Response to Reviewer comments to manuscript "Arctic Mission Benefit Analysis: Impact of Sea Ice Thickness, Freeboard, and Snow Depth Products on Sea Ice Forecast Performance"

June 22, 2018

We thank the reviewers for their careful inspection of the manuscript. In the following we address their comments point-by-point (using *italics* to repeat them) We provide the revised manuscript with changes highlighted in an annex to this document.

1 comments by Anonymous Referee #1

The three technical comments were all considered: Figs 15 and 17 are enlarged, and we'll see with the copy editor how to ensure good readability in the copy-edited version. The background of Fig 18 is lightened.

2 comments by Anonymous Referee #2

Similar to the first round we found some of the reviewer's comments very helpful to further improve the presentation quality. Others were difficult to address because they made no sense to us. Sometimes the reviewer asked us to undo changes they had requested in the first round: For example we got this comment in the first round: *The first time the notion "Archimedes principle" shows up, it could be shortly explained, if the author want to be self-explanatory.* In response we had added a sentence with a reference. And now the reviewer asks us: *remove (Archimedes …(1970)).*

Here is another example: We split off (from the subsequent section) a dedicated a section on the experimental setup in response to this comment from the first round: *Remark on Section 2.3 Model: I understand that in this section the authors introduce the model and refer to related literature, introduce the forcing (though it should be indicated in the Section title as well). Starting from p.10 l.11, the authors describe the initialization of the MPI-OM. This belongs to the presentation of the experimental design. I suggest to separate the experimental setup from the description of the model. I suggest to dedicate a separate section with a clear description of the experimental setup, starting from initialisation, perturbation strategies of the control vector variables, etc.* And now we are asked to put that new section back to where it came from: *4. Experimental Setup: This section carries very little information. And the most information about the particular setting is already formulated in the former sections, i.e. assimilation window, control vector, forecast window, initialisation. As well, the referred Table 3 contains results. I suggest to shift the content to the next section entirely.*

We thank the reviewer for his general comment: *The authors made a great attempt in the reviewing process in improving the understanding of the manuscript.*

We also appreciate that the reviewer explains in detail their difficulties in understanding the manuscript. We have make two types of changes to further clarify:

- We extended the description of the methodological framework. In particular we clarified the generic nature of this description and repeated the approach/equations we use to rule out further possibilities for misunderstandings.

- For those (sub)sections that did not yet have an introductory sentence/paragraph we added/extended it.

We will describe further changes in response to the reviewers *Detailed remarks*:

- *p.1 l.10: replace ; by :* Done

- *abstract: The authors might consider to replace increase of performance by decrease of uncertainty, as this is what application of information on different EO products effect to my understanding.* We had introduced our performance measure above.

- *p.2 l.10: models initial state* Done

- *p.2 l.11f: can help to reduce [] to reduce* Done

- *p.2 l.14: more directly relate* Done

- *p.2 l.18: It is only one order of magnitude to my understanding.* No, see Fig 13.

- *p.2 l.13: with other variables* Not found.

- *articles are missing at several places in the manuscript. Please check, e.g. p.3 l.3, l.8 etc* We'll check with copy editor.

- *p.3 l.4: on uncertainties of forecasts of snow...* We have stated this above.

- *p.3 last paragraph in Introduction: correct the numbering of the Secions (e.g. Section 4 is missing)* Added description of section 4.

- *p.4: explain/sketch backward integration and purpose, forward propagation, representation of the PDF in the formalism* Refs to equations added in Fig. caption.

- *p.4 l.14: Instead of Here we refer to M as model I would write It consists of a (sea ice-ocean) model run and a projection from the model onto the observational space. And later in that line Let us first consider M to be linear, ... As well, later in the section mention similarly that/how the (sea ice-ocean) model is involved in N.* Here we refer to M as model was suggested by this reviewer in the first round. Text changed nevertheless.

- *p.4f: When mentioning M and N indicate that you detail them in Sections X and Y.* We say that elsewhere.

- *p.4 eq (1): add , and at end of eq (2) add . Done.*

- *p.5 l.19: simulation of [] is incorrect* Done

- *p.6 Fig2: needs lots of improvements, see in text above. Add . at the end of the caption. In the caption: the model M instead of the model.* Should be clearer with text extension.

- *p.6 l.10f: It is not clear how the model (M? MPIOM?) is constrained.* Through data.

- *p.8: Fig.4: unclear why here and relation to Fig.1, see also above.* Fig 1 is generic and Fig 4 specific.

- *p.8 Fig.4: Comparing with Fig.1 I presume, that by SIV and SNV the authors mean uncertainties of SIV and SNV.* No.

- *How do the illustrations of Fig.1, Fig.2 and Fig.4 fit together? It appears to me that these are three different descriptions of the same formalism.* See above.

- *p.9 l.29: Jacobian* Done

- *p.9 l.29: I would remove (introduced in Section 2.1), if the authors do not further explain in that section.* This is exactly the type of cross ref that we introduced for clarification.

- *p.9 l.33: The ocean initially is ...* Done

- *p.11 l.2: In our target regions the misfit remains very small plus p.12 .13ff: In the study the authors analyse sensitivities for the entire Arctic (Fig14). Thus, possible of impacts larger misfits in remote regions should be discussed when the results are presented.* We don't think this is needed.

- *p.11 Fig 6: Graphs (b) and (e) are not discussed. Either discuss or remove.* They are discussed.

- *p.12 l.7: Could the authors provide magnitudes for the bias?* Done

- *p.12 l.15: more than one member* Probably "one meter"?

- *p.13 l.3 As described in ... The discussion on the Jacobian is confusing here. I would remove the sentence.* No, we think it is useful.

- *p.13 l.7f In each of ...: This is misleading, for instance for the reference run the authors do not add perturbation, of I understood correctly. I would mention something along the line: Each of the entries is assigned a perturbation. For each forcing field we add a constant perturbation ...* We think the current formulation is fine.

- *p.14 l.1: I presume: The reason of choosing the diagonal form is, that the proper cross-correlations are unknown and the next natural choice is to neglect any cross-correlations. Furthermore, the effect might be, that only one control vector entry is perturbed in the definition of the Jacobian. One might add a statement to the text. It could be an idea to shift the discussion of the cross-correlation of the uncertainties to the introduction of the Jacobian.* Comment made no sense to us.

- *p.14 l3ff: When perturbing an initial state variable or a boundary variable: Is the statistics you derive space-dependent, and if so, is the perturbence you add to this initial/boundary vector inthe definition of the Jacobian also varying in space? Or is it a mean over the entire space?* Comment made no sense to us.

- *p.14 Fig.8, and p.16 Fig.9 caption: a) The modelled...* Done

- *Section 2.5: To simplify reading, the authors could also write observation operator M, at least the first time mentioned in this section.* M is not the observation operator, see section 2.1.

- *p.15, Name of entries 7, 29 and 30 should have the same font as the other entries.* Done.

- *p.15: Meaning of entries 32-45: these should be regional averages of the mentioned values and not values themselves?* No.

- *p.15: Caption: l.2: f,i,p: Write in order of occurrence in the table.* Done.

- *p.15: Caption: l.1: replace ; by , — l.4: magnitude: Does that mean the mean? If so, then also replace value by mean in the header of the table.* Done.

- *p.15: Meaning of entries 19ff: coeff.* Spelled out.

- *p.19 caption, l.2: after rhs: I suppose to add: (Model M)*

- *p.19 caption l.3: I suggest to add (from MPIOM) after model variables. In the mansucript there were mentioned too many models to easily get confused, what the authors mean here.* We think the current formulation is better.

- *p.19: caption: clarify abbreviation CS used in the graph.* Done.

- *p.19ff: The first time you mention retrieval chain add a note that this is used to determine the uncertainties in the EO products and refer to Fig.1, where these data find entry into the formalism and how.* The reference to section 2.1 does this job perfectly.

- *p.20, l.1f: recall that... spatio-temporal coverage needed as well as the uncertainty ranges: I am not aware that the former has been mentioned before. I would remove recall that.* We prefer to leave it in.

- *p.20, l.5: Add M after observational Jacobian.* Done.

- *p.20 l.11: remove (Archimedes ...(1970)).* We had put it in upon request of this reviewer in the first round. Now we keep it.

- *p.21 l.3: ρ_i and ρ_s* Done.

- *p.21 Fig. 13: add to the titles (m) and remove the label of the colorbar. It is redundant. The title of the lower left panel should be changed to sea ice thickness random error (m). According changes should be made in the lower rigth panel. Moreover, replace sea-ice by sea ice in the titles of the upper two panels. Increase the fontsize of minimum and maximum values.* Done

- *p.21 l.9: The authors might add something along the line derived via the method depicted on the left-hand side of Fig.12 after April 2015.* We prefer the current phrasing.

- *p.22 Caption Table 2: Add (column 8) at the end.* Done.

- *p.22 .15: Add EO: For a given EO product...* The products are clearly defined.

- *p.22 l.21: It is unclear how eps_i has been chosen and whether the PDF has been represented via ensemble runs. Explain it in the Section about control vectors and refer to there.* There are no ensembles involved.

- *p.23 l.1: I would dedicate the Jacobian a separate line (extra equation).* We think the compact notation is fine here.

- *p.23 l.1: I presume that there is a tight relation between eps_i, $sigma_i$ and the difference between $M(x_p)$ and $M(x)$. Could the authors elaborate a bit on that after introducing the Jacobian to prepare the reader for the analysis?* No tight relation.

- *p.23 l.4: ith component of the control vector, x_i,* Done.

- *p,23 l.9: The SIT sensitivy and p.24 l.5: Add information about the time (May 28?).* Done

- *p.23 l.26: refer to Fig.15 instead.* Refs to both now.

- *p.23 l.32f: The impact of ...: Indicate which bar you are refering to.* We think this is fine.

- *How is Eq. (1) implemented? How do the authors derive at $C(x)$, $C(x)^{-1}$? Could the authors identify this, maybe in Section 3 or later?* We don't understand the question.

- *p.24 l.9: overlaps* No.

- *p.24 l.14: Consider to replace high enough concentration by sufficiently high SIC (sea ice concentrations)* Done.

