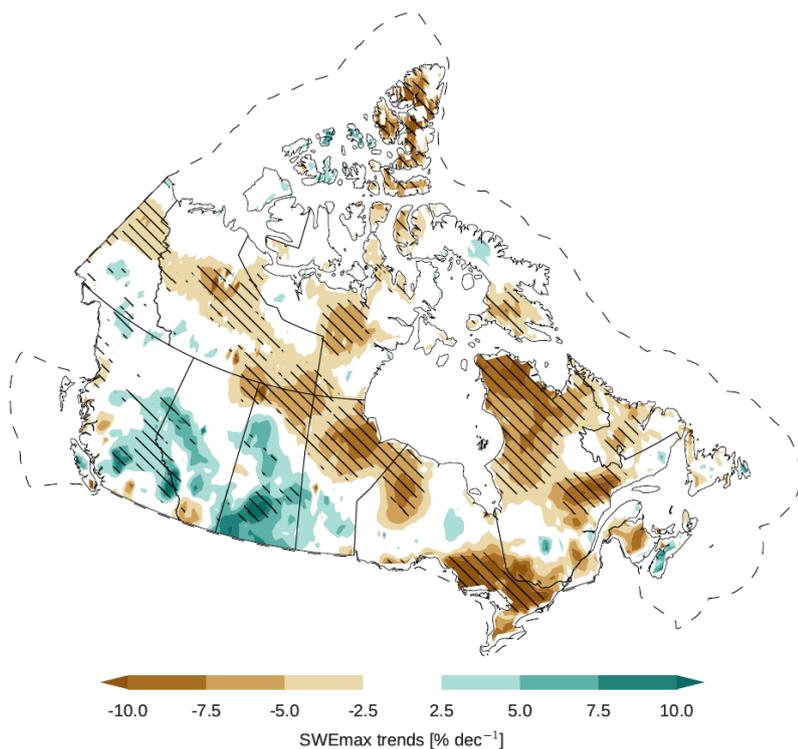

Figure 4: SWEmax trends for 1981-2015 (see Figure 1 for explanation of hatching)

680

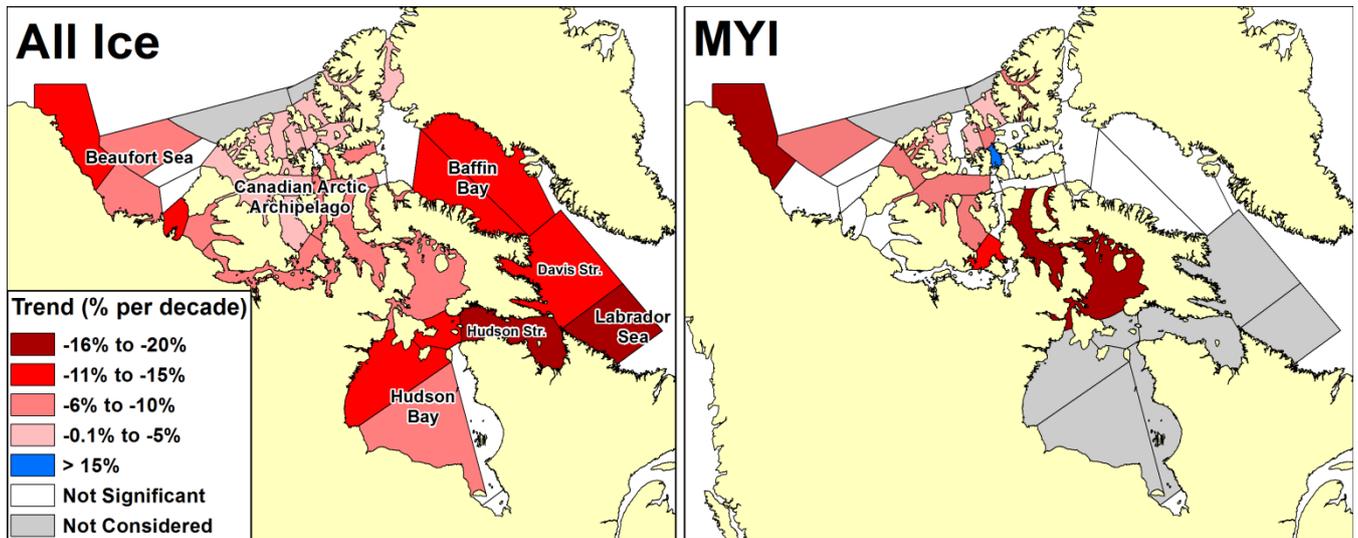

Figure 5: Trends in summer all ice (left) and multi-year ice (right) area from 1968 to 2016 from the CISDA. Only trends significant to the 95% confidence level are shown.