- *p.24 l.17f: The largest...: This is not clear to me. If I look at the graph in Fig. 17, it appears that albsnm is strongest. For snow volume, the statement appearrs correct.* We think the reviewer is wrong.

- *Section 3: Before the authors start to explain the derivation of the Jabobian M, they could refer to the former section (2.5) and mention, that they detailed the construction of M (rhs of Fig. 12 plus equations (8)-(10) I presume) of the first step of the QND formalism there. It is not mentioned that clearly and leads to confusion, when the reader does not know how M is defined.* Section 2.1 is very clear about this.

- *Sectioning: It is not clear why the Jacobians are given a separate Section, while they are tightly linked to Section 2.4.* As tightly as to to sections 2.1 to 2.4 and to sections 4 and 5.

- *Section 3: The authors might consider to separate the construction of the two Jacobians, i.e. using two subsections: one referring to step one of the algorithm and one to the second step.* We suspect this would interrupt the flow of reading to much.

- *Section 4: Lots of information missing, if this section is kept. E.g. the restriction to the target regions and the focus on one day after May 28.* All explained in section 2.

- *Section 5: The section should be started with a short introduction/overview and not straight with the discussion of a special case.* Done.

- *p.25 l.14: remove and listed in the last but one row.* Done.

- *p.25 l.24: add (yellow bar) after SIT* Done.

- *p.25 l.25f: only difference consists in the target Jacobians...: How do you draw that conclusion? In the upcoming you explain that there is a difference in the target Jacobians, but there is no explanation, why there is no other difference elsewhere.* Clarified.

- *p.26 Table 3, caption: Except for the first line, the authors only show posterior uncertainties. This is not written in the caption (where it is stated that for all columsn 4-9 there are prior and posterior uncertainties, which I do not see). Mention, what the prior uncertainty is (sigma(y0)?).* We think the table is fine.

- *p.29-32: enlargen font size. This cannot be read. Titles of the graphs are missing in Fig. 15 and Fig.17.* Figures are larger now

- *p.30 and p.32: The plot is not easy to be read. The authors should use a grouping, which enables to read which bar belongs to which quantity.* We will check with copy editor.

- *p.33: Improve labeling of the graph. Instead of using machine representation of the variable names, use the abbreviations used in the text, e.g. SIT instead of sit, etc.* We will check with copy editor.

- *p.34 l.11: sea ice-ocean* Done

- *p.34 l.26 cross-correlation for each of the products as the autocorrelations are not set to zero.* No.

- *p.34 l.30: How can the mean values be that low?* Because of the square root of n.

- *4. Experimental Setup: This section carries very little information. And the most information about the particular setting is already formulated in the former sections, i.e. assimilation window, control vector, forecast window, initialisation. As well, the referred Table 3 contains results. I suggest to shift the content to the next section entirely.* We had introduced section 4 upon request of the reviewer and now keep it.

- *Discussion section: In Section 2.3, the authors identified regions, where the differences between model and observations are not small. Recalling, that MPIOM runs are involved in both steps of the formalism, possible impacts of these inconsistencies need to be discussed when presenting the results, in particular, when remote effects are discussed.* We think this is fine.

Arctic Mission Benefit Analysis: Impact of Sea Ice Thickness, Freeboard, and Snow Depth Products on Sea Ice Forecast Performance

Abstract. Assimilation of remote sensing products of sea ice thickness (SIT) into sea ice-ocean models has been shown to improve the quality of sea ice forecasts. Key open questions are whether assimilation of lower-level data products such as radar freeboard (RFB) can further improve model performance and what performance gains can be achieved through joint assimilation of such data products in combination with a snow depth product. The Arctic Mission Benefit Analysis system was developed to address this type of question. Using the quantitative network design (QND) approach, the system can evaluate, in a mathematically rigorous fashion, the observational constraints imposed by individual and groups of data products. We present assessments of the observation impact (added value) of different Earth Observation (EO) products in terms of the uncertainty reduction in a four-week forecast of sea ice volume (SIV) and snow volume (SNV) for three regions along the Northern Sea Route using a coupled model of the sea ice-ocean system, specifically the Max Planck Institute Ocean Model. We assess seven satellite products: three real products and four hypothetical products. The real products are monthly SIT, sea ice freeboard (SIFB), and RFB, all derived from CryoSat-2 by the Alfred Wegener Institute. These are complemented by two hypothetical monthly laser freeboard (LFB) products with low and high accuracy, as well as two hypothetical monthly snow depth products with low and high accuracy.

On the basis of the per-pixel uncertainty ranges provided with the CryoSat-2 SIT, SIFB, and RFB products, the SIT and RFB achieve a much better performance for SIV than the SIFB product. For SNV, the performance of SIT is only low, the performance of SIFB higher and the performance of RFB yet higher. A hypothetical LFB product with low accuracy (20 cm uncertainty) falls between SIFB and RFB in performance for both SIV and SNV. A reduction in the uncertainty of the LFB product to 2 cm yields a significant increase in performance.

Combining either of the SIT/freeboard products with a hypothetical snow depth product achieves a significant performance increase. The uncertainty in the snow product matters: A higher accuracy product achieves an extra performance gain. Providing

spatial and temporal uncertainty correlations with the EO products would be beneficial not only for QND assessments, but also for assimilation of the products.

1 Introduction

Over the last few decades the state of the Arctic climate system has undergone rapid change. Most pronounced are major
decreases in summer sea ice extent and sea ice volume throughout the year. This transformation is affecting marine ecosystems and coastal communities in an unprecedented way. Economic activities such as resource extraction, maritime transportation, and tourism may benefit from these changes provided that risks, e.g. of sea ice hazards, can be managed. In this context, the performance of short-term to seasonal forecasts of sea ice conditions is of crucial importance (Eicken, 2013).

Forecasts of the sea ice and the ocean state are routinely performed by coupled sea ice-ocean models that are driven by
prescribed atmospheric conditions. In order to derive reliable forecasts, uncertainties in the ~~model~~ models' initial state, of the atmospheric boundary conditions, and in the parameterisations of physical processes need to be minimised. Observations can help reduce such uncertainties and, thus, to improve the forecast quality. Recently Earth observation (EO) products of sea ice thickness (SIT) have been shown to provide particularly valuable constraints (Lisaeter et al., 2007; Yang et al., 2014; Day et al., 2014; Kauker et al., 2015; Xie et al., 2016). The constraints from lower-level EO products (i.e. rawer products that more directly
~~related~~ relate to the actual measurement) that are used to derive SIT products may be even stronger, because such products that conform more closely to the raw EO data are typically more accurate. For the example of the CryoSat-2 SIT product (Ricker et al., 2014) retrieved by the Alfred Wegener Institute (AWI) the uncertainty in the radar freeboard (RFB) product underlying their SIT retrieval is smaller by about two orders of magnitude compared to the derived ice thickness product (Figure 13). This difference is a consequence of the uncertainty associated in particular with snow and ice density and snow depth, which are
used to retrieve SIT from RFB. For direct assimilation of RFB these variables can be extracted from the model into which the data are assimilated, but even in this approach significant uncertainty remains. Hence, the trade-off between assimilation of SIT or RFB requires a rigorous quantitative assessment. This is even more important, when the products are assimilated jointly with variables such as snow depth (SND) that introduce complementary information.

Such rigorous assessments can be performed in an efficient manner by the quantitative network design (QND) approach,
allowing for an objective evaluation of the added value of observations for a given aspect of a model simulation or forecast. The technique originates from seismology (Hardt and Scherbaum, 1994) and was first applied to the climate system by Rayner et al. (1996), who optimised the spatial distribution of in situ observations of atmospheric carbon dioxide to achieve minimum uncertainty in inferred surface fluxes. After an initial QND study that demonstrated the feasibility of the approach for remote sensing of the column-integrated atmospheric carbon dioxide concentration (Rayner and O'Brien, 2001) QND is now routinely
applied in the design of CO2 space missions (e.g., Patra et al., 2003; Houweling et al., 2004; Crisp et al., 2004; Feng et al., 2009; Kadygrov et al., 2009; Kaminski et al., 2010; Hungershoefer et al., 2010; Rayner et al., 2014; Bovensmann et al., 2015). For the western Arctic domain, the QND approach has been successfully applied to evaluate the impact of (hypothetical) airborne measurements of SIT/SND in improving sea ice predictions (Kaminski et al., 2015). The study evaluated two idealised flight

transects derived from NASA's Operation IceBridge airborne altimeter ice surveys in terms of their potential to improve ten-day to five-month forecasts of sea ice conditions, including for operational purposes.

The present study describes the implementation of the QND methodology into a system for Arctic mission benefit analysis (ArcMBA) and then applies the system to investigate the impact of a series of EO products on forecasts of snow and ice volume over three regions along the Northern Sea Route (NSR). It addresses products of SIT, ~~SIFB~~sea ice freeboard (SIFB), RFB, laser freeboard (LFB), and SND. The layout of the remainder of this article is as follows: Section 2 will describe the methodological aspects, including the QND approach, the coupled sea ice-ocean model, and the EO products. Section 3 will present the simulated sensitivities of target quantities and observation equivalents to the model's control vector that is composed of process parameters, initial and boundary conditions. Section 4 will describe the experimental setup. Section 5 will present the QND assessments, followed by a discussion of these findings in Section 6. Finally, Section 7 provides a summary and conclusions.

2 Methods

2.1 Quantitative network design

The QND methodology is presented by Kaminski and Rayner (2017), partly based on Tarantola (2005) and Rayner et al. (2016). For the sake of self-containedness we provide a shortened form of the presentation by Kaminski and Rayner (2017). QND is a generic concept that is applicable beyond the context of Arctic modelling (see examples in Section 1), It is, hence, useful to provide a generic presentation in this subsection. The specific elements of our application will be described in the subsequent subsections.

As mentioned, the QND formalism performs a rigorous uncertainty propagation from the observations to a target quantity of interest relying on the indirect link from the observations to the target variables established by a numerical model. We distinguish between four sources of uncertainty in a model simulation:

1. Uncertainty caused by the formulation of individual process representations and their numerical implementation (structural uncertainty).

2. Uncertainty in constants (process parameters) in the formulation of these processes (parametric uncertainty).

3. Uncertainty in external forcing/boundary values (such as surface winds or precipitation) driving the relevant processes.

4. Uncertainty in the state of the system at the beginning of the simulation (initial state uncertainty).

The first category reflects the implementation of the relevant processes into the model (code) while the others can be represented by a set of input quantities controlling the behaviour of a simulation using the given model implementation. The QND procedure formalises the selection of these input quantities through the definition of a control vector, x. The choice of the control vector is a subjective element in the QND procedure. A good choice covers all input quantities with high uncertainty and high impact on simulated observations d_{mod} or target quantities y (Kaminski et al., 2012; Rayner et al., 2016).
Figure 1. Data flow through two-step procedure of QND formalism. Oval boxes denote data, rectangular boxes denote processing. "Backward propagation with inverse model" implements Equation (1), and "forward propagation with model" implements Equation (3). Figure taken from Kaminski and Rayner (2017).

The target quantity may be any quantity that can be extracted from a simulation with the underlying model (in the current study regional integrals of predicted sea ice and snow volumes, see Section 2.2), but also any component of the control vector, for example a process parameter such as the snow albedo. In the general case, where the target quantity is not part of the control vector, the QND procedure operates in two steps (Figure 1). The first step (inversion step) uses the observational information

5   to reduce the uncertainty in the control vector, i.e. from a prior to a posterior state of information. The second step (prognostic step) propagates the posterior uncertainty forward to the simulated target quantity.

Within the QND formalism, we present all involved quantities by probability density functions (PDFs). We typically assume a Gaussian form for the prior control vector and the observations, if necessary after a suitable transformation. The Gaussian PDFs' covariance matrices express the uncertainty in the respective quantities, i.e. $\mathbf{C}(x_0)$ and $\mathbf{C}(d_{\mathrm{obs}})$ for the prior control

10 vector and the observations. In the context of these PDFs we will use the term uncertainty to refer to its full covariance matrix in the case of a vector quantity, and in the case of a scalar quantity or a given vector component it refers to the square root of the entry on the diagonal of the full covariance matrix corresponding to that particular vector component. In the latter case the uncertainty refers to one standard deviation of the marginal PDF corresponding to that component, and we use the notation $\sigma(d_2)$ to denote, for example, the standard deviation of the second component of d.

15 For the first QND step we use a mapping M from control variables onto equivalents of the observations. In our notation the observation operators that map the model state onto the individual data streams (see Kaminski and Mathieu (2017) and Section 2.5) are incorporated in M. ~~Here we refer to~~ M ~~as model~~ is in practise computed by a specific numerical model with specific inputs and outputs. Let us first consider the case of a linear model, for which we denote by $\mathbf{M}'$ the Jacobian matrix of M, i.e. the derivative of M with respect to x. In this case, the posterior control vector is described by a Gaussian PDF with

20 uncertainty $\mathbf{C}(x)$, which is given by

$$\mathbf{C}(x)^{-1} = \mathbf{M}'^T \mathbf{C}(d)^{-1} \mathbf{M}' + \mathbf{C}(x_0)^{-1}, \tag{1}$$

where the data uncertainty $\mathbf{C}(d)$ is the combination of two contributions:

$$\mathbf{C}(d) = \mathbf{C}(d_{\mathrm{obs}}) + \mathbf{C}(d_{\mathrm{mod}}). \tag{2}$$

The term $\mathbf{C}(d_{\mathrm{obs}})$ expresses the uncertainty in the observations and $\mathbf{C}(d_{\mathrm{mod}})$ the uncertainty in the simulated equivalents of the observations $M(x)$. The first term in Equation (1) expresses the impact of the observations and the second term the impact of

5 the prior information. In the non-linear case we use Equation (1) as an approximation of $\mathbf{C}(x)$.

The mapping N involved in the second, the uncertainty propagation step, is the mapping from the control vector onto a target quantity, y. The Jacobian matrix $\mathbf{N}'$ of the mapping N is employed to approximate the propagation of the posterior uncertainty in the control vector $\mathbf{C}(x)$ forward to the uncertainty in a target quantity, $\sigma(y)$ via

$$\sigma(y)^2 = \mathbf{N}'\mathbf{C}(x)\mathbf{N}'^{T} + \sigma(y_{\mathrm{mod}})^2. \tag{3}$$

10 If the model were perfect, $\sigma(y_{\mathrm{mod}})$ would be zero. In contrast, if the control variables were perfectly known, the first term on the right-hand side would be zero. The terms $\mathbf{C}(d_{\mathrm{mod}})$ in Equation (2) and $\sigma(y_{\mathrm{mod}})$ in Equation (3) capture the structural uncertainty as well as the uncertainty in those process parameters, boundary and initial values that are not included in the control vector. These two terms typically rely on subjective estimates. When comparing the effect of different data sets in the same setup, $\sigma(y_{\mathrm{mod}})$ acts as an offset (for the respective variance) in Equation (3). ~~To sharpen the contrast between the products~~

15 ~~we remove it from the assessment and~~ In our assessments (Section 5) we provide both terms in Equation (3) separately: We first report two plausible estimates ~~separately~~ of $\sigma(y_{\mathrm{mod}})$, and then, for each product, evaluate Equation (3) with $\sigma(y_{\mathrm{mod}})$ set to zero, which sharpens the contrast between the products.

To conduct a valuable QND assessment, the requirement on the model is not that it simulates the target quantities and observations under investigation realistically, but rather that it provides a realistic *sensitivity* of the target quantities and observations

20 under investigation with respect to a change in the control vector. (As a hypothetical example we can think of a perfect regional tracer model that is run with an offset in the initial or boundary conditions for a passive tracer. The simulated tracer concentration will carry this offset, but all sensitivities will be perfect.) If the sensitivities of the target quantities and observations (i.e. the Jacobians) are realistic, but the simulation of target quantities and observations is incorrect, we can always obtain a valuable QND assessment with appropriate model uncertainty. The result of the assessment may then be that a particular data

25 stream is not useful in constraining a particular target quantity given current modelling capabilities. Under such circumstances, the QND system could be operated with reduced model uncertainty to explore the level of accuracy required of the model for a data stream to serve as a useful constraint on a given target quantity. In particular when it comes to newly available, unvalidated data streams and target quantities the accuracy of both, the simulation and the sensitivities, is hard to assess. In the case of a model that does not capture relevant processes we may expect errors in both the simulation and the sensitivities, and

30 consequently also in the QND assessment.
Figure 2. Schematic presentation of the QND procedure: Each coloured line illustrates a model trajectory that simulates for a given value of the control vector (x) counterparts of the observations (d_1 and d_2) and a target quantity (y). Through the model, the observations act as constraints on the control vector, which reduces its uncertainty from $C(x_0)$ to $C(x)$. This uncertainty reduction on the control vector translates into an uncertainty reduction in the target quantity from $\sigma(y_0)$ to $\sigma(y)$.

Our performance metric is the (relative) reduction in posterior target uncertainty $\sigma(y)^2$ with respect to a reference. To compare against the case without any observations we first compute, as the reference, the prior target uncertainty, $\sigma(y_0)$, via

$$\sigma(y_0)^2 = \mathbf{N}'\mathbf{C}(x_0)\mathbf{N}'^{T} + \sigma(y_{\mathrm{mod}})^2. \tag{4}$$

The uncertainty reduction with respect to the prior,

$$5 \qquad \frac{\sigma(y_0) - \sigma(y)}{\sigma(y_0)} = 1 - \frac{\sigma(y)}{\sigma(y_0)}, \tag{5}$$

quantifies the impact of the entire network. A schematic illustration of the approach with the prior and posterior uncertainty ranges is shown in Figure 2. The observations d_1 and d_2 render a range of trajectories unlikely, which in the first step (Equation (1)) leads to a reduction of uncertainty in the control vector (from $C(x_0)$ to $C(x)$) and in the second step

(Equation (3)) to a reduction in the target uncertainty (from $\sigma(y_0)$ to $\sigma(y)$). Note that the model trajectories in Figure 2 are for illustration purposes only; the algorithm employs the linearisations M' and N' for the uncertainty propagation.

We note that (through Equation (1) and Equation (3)) the posterior target uncertainty solely depends on the prior and data uncertainties, the contribution of the model error to the uncertainty in the simulated target variable, $\sigma(y_{\text{mod}})$, as well as the
5 ~~observation~~ observational and target Jacobians (quantifying the linearised model responses of the simulated observation equivalent and of the target quantities). Hence, the QND formalism can be employed to evaluate hypothetical candidate networks. Candidate networks are characterised by observational data type, location, sampling frequency and time, and data uncertainty but not the observational value. Here, we define a network as the complete set of the characterisation of observations, d, used to constrain the model. The term network is not meant to imply that the observations are of the same type or that their sampling
10 is coordinated. For example, a network can combine different types of in situ and satellite observations.

In practice, for pre-defined target quantities and observations, model responses can be pre-computed and stored. A network composed of these pre-defined observations can then be evaluated in terms of the pre-defined target quantities without any further model runs. Only matrix algebra is required to combine the pre-computed sensitivities with the data uncertainty. This aspect is exploited in our ArcMBA system.

15 **2.2 Target quantities**

For this study we selected target quantities, y, that are particularly relevant for maritime transport, namely predicted sea ice volume (SIV) and snow volume (SNV) over three regions along the NSR. These three regions are displayed in Figure 3 and respectively denoted as "West Laptev Sea" (WLS), "Outer New Siberian Islands" (ONSI), and "East Siberian Sea" (ESS). We perform these predictions for May 28, 2015, a point in time at which there is still sufficient snow cover for our prediction to
20 be relevant. These predictions are started on April 1 and are constrained by observational information until April 30, i.e. the assimilation window in April is followed by a four-week prediction period (Figure 4).

2.3 Sea ice-ocean model

To simulate observation equivalents (M in Equation (1)) and target quantities (N in Equation (3)) we employ a coupled model of the sea ice-ocean system. The model is required to provide realistic simulations of the sensitivity of observation equivalents
25 and target quantities to changes in the control variables. In the present study we use the Max-Planck-Institute Ocean Model (MPIOM, Jungclaus et al., 2012, 2013; Haak et al., 2003), i.e. the sea ice-ocean component of the Max-Planck-Institute Earth System Model (MPI-ESM, Giorgetta et al., 2013). MPI-ESM regularly provides climate projections for the Intergovernmental Panel on Climate Change (IPCC) in particular to the IPCC's 5th assessment report (Stocker et al., 2013) and the upcoming 6th assessment report (AR6) and within the seasonal to decadal prediction system (Müller et al., 2012). In the following we
30 provide a brief description of the current model development status, largely following Jungclaus et al. (2006) and Niederdrenk (2013).