685

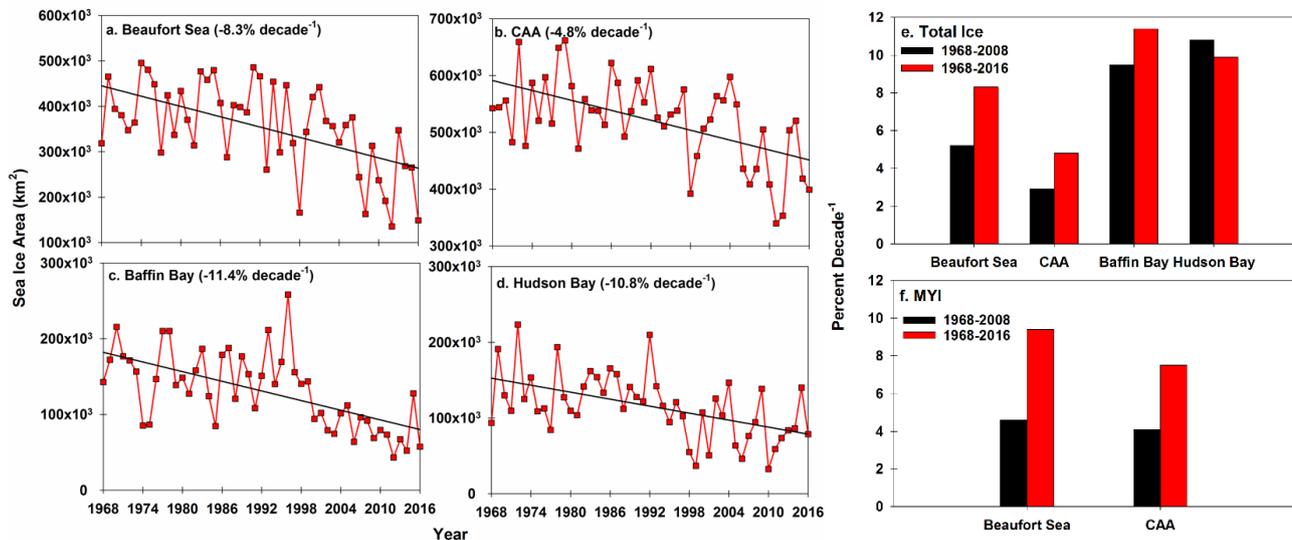

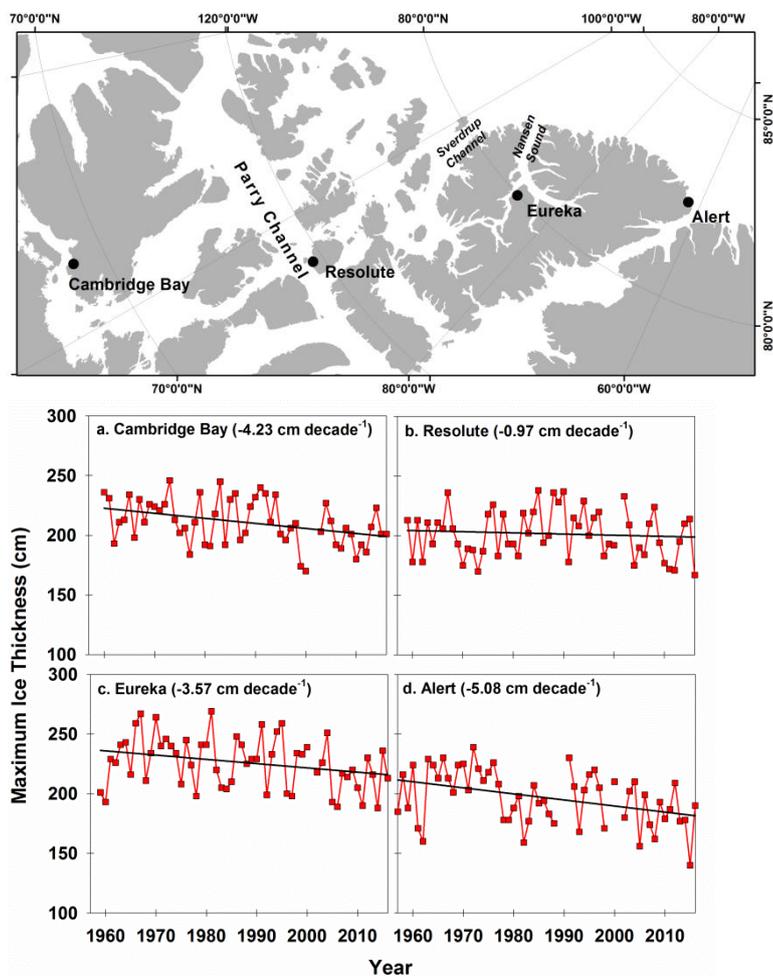

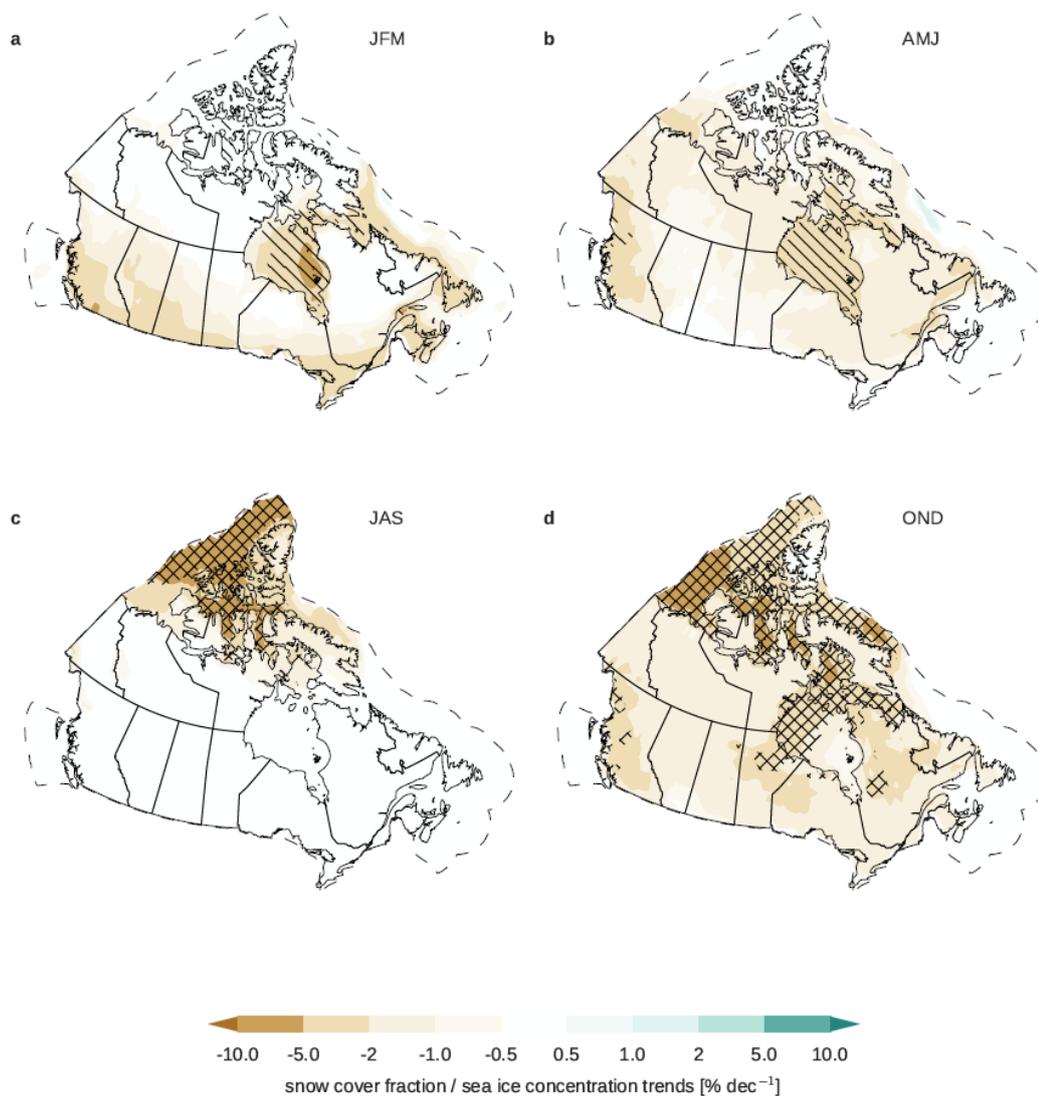

Figure 6: Time series of summer total sea ice area for the (a) Beaufort Sea, (b) Canadian Arctic Archipelago (CAA), (c) Baffin Bay and (d) Hudson Bay regions from 1968 to 2016. Comparison of trends