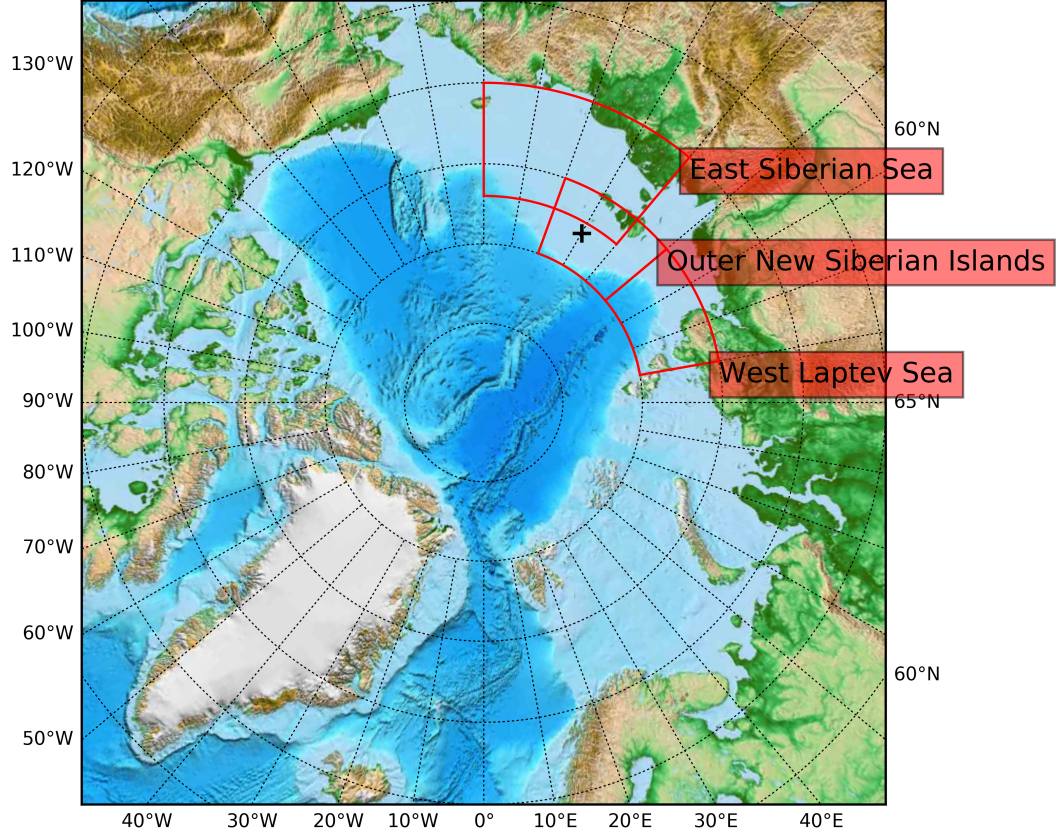
Recent development of the ocean part of the model includes the treatment of horizontal discretisation which has undergone a transition from a staggered E-grid to an orthogonal curvilinear C-grid. The treatment of subgridscale mixing has been improved


Figure 3. Target regions along the NSR. Black cross indicates a location for further use in Figure 14.

through the inclusion of a new formulation of bottom boundary layer slope convection, an isopycnal diffusion scheme, and a Gent and McWilliams style eddy-induced mixing parameterisation (Gent and McWilliams, 1990). Along-isopycnal diffusion is formulated following Redi (1982) and Griffies (1998). Isopycnal tracer mixing by unresolved eddies is parameterised following Gent et al. (1995). For the vertical eddy viscosity and diffusion the Richardson number–dependent scheme of Pacanowski and Philander (1981) is used. An additional wind mixing proportional to the cube of the 10-m wind speed (decaying exponentially with depth) compensates for too low turbulent mixing close to the surface. Static instabilities are removed through enhanced vertical diffusion.

A viscous–plastic rheology (Hibler, 1979) is used for the sea ice dynamics. Sea ice thermodynamics are formulated using a Semtner (1976) zero-layer model relating changes in sea ice thickness to a balance of radiant, turbulent, and oceanic heat
Figure 4. Time line of assimilation and forecast setup.

fluxes. In the zero-layer model the conductive heat flux within the sea ice/snow layer is assumed to be directly proportional to the temperature gradient across the sea ice/snow layer and inversely proportional to the thickness of that layer, i.e. the sea ice does not store heat. The effect of snow accumulation on sea ice is included, along with snow–ice transformation when the snow/ice interface sinks below the sea level because of snow loading (flooding). The effect of ice formation and melting is accounted for within the model assuming a sea ice salinity of 5 psu.

MPIOM allows for an arbitrary placement of the model's poles on an orthogonal curvilinear grid. In the setup used here (taken from Niederdrenk (2013); Mikolajewicz et al. (2015); Niederdrenk et al. (2016)) the poles are located over Russia and North America (Figure 5). Placement over land avoids numerical singularities that for poles over the ocean would be caused by the convergence of the meridians, and the non-diametric placement allows to reach high resolution (average of about 15 km) in the Arctic. This setup achieves a spatial resolution as high as that of the EO products we analyse (in fact over the target regions the model resolution is higher) without major computational constraints, which allows an evaluation of the full spatial information content provided by the respective EO products. Here, we will refer to this particular model configuration as Arctic MPIOM.

As forcing data at the ocean's surface, the model needs heat, freshwater, and momentum. These data are taken from ECMWF's ERA-Interim reanalysis (Dee et al., 2011). ERA-Interim is a global atmospheric reanalysis (of the period from 1979 to present) that is produced by a 2006 release of the Integrated Forecasting System (IFS – version Cy31r2) and applies a 4-dimensional variational analysis with a 12-hour analysis window. The spatial resolution of the data set is approximately 80 km (T255 spectral) on 60 vertical levels from the surface up to 0.1 hPa. ERA-interim surface variables that force Arctic MPIOM are 2-meter temperature, 2-meter dew point temperature (surrogate of 2-meter specific humidity – not provided by ECMWF), 10-meter zonal and meridional wind velocity (to calculate the wind speed), total cloud cover and the following fluxes (provided in accumulated form over the 12-hourly forecast window): surface downward solar radiation, surface downward thermal radiation, total precipitation, zonal and meridional wind stress. Land runoff into the ocean is taken from the German Ocean Model Intercomparison Project (OMIP, Röske, 2001).

For the computation of the ~~jacobians~~ Jacobians M' and N' (introduced in Section 2.1) that is described in Section 3 we run Arctic MPIOM from a restart file for April 1, 2015. This restart file is in turn generated from a hindcast run of Arctic MPIOM that is initialised on January 1, 1979. This initialisation is based on a set of observations that consists of a topography data set (ETOPO5 5-minute gridded elevation data, NOAA, 1988), and a hydrographic climatological data set (Polar science

5   center Hydrographic Climatology, PHC3; Steele et al., 2001) containing potential temperature and salinity. The ocean initially is assumed to be at rest. Sea ice is assumed to be present if the sea surface temperature falls below the freezing temperature of sea water. 100% ice cover and a sea ice thickness of 2m is assumed where sea ice is present and sea ice is assumed to be at rest. From this initial state the model is integrated with the ERA-Interim surface forcing until March 31, 2015 (the beginning of our assimilation window). While a 36 year integration is certainly too short to spin up the deep ocean, it is sufficient for the

10   purpose of this study, because the spinup time of sea ice and the upper ocean (depth above about 500m) is generally assumed to be only a few decades.
Figure 5. Model grid, mesh indicates groups of 4 by 4 grid cells.

For a successful QND assessment it is essential that MPIOM provides realistic sensitivities of the observation equivalent and the target quantities to the changes in the control vector (Equation (1) and Equation (3)). However, observations are not available to validate these sensitivities. The only validation of MPIOM possible is against observations of the state of the sea

15   ice and ocean. In the following we present comparisons with selected ~~observation based~~ observation-based products first for the hindcasting period, and then for the assimilation window and the forecasting period.

The hindcast with Arctic MPIOM has been validated against remotely sensed ice concentration from the reprocessed Ocean and Sea Ice Satellite Application Facility (OSI SAF) sea ice concentration product (Eastwood et al., 2015) and against a combination of in situ and remotely sensed ice thickness observations. In situ observations of sea ice thickness still have a

20   high uncertainty, and each data source has its own strengths and weaknesses. As of today the most reliable pan-Arctic sea ice thickness data set is derived from a combination of various sources of in situ observations and remotely sensed satellite sea ice thickness products (Lindsay and Schweiger, 2015).

The reprocessed OSI SAF sea ice concentration product is available daily on a 10 km spatial grid and includes spatially and temporally varying uncertainty estimates. For an assessment of the performance of the Arctic MPIOM, the sea ice concentration

has been compared to the long-term means of the March, June, and September monthly means for the period 1990 to 2008 (Figure 6). In March (panel d) and June (panel e) only relatively small scale misfits to the OSI SAF ice concentration are found but they can reach up to 50% (here and in the following we use the term "misfit" for the model-observation difference). The sea ice margin in the Nordic Seas and Barents Sea is captured well. The anomalies apparent in March correspond to the results

5 of a study performed with the MPIOM version of the Max-Planck-Institute's Earth System model MPI-ESM-LR (Notz et al., 2013), for which the MPIOM was forced with the same atmospheric forcing data set as used in our study (ERAinterim) (see panel f of their Figure 3). In September large misfits to the OSI SAF sea ice concentration are obtained (Figure 6 panel f). Especially over the Eurasian basin the model's sea ice margin is located too far north, but also over the central Arctic the model underestimates the sea ice concentration. In our target regions the misfit remains relatively small. The aforementioned analysis

10 by Notz et al. (2013) shows similar misfits (see panel f of their Figure 4) to a different sea ice concentration data set, namely NSIDC-CDR (National Snow and Ice Data Center Climate Data Record).

An evaluation of the hindcast simulation with Arctic MPIOM with respect to the modelled SIT is much more difficult, because the observation-based products exhibit large uncertainties reflecting the corrections imposed by the respective measurement principle. For example, electro-magnetic Air-EM measurements detect the air-snow interface, and not the interface

15 between snow and sea ice, introducing significant errors in the SIT estimates that are corrected by assumptions or measurements of snow depth. Moored and submarine ULS measurements have to be corrected for the first return echo. Differences in the observed and measured spatial scales further complicate the comparison. The aforementioned study of Lindsay and Schweiger (2015) synthesises all available in situ and remotely sensed satellite SIT products in an ice thickness regression procedure (ITRP) for the time period 2000 to 2012. Low order spatial and temporal polynomials are fitted to the available sea

20 ice thickness measurements. The resulting sea ice thickness regression product describes the evolution in the central Arctic and is linear in time plus a quadratic time-dependent component, i.e. it does not contain year-to-year variability. Uncertainty ranges are deduced from the uncertainty of the individual regression coefficients. The year-to-year variability is reflected in this uncertainty. Lindsay and Schweiger (2015) show for example that the ICESat ice thickness product from the Jet Propulsion Laboratory (ICESat-JPL, Kwok and Cunningham (2008)), which is widely used for model validation, ~~had~~ has a large positive

25 bias of about 40 cm. Here we compare the modelled long-term mean (2000 to 2012) sea ice thickness of the Arctic MPIOM hindcast to the ITRP sea ice thickness for the two-months periods February/March and October/November. We selected these two-month periods, because the availability of the ICESat satellite product ensures a high data coverage in the ITRP. The long-term mean sea ice thickness of the Arctic MPIOM hindcast simulation for February/March and October/November is depicted in Figure 7 (panel a and panel b) together with the misfit to the ITRP ice thickness (panel c and panel d). A prominent feature

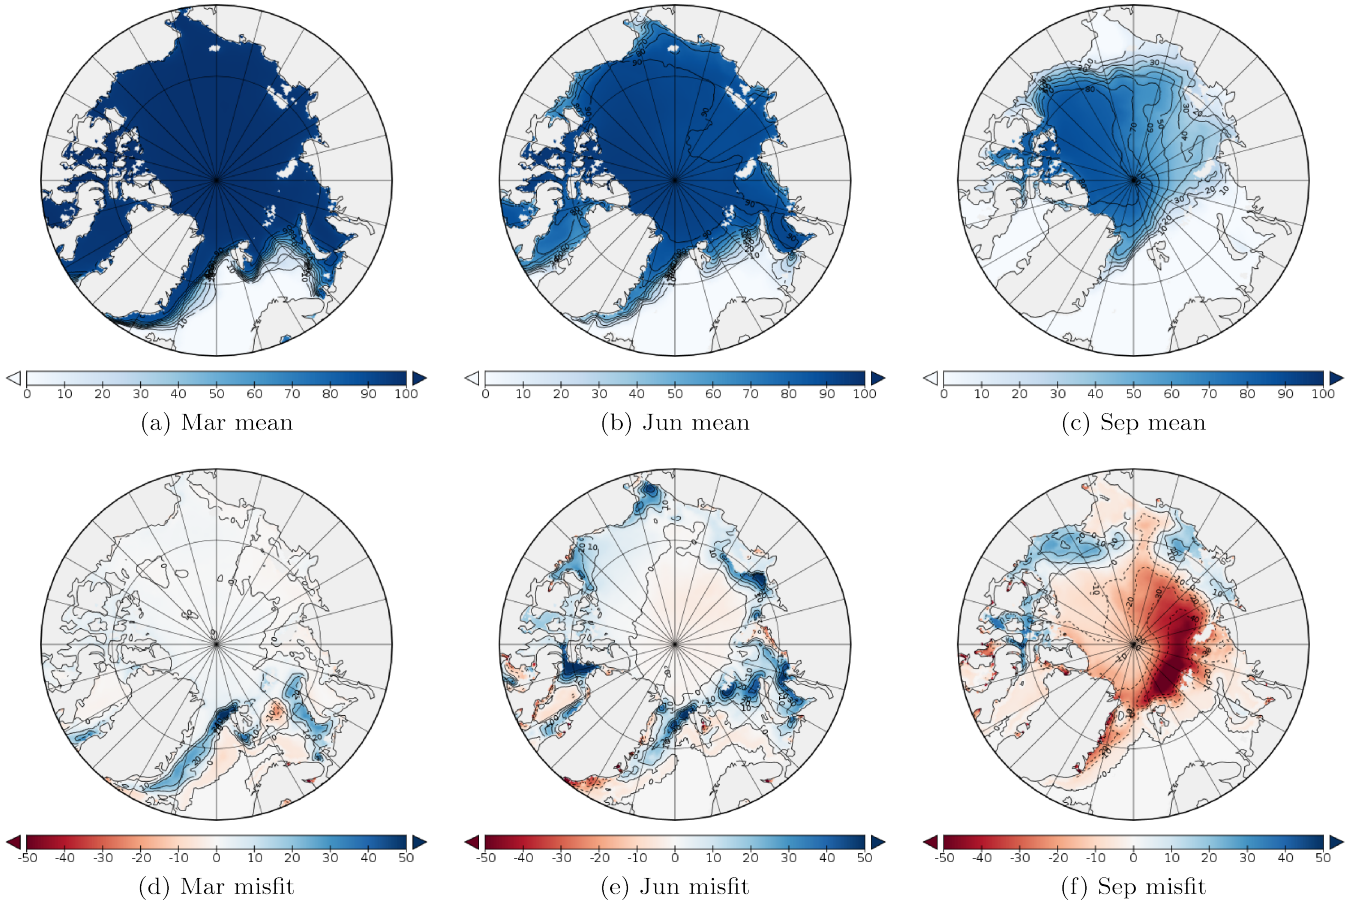
30 is a strong underestimation of the Arctic MPIOM sea ice thickness north and west of Fram Strait and in the strait itself. In the regions of interest for our QND study (the areas around the NSR) the misfit is moderate in February/March (overestimation of about 25%) with the exception around the New Siberian Islands where the misfit can reach more than ~~1~~ one meter (overestimation of about 50%). In October/November the misfit is very moderate in these areas except for Bering Strait where Arctic MPIOM underestimates the sea ice thickness by more than 50cm.


Figure 6. The long-term mean sea ice concentration [%] of the Arctic MPIOM for 1990 to 2008 for March, June and September (panel a to c) and the misfit to the OSI SAF sea ice concentration (panel d to f). In panels d to f, red colours indicate underestimation and blue colours overestimation of sea ice concentration in the model.

Next we address Arctic MPIOM performance over our assimilation and forecasting period (see Figure 4). We show the April mean and the May 28 mean of the modelled SIT and the misfit of the April mean thickness to that retrieved from CryoSat-2 (Figure 8). For a comparison of CryoSat-2 thickness to in situ observations we refer to Haas et al. (2017). The misfit to the CryoSat-2 ice thickness in April 2015 is similar to the misfit to the ITRP shown in Figure 7: a strong underestimation north of the Canadian Archipelago and north and west of Fram Strait and a moderate overestimation in the area of the target quantities of about or less than $50cm$ (about 25% relative error). Figure 9 depicts the April mean and the May 28 mean of the modelled snow depth and the misfit to the modified Warren climatology (Warren et al., 1999) that is used in the CryoSat-2 retrieval (see Section 2.5). The main challenge for sea ice thickness retrieval with satellite altimeters is the parameterisation of snow depth on sea ice, which is still not measured routinely. The current CryoSat-2 retrieval uses a modified snow climatology that addresses shortcomings of the Warren et al. (1999) climatology that was based largely on data from drifting stations mainly on multi-year

(a) Feb/Mar mean

Figure 7. The long-term mean (2000 to 2012) of the simulated sea ice thickness [m] for the two-month periods February and March and October and November (panel a and b) and the misfit (model – observations) to the ITRP (panel c and d). In panels c and d, red colours indicate underestimation and blue colours overestimation of sea ice thickness in the model.

sea ice collected over the past decades, and hence is not reflective of a much younger, more seasonal Arctic ice cover. Given the increased fraction of first-year ice in the Arctic Ocean, the approach proposed by Kurtz and Farrell (2011) is used and the climatological snow depth values used in the retrieval are multiplied over first-year ice by a factor of 0.5. Note that on May 28 over the target regions a large fraction of snow cover has already melted. The misfit to the modified Warren climatology in the target area East Siberian Sea is on the order of about $10cm$ (50% relative error) but much less for the other target areas.

Overall, the misfits of the Arctic MPIOM are acceptable in particular for our target regions along the NSR (Figure 3) and are comparable to misfits found in sea ice-ocean model intercomparison projects (e.g, Chevallier et al. (2017)).