between 1968-2008 and 1968-2016 for all ice (e) and multi-year ice (MYI) (f) for selected regions in the Canadian Arctic.

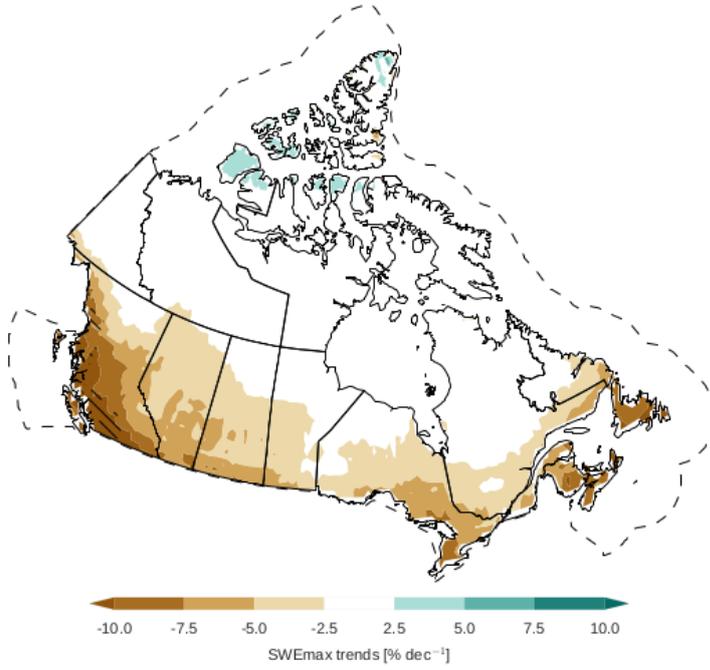

690

Figure 7: Time series and trend of observed maximum ice thickness at (a) Cambridge Bay, (b) Resolute, (c) Eureka and (d) Alert locations in the Canadian Arctic.