2.4 Control vector

Criteria for the choice of the control vector are presented in Section 2.1. The specification of prior, both mean (x_0) and uncertainty ($C(x_0)$), follows Kaminski et al. (2015), and is listed in Table 1. The largest possible control vector in our modelling system is the superset of initial and surface boundary conditions as well as all parameters in the process formulations, including

(a) Apr mean

(b) May 28

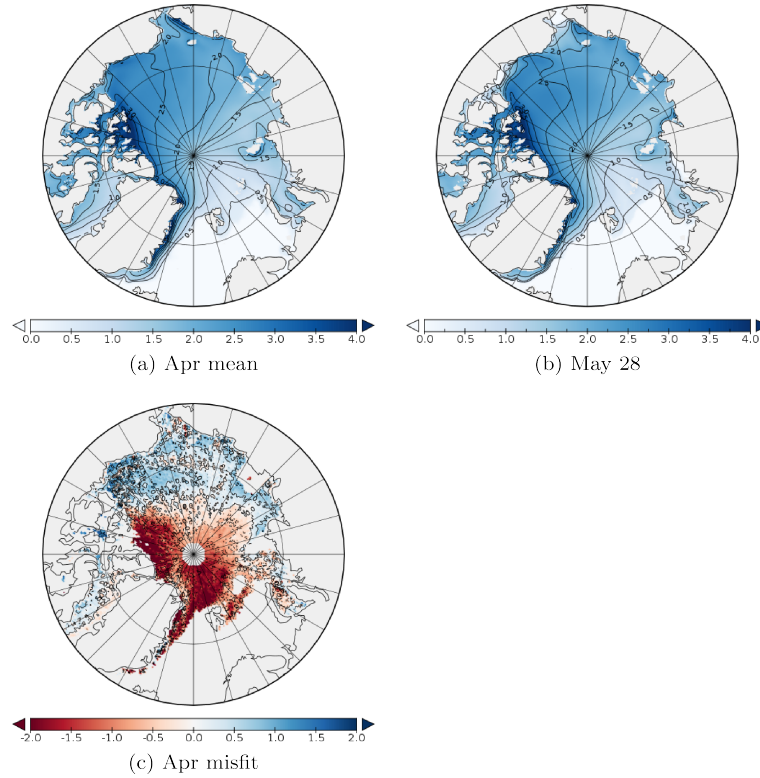
(c) Apr misfit


Figure 8. ~~The a)~~ a) The modelled mean April 2015 sea ice thickness [m], b) the modelled sea ice thickness on May 28 2015, and c) the mean April 2015 misfit of the modelled sea ice thickness relative to the CryoSat-2 sea ice thickness. In panel c, red colours indicate underestimation and blue colours overestimation of sea ice thickness in the model.

the observation operators. As described in Section 3, the Jacobian computation requires an extra run for each additional component of the control vector. To keep our ArcMBA system numerically efficient, two and three-dimensional fields are partitioned into regions. More precisely, we divide the Arctic domain into nine regions (shown in Figure 10). In each of these regions we add a scalar perturbation to each of the forcing fields (indicated in Table 1 by "f" in the type column); the perturbation is
5   applied for the entire simulation time. Likewise we add a scalar perturbation to six initial fields indicated in Table 1 by "i" in the type column. For the ocean temperature and salinity the size of the perturbation is reduced with increasing depth (and zero below 500 m). Finally we have selected 29 process parameters from the sea ice–ocean model plus two parameters from the observation operators for freeboard products (see Section 2.5 for details). This procedure results in a total of 157 control variables. We assume the prior uncertainty to have diagonal form, i.e. there are no correlations among the prior uncertainties
10   relating to different components of the control vector. The diagonal entries are the square of the prior standard deviation. For process parameters this standard deviation is estimated from the range of values typically used within the modelling community. The standard deviation for the components of the initial state is based on a model simulation over the past 37 years and

(a) Apr mean   (b) May 28

(c) Apr misfit
Figure 9. ~~The a)~~ a) The modelled mean April 2015 snow depth [m], b) the modelled snow depth on May 28 2015, and c) the mean April 2015 misfit of the modelled snow depth relative to the modified Warren climatology used in the CryoSat-2 sea ice thickness retrieval. In panel c, red colours indicate underestimation and blue colours overestimation of snow depth in the model.

computed for the 37 member ensemble corresponding to all states on the same day of the year. Likewise the standard deviation of the surface boundary conditions is computed for the 37 member ensemble corresponding to the April-October means of the respective year.

2.5 Data sets and observation operators

The study evaluates three data sets retrieved by the AWI (Ricker et al., 2014) from observations provided by the CryoSat-2 mission, two data sets characterising hypothetical LFB products, and two data sets characterising hypothetical SND products. Below, we describe these data sets and the simulation of their model equivalents, i.e. the respective observation operators that provide the links from the model's state variables to the respective data sets (Kaminski and Mathieu, 2017) . Recall that the (combination of) data set(s) enters the QND algorithm through its uncertainty $C(d)$ and that the observation operator is incorporated in the model M (see Section 2.1).

Table 1. Control variables. Column 1 lists the quantities in the control vector; column 2 gives the abbreviation for each quantity; column 3 indicates whether the quantity is ~~an atmospheric boundary field~~ a process parameter (~~forcing, i.e. f~~"p"), an initial field ("i"), or ~~a process parameter~~ an atmospheric boundary field (~~p~~denoted by "f" for forcing); column 4 gives the name of each quantity; column 5 indicates ~~(the~~ prior uncertainty (one standard deviation~~of)~~ ~~the prior uncertainty~~ and the corresponding units (unless unitless) and provides the ~~magnitude of the~~ mean parameter value in parenthesis, where applicable; and column 6 identifies the position of the quantity in the control vector – for initial and boundary values (which are differentiated by region) this position refers to the first region, while the following components of the control vector then cover regions 2 to 9.

Index #	Name	Type	Meaning	Prior uncertainty (~~value~~Mean)	Start

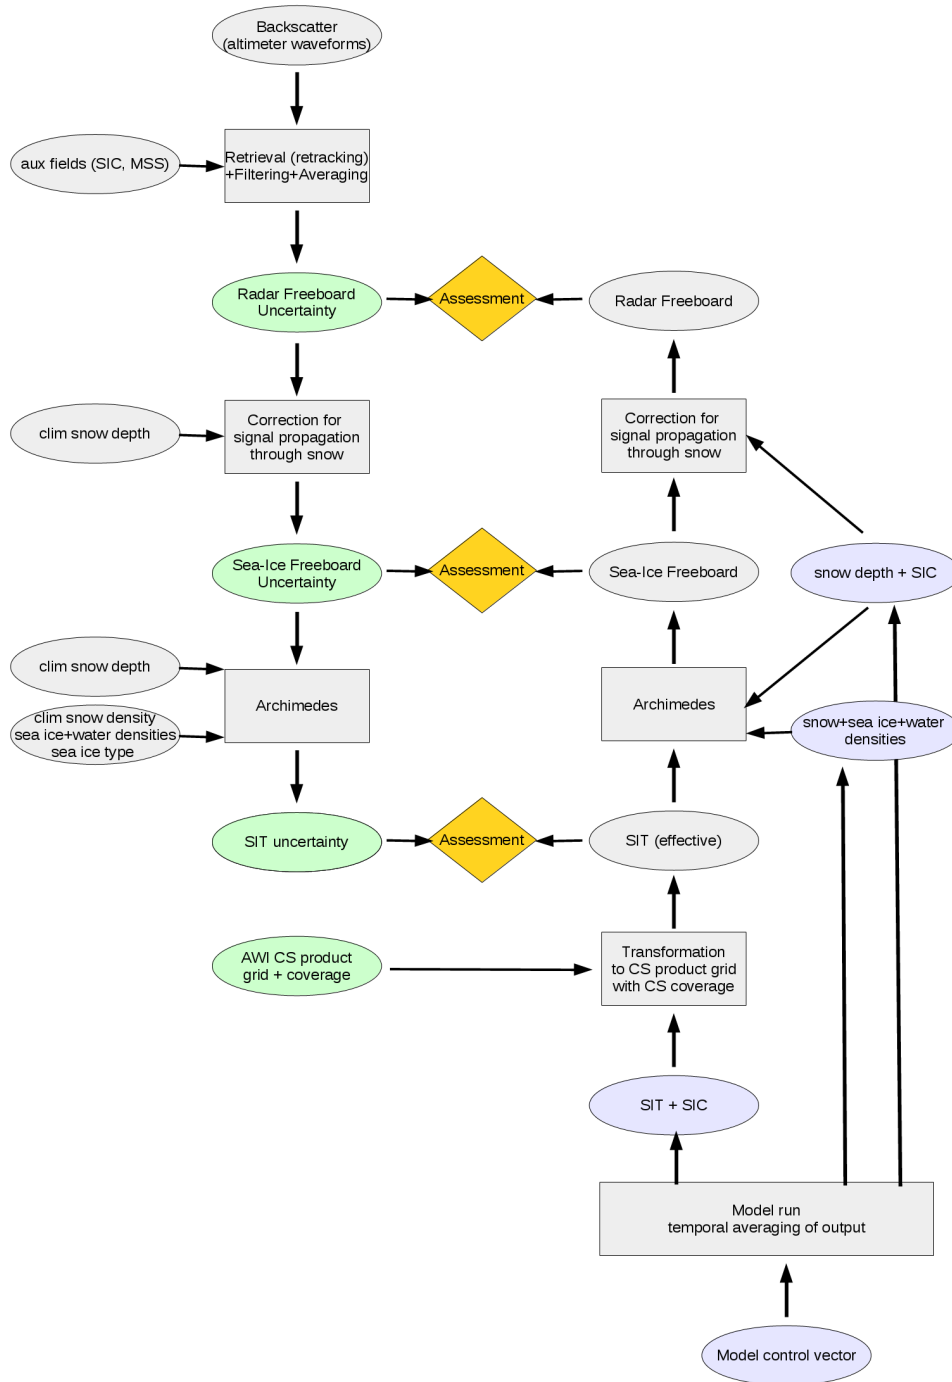
The three products derived by AWI from CryoSat-2 are SIT (h_i), SIFB (f_i), and RFB (f_r). Their definition is illustrated in Figure 11 together with that of LFB (f_l).
Figure 11. Schematic illustration of sea ice thickness and different freeboard variables.


Figure 12. Overview on the processing chain for CryoSat-2 (CS) product retrievals (left-hand side) and the chain for modelling product equivalents from the control vector ($M(x)$, right-hand side). Oval boxes denote data and rectangular boxes processing steps. Green colour emphasises remote sensing products and violet colour model variables. Yellow diamonds mark the assessment of the EO products with the QND algorithm. MSS: mean sea surface height.

The retrieval chain is described in detail by Ricker et al. (2014) and Hendricks et al. (2016). Recall that for each product, in order to run an assessment, we need the spatio-temporal coverage as well as the uncertainty ranges. The left-hand side of Figure 12 summarises the main steps in the retrieval chain, starting with the rawest (lowest-level) product (RFB) on top. When descending from RFB via SIFB to SIT each step adds further assumptions, which contribute to the product uncertainty. The other element required to evaluate a given product is the observational Jacobian (M'), i.e. the sensitivity of the model simulation to a change in the control vector. The right-hand side of the graph illustrates how the equivalents of the respective products are simulated from the relevant model variables, which are denoted in violet colour. On this side of the graph, the complexity increases from bottom to top, i.e. from SIT via SIFB to RFB. For example, in the assessment of the SIT product, the uncertainty in quantities needed to apply the Archimedes' principle (including that of snow depth derived from climatology) is contained in the retrieval product, whereas the observation operator that extracts the product equivalent from the model is relatively simple (Archimedes' principle is described, for example, by Guerrier and Horley (1970)). We note that, while retrieved SIT is the effective SIT ($h_{i,eff}$), i.e. refers to the average over the ice-covered area of a grid cell, simulated SIT refers to the grid-cell average, i.e. for the Jacobian calculation it has to be divided by the simulated sea ice concentration (SIC, denoted by c):

$$h_{i,eff} = h_i/c. \tag{6}$$

Likewise for snow depth:

$$h_{s,eff} = h_s/c. \tag{7}$$

At the level of RFB, by contrast, it is the observation operator that includes inter alias, on the modelling branch, the application of Archimedes' principle for which it requires simulated snow depth and the densities of snow (ρ_s), sea ice (ρ_i), and water (ρ_w), while the retrieval product is relatively raw. In particular this retrieval product is not affected by uncertainties due to assumptions concerning the snow depth, ρ_s, ρ_i, and ρ_w.

The observation operators for f_i, for f_r, and for f_l are:

$$
\begin{aligned}
f_i &= h_i/c - (\rho_i h_i/c + \rho_s h_s/c)/\rho_w \\
&= (1 - \rho_i/\rho_w)h_i/c - (\rho_s/\rho_w)h_s/c \tag{8} \\
f_r &= f_i - 0.22 h_s/c \\
&= (1 - \rho_i/\rho_w)h_i/c - (0.22 + \rho_s/\rho_w)h_s/c \tag{9} \\
f_l &= f_i + h_s/c \\
&= (1 - \rho_i/\rho_w)h_i/c + (1 - \rho_s/\rho_w)h_s/c. \tag{10}
\end{aligned}
$$

The term $-0.22 h_s/c$ in Equation (9) adds to the simulated f_i the correction for the ~~different~~ difference in propagation speed of the radar signal in snow compared to air, which is affecting f_r (Hendricks et al., 2016). This is the reason why f_r is located

below f_i in Figure 11. We note that, in these three observation operators, f_i, f_r, and f_l have the same sensitivity to h_i, but sensitivities to h_s and c differ. The sea ice component of the MPIOM uses constant densities of snow, sea ice, and water. As simulated freeboard is relatively sensitive to densities of snow and sea ice, we have, however, included these quantities as parameters of the observation operator in the control vector (see Section 2.4). For $\rho_T \rho_i$=910.0 kg/m^3, $\rho_S \rho_s$=330.0 kg/m^3,

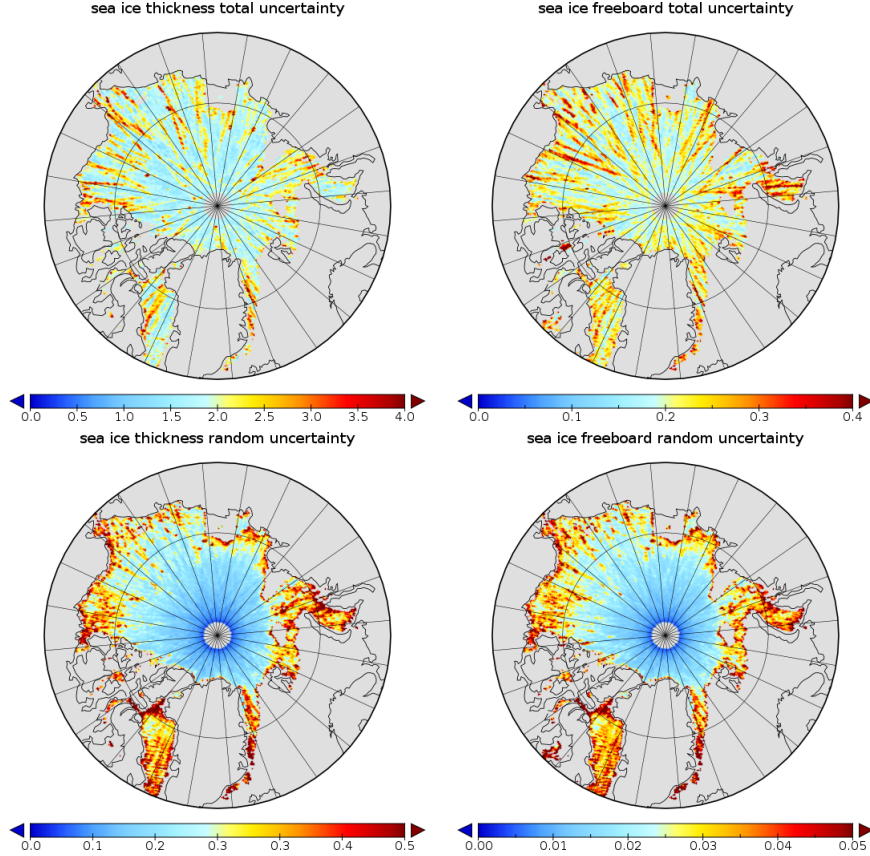
5 ρ_w=1025.0 kg/m^3, the sensitivity of f_i, f_r, and f_l to a change in h_i/c is $a = 0.112$, and the respective sensitivities to a change in h_s/c are $b = -0.322$, $b = -0.542$, and $b = 0.678$.


Figure 13. Uncertainty ranges [m] of CryoSat-2 products for April 2015: SIT (left), SIFB (right), total uncertainty (top), random ~~component~~ uncertainty (bottom)~~for April 2015..~~

The CryoSat-2 product files used in this study directly contain monthly SIT and SIFB on the Equal-Area Scalable Earth Grid (EASE) 2.0 grid, respectively with random (based on standard uncertainty propagation) and total (random plus systematic) per-pixel uncertainty ranges (for details see Hendricks et al., 2016, and references therein). Figure 13 shows product uncertainties

10 for April 2015. In our assessments we use the total uncertainties for the SIT and SIFB products, and for the RFB product the random uncertainty component of the SIFB product. Recall, that we assume uncertainties to be uncorrelated in space.

For our hypothetical monthly LFB products, we assume a coverage of the northern hemisphere with a retrieved value over each cell of the EASE 2.0 grid with SIC above 0.7, in analogy to the threshold used in the CryoSat-2 retrieval (Hendricks et al., 2016). We explore two assumptions with respect to the uncertainty of the products, a mission with a high accuracy (uniform uncertainty of 0.02 m) and a mission with low accuracy (uniform uncertainty of 0.20 m). In both cases uncertainties are uncorrelated in space.

For our hypothetical monthly mean SND products, we also assume a coverage of the northern hemisphere with a retrieved value over each cell of the EASE 2.0 grid with SIC above 0.7. As for LFB we explore two assumptions on the uncertainty of the products, a mission with a high accuracy (uniform uncertainty of 0.02 m) and a mission with low accuracy (uniform uncertainty of 0.15 m). In both cases uncertainties are uncorrelated in space.

Table 2 provides an overview on the products we assess. For later use, it also lists for each product and the three control regions the number of sampled EASE 2.0 grid cells and the corresponding regional average uncertainties. Finally, it also shows the uncertainties on the spatial average of the sampled variable over all sampled EASE 2.0 grid cells based on the assumption of uncorrelated observational uncertainty.

Table 2. Overview on data sets, the # of sampled EASE 2.0 grids in control regions 5-7 (columns 2-4), the respective average uncertainties (columns 5-7), the uncertainty of the product aggregated over all sampled EASE 2.0 grid cells (column 8).

Product	n			average uncertainty			aggregated uncertainty
	5	6	7	5	6	7	[m]
SIT	937	1425	1377	1.86	1.95	1.94	0.0181
SIFB	937	1425	1377	0.21	0.20	0.21	0.00188
RFB	937	1425	1377	0.029	0.024	0.027	0.000364
LFB low accuracy	1104	1500	1429	0.20	0.20	0.20	0.00145
LFB high accuracy	1104	1500	1429	0.02	0.02	0.02	0.000145
SND low accuracy	1104	1500	1429	0.15	0.15	0.15	0.00108
SND high accuracy	1104	1500	1429	0.02	0.02	0.02	0.000145

3 Target and observational Jacobians

We compute The evaluation of Equation (1) and Equation (3) requires a target Jacobian $\mathbf{N}'$ for each target quantity and an observational Jacobian $\mathbf{M}'$ for each of the observational products we assess . (Table 2). This subsection first describes the computation of these Jacobians and then discusses them. For a given product, the observational Jacobian is computed in two steps. The first step performs the following actions: a reference run is performed using the prior control vector x, the input variables to the observation operator are stored over the observational period, aggregated to the model grid, and the observation operator is applied to derive the observation equivalent $M(x)$ on the space-time grid of the observational product. In the second step, for each component of the control vector the following procedure is applied: A sensitivity run is performed with

a control vector $x + p_i$ that is identical to the prior control vector but with the i-th component changed by a perturbation ϵ_i, and an observation equivalent $M(x + p_i)$ is computed in the same way as for the reference run. The Jacobian column is then computed as $\sigma_i(M(x + p_i) - M(x))/\epsilon_i$ where σ_i is the prior uncertainty of x_i. As a consequence of the normalisation by the prior uncertainty, each row in the Jacobian has the same unit as the respective observation. For a given product, column i of the

5 corresponding observational Jacobian quantifies the sensitivity of the model-simulated equivalent to that product with respect to a change of the i component of the control vector x_i by one standard deviation (see Table 1 for the value).

For any given product the dimension of the observational Jacobian is the product of the dimension of the control space and the grid size of the observational product. As an example, Figure 14 displays the row of the Jacobians for April means of SIT, SIFB, RFB, LFB, and SND over a single point in space indicated by the black dot (and by the black cross on Figure 3).