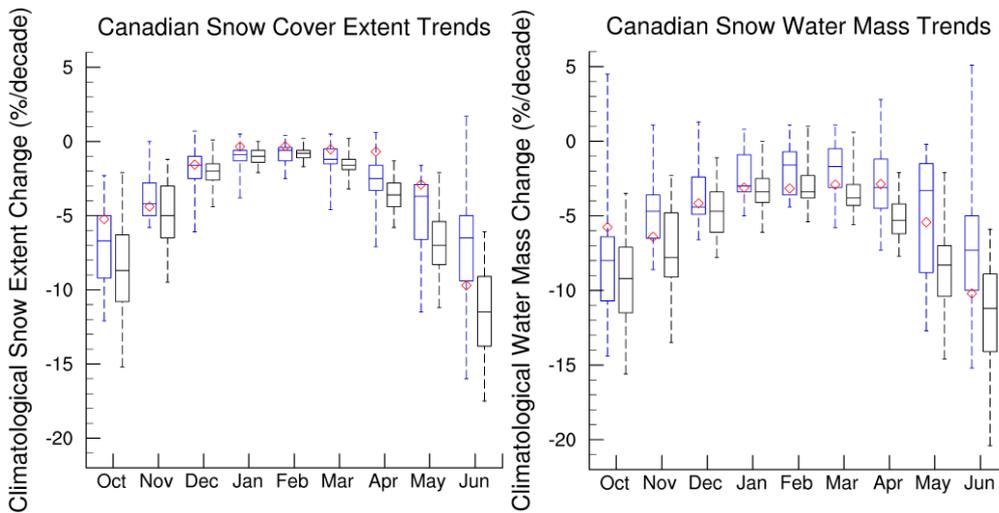

695

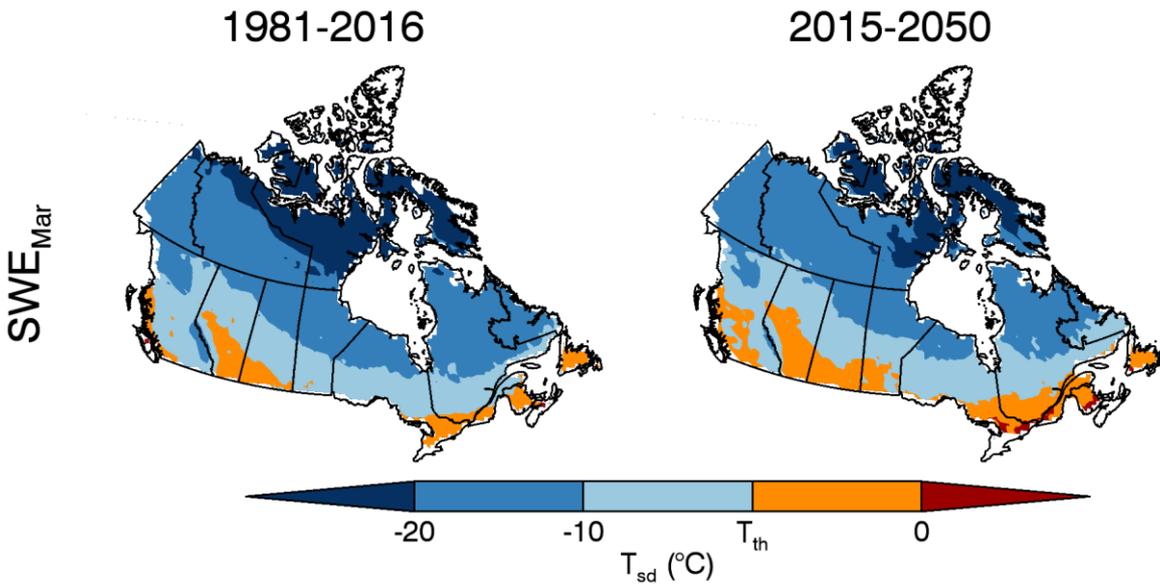

Figure 8: Projected terrestrial snow cover fraction and sea ice concentration trends for 2020-2050. Model simulations are described in Section 2.2. See Figure 1 for explanation of hatching.

700 **Figure 9: 2020-2050 trends in SWEmax from the CMIP5 ensemble. See Figure 1 for explanation of hatching. We show percent change relative to the climatological (1981-2015) mean because there is large variability in SWEmax across the country (high SWE in western cordillera; low SWE in the Prairies).**

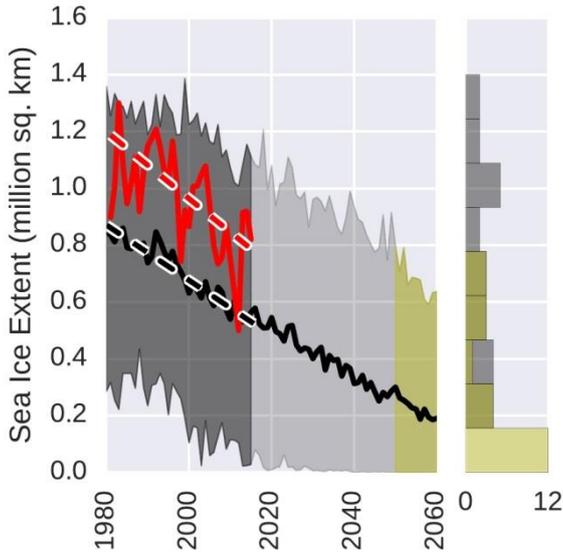

705 **Figure 10: 2020-2050 monthly trends in Canadian snow cover extent (left) and snow water mass (right) from the CMIP5 multimodel ensemble (blue) and CanESM large initial condition ensemble (black). Monthly mean observational trends (1981-2015) from the snow dataset used in Section 2 are shown in red. For each box the enclosed region shows the 25th-75th percentile range, the horizontal line shows the median, and the dashed whiskers illustrate the minimum and maximum.**

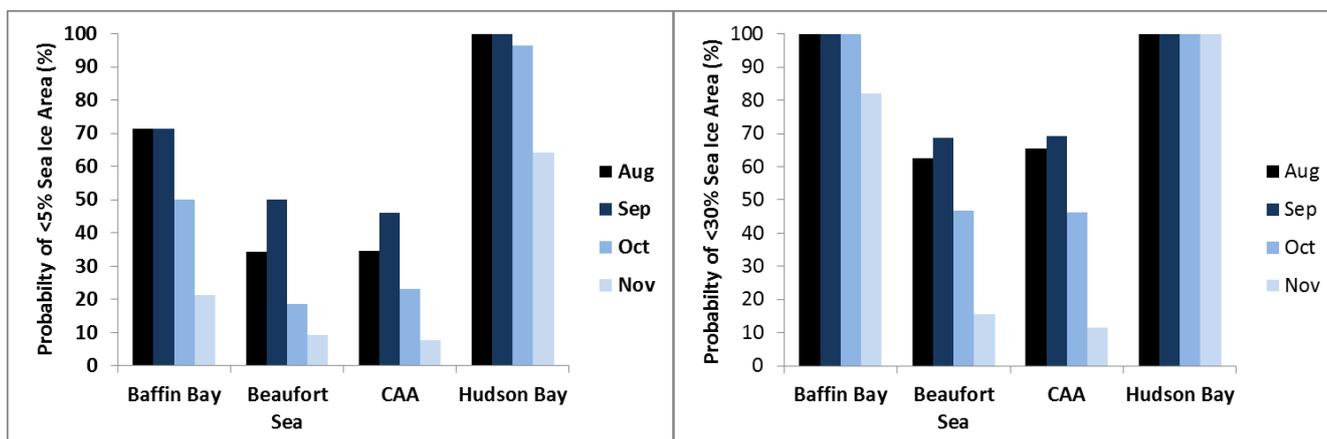

710

Figure 11: Projected temperature and precipitation controls on changes in March snow water equivalent, 1981-2016 (left); projection to 2050 (right).

715

Figure 12: Observed (red line) sea ice extent over Canadian marine regions ($SIC > 0.15$); CMIP-5 multi-model mean (black line) and spread (shading). Histogram on the right shows the model distribution for 1980-2015 in black and for 2050-2060 in yellow.

720 **Figure 13: Probability of sea ice free conditions by 2050 from the CMIP5 multi-model mean using a 5% (left) and 30% (right) sea ice area threshold.**