10 The SIT sensitivity is dominated by the model's initial SIT in control region 6 (black bars in Figure 14 and enlarged in Figure 15) but shows also considerable sensitivities to the initial SIC, the initial SND, the initial ocean temperature (TEMP) and the zonal wind stress (WIX). The negative sensitivity to SIC in that region is caused by two mechanisms. The first mechanism is expressed by Equation (6): The observation $h_{i,eff}$ is the effective SIT (thickness averaged over the ice-covered grid cell) and is reduced if the initial SIC is increased (and vice versa) because the model conserves the total sea ice volume. The second

15 mechanism is related to sea ice growth which depends on the open water fraction, i.e. more (less) sea ice can grow if the SIC is reduced (increased). The small negative sensitivity of SIT to SND is caused by the strong insulation effect of snow, which hampers the growth of sea ice (or fosters the growth if SND is reduced). The physical process behind the small negative sensitivities on the initial ocean temperature needs no further explanation; we recall, however, that, in the presence of sea ice, the control variable relates to a temperature change below the second model layer (at 17m depth). The negative sensitivity

20 with respect to the zonal wind stress (WIX) mirrors less advection of thick sea ice originating from the Beaufort Gyre. WIX is positive for eastward wind stress. A positive ~~perturbation on~~ sensitivity to WIX is most distinct in region 6 (but also evident in regions 7 and 8) and slows down the Beaufort Gyre which advects less sea ice into the target region (sea ice behaves, at least in April and May, to a large extent like a rigid body, i.e. ~~the impact~~ a change in regions 7 and 8 ~~acts~~ impacts almost instantaneously on the target regions) resulting in a negative sensitivity. The SIT sensitivities on model parameters (Figure 14 and enlarged in

25 Figure 15) are very small compared to the sensitivities on the initial state or the atmospheric boundary conditions, as the short integration time (we sample the April mean of a model simulation starting on April 1) restricts the impact of the parameters.

The various freeboard products exhibit high sensitivity to initial SIT and SND (orange, red, and green bars in Figure 14 and enlarged in Figure 15). As SIT enters all freeboard observation operators in the same way (Section 2.5), the freeboard sensitivity to April mean SIT is equal for all products, which also renders their sensitivity to initial SIT almost equal. The LFB

30 sensitivity on the initial SND is positive (LFB is the freeboard at the top of the snow layer) while the sensitivity of the RFB and SIFB is negative because an increased SND will reduce the RFB and SIFB through the increased weight on the ice floe (see Figure 11). Due to the definition of the observation operator for RFB (Equation (9)) its sensitivity to initial SND is larger than that of the SIFB (Section 2.5). The sensitivity of the freeboard products (yellow, red, and green bars) with respect to the parameters of the sea ice and ocean model is low. The impact of the sea ice density on the respective observation operators

35 (Equation (8) to Equation (10)) is high, though, while sensitivity with respect to the snow density is much lower (because the

sea ice thickness is much larger than the SND at the observational point). The SND shows only considerable sensitivity to the initial SND in control region 6 and some minor positive sensitivity with respect to the precipitation in the same region.

Likewise we computed target Jacobians $\mathbf{N}'$ for each of the six target quantities (SIV and SNV each over 3 regions) described in Section 2.2. Each target quantity is a scalar and thus the Jacobian has one entry for each component of the control vector. As an example Figure 16 displays the Jacobians for SIV and SNV (on May 28) over the Outer New Siberian Islands (ONSI) region. The first point to note is that sensitivities of regional SIV and SNV to the control vector differ, so an observation must constrain different components of the control vector to perform well for one or the other target quantity.

SIV over the ONSI region is highly sensitive to initial SIT over control regions 5 and 6 (Figure 17) which at least partly overlap with the target area. As the SIT observation and due to the same mechanisms discussed above, the SIV target quantity also exhibits a negative sensitivity to the initial SIC, SND, and zonal wind stress. It is interesting to note that SIV is also sensitive to initial and boundary conditions over more remote control regions. For example, it exhibits a positive sensitivity to the initial SIT in the control regions 1 and 7 from which thick sea ice is advected into the target region during the period from April 1 to May 28. This also explains the negative sensitivity to the zonal wind stress in region 7 and the meridional wind stress in region 1: For ~~high enough concentration~~ sufficiently high SIC the sea ice almost behaves as an incompressible fluid allowing even for a sensitivity to wind stress changes in very remote control regions, e.g. the negative sensitivity to the zonal wind stress in region 8. The positive sensitivity to the zonal wind stress in region 1 (with thick ice) may be less obvious, as it follows the deflection of ice drift by about $20°$ to the right. The largest SIV sensitivity to model parameters (Figure 17) is found for the snow albedo of freezing conditions (albsn), but still that sensitivity is low compared to the sensitivity with respect to the initial state and atmospheric boundary conditions.

SNV shows particularly high sensitivity to the initial SND but also considerable sensitivity with respect to the precipitation and air temperature in region 6. The largest model parameter sensitivity is found for the snow albedo for melting conditions: Increasing the snow albedo will reduce the melting.

4 Experimental setup

Based on the products shown in Table 2, we conducted assessments for the 15 cases listed in rows 4-18 of Table 3. These 15 cases cover all combinations of the five SIT/freeboard products described in Section 2.5:

1. SIT,

2. SIFB,

3. RFB,

4. hypothetical low accuracy LFB, and

5. hypothetical high accuracy LFB

and the following three assessments variants:

1. product evaluated individually,

2. product evaluated together with a hypothetical low accuracy SND product, and

3. product evaluated together with a hypothetical high accuracy SND product.

The reference for these assessments is a case without observations. Row three ("prior") shows the uncertainties in the target quantities that result from the prior uncertainty in the control vector.

5   Sea ice and snow volume uncertainty

The section presents the results of our assessments. As explained in Section 2.1 the uncertainty component from the model error $\sigma(y_{\mathrm{mod}})$ in Equation (3) covers the residual uncertainty that remains with an optimal control vector, i.e. it reflects uncertainty from uncertain aspects not included in the model error and structural uncertainty reflecting wrong or missing process formulations. $\sigma(y_{\mathrm{mod}})$ is model-dependent and is probably the most subjective component in the prior and posterior uncertainties. $\sigma(y_{\mathrm{mod}})$ acts as an offset (for the respective variance) for all cases, and reduces the contrast between the cases. As our assessments focus on the differences between the cases, we exclude it from the target uncertainties in rows 3-18 of Table 3 and provide estimates in separate rows. To illustrate the subjective nature of this estimate and possible ranges, we derive two crude estimates (last two rows). The first estimate (denoted by $\sigma_{\mathrm{mod, \, absolute}}$ ~~and listed in the last but one row~~) assumes a model that perfectly simulates the same ice-covered area of all three regions as our model and that, over this area, achieves an uncertainty of 0.2 m for SIT and of 0.1 m for SND. The second estimate (denoted by $\sigma_{\mathrm{mod, \, relative}}$) assumes a model that simulates the same SIV and SNV as our model with an uncertainty of 10% for SIV and 30% for SNV. We use a higher uncertainty for SNV because it has a stronger dependence on the surface forcing (mainly precipitation), for which the temporal and small-scale spatial structures are not resolved in the control vector.

Figure 18 shows the uncertainty reduction with respect to the prior case as defined in Equation (5) for both SIV and SNV and all three target regions. A value of 100% means that the product has resolved all uncertainty in the respective target quantity, while a value of 0% means that the product was not useful to improve the forecast of the target quantity. We first discuss the single product assessments, i.e. without additional use of a hypothetical snow product. For all three regions, the SIT (yellow bar) has considerably better performance for SIV than for SNV. Between SIV and SNV the only difference in our QND assessments consists in the target Jacobians, $\mathbf{N}'$. For example for target region ONSI, Figure 16 shows particularly high sensitivity of SIV to initial SIT and of SNV to initial SND in control regions 5 and 6. Hence, to constrain SIV (SNV) over that target region a product has to constrain primarily initial SIT (SND) over these two control regions. Figure 14 shows that, indeed, SIT provides a much stronger constraint on initial SIT than on initial SND. In contrast to SIT, SIFB has similar performance for SIV and SNV, over all target regions (Figure 18). Compared to SIT, SIFB shows a much lower sensitivity to initial SIT but a higher sensitivity to initial SND (Figure 14 - the sign of the sensitivity is irrelevant in this consideration), and thus a more balanced performance for SIV and SNV than the SIT product. RFB and the two hypothetical LFB products achieve a better performance for SNV than for SIV. The only difference between the RFB and SIFB Jacobians is the larger impact of

Table 3. Prior and posterior uncertainties of sea ice volume (SIV, columns 4-6) and snow volume (SNV, columns 7-9) respectively for three regions in km^3. Column 1 indicates observation, column 2 indicates uncertainty range ("product" refers to uncertainty specification provided with product), column 3 indicates uncertainty range of additional hypothetical snow product ("–" means no snow product is used). In each of columns 4-9 the lowest uncertainty range is highlighted in bold face font. The two bottom rows give estimates for the uncertainty due to model error, i.e. the residual uncertainty with optimal control vector.

h_s/c for RFB, as a consequence of the correction for the signal propagation through snow (see Section 2.5). Hence, why RFB shows a better performance for SNV than for SIV, while SIFB had about equal performance for SIV and SNV. LFB has the same sensitivity to initial SIT as RFB but an even larger sensitivity to initial SND. Consequently, for the low accuracy LFB product, the imbalance between the performance for SIV and SNV is even higher than for the RFB product. This imbalance is lower for the high accuracy LFB product, because this product already performs excellently on SIV such that there is not much scope for further increases in performance on SNV.

So far we have discussed differences in performance for SIV and SNV for a given product. Next we address performance differences between products. First, we note that switching from SIT to SIFB drastically reduces the performance for SIV. As explained in Section 2.5, on the left-hand side of Figure 12 (retrieval branch) switching from SIFB to SIT applies Archimedes'

principle, with uncertain assumptions primarily on the input variables snow and ice density and snow depth, which yield an increase in product uncertainty by about an order of magnitude (Figure 13 and Table 2). On the right-hand side of Figure 12 (modelling branch) switching from SIT to SIFB is dealing with uncertainty on the same input variables (snow and ice densities and snow depth), which renders the simulation of SIFB more uncertain than that of SIT. In the model, the uncertainty in these variables is determined by the prior uncertainty of the control vector, either directly (snow and ice densities) or indirectly (snow depth) through their model-simulated dependency on the control vector. It appears that the increase in uncertainty, when going from SIT to SIFB on the modelling branch, overcompensates for the reduction in uncertainty on the retrieval side, when going back from SIT to SIFB. In other words, on the modelling branch, the assumptions on uncertain input appear more conservative than those on the retrieval branch. On the retrieval branch going (backwards) from SIFB to RFB consists in a reduction of product uncertainty by about another order of magnitude, as the retrieval of RFB does not require information on snow depth. Even with this further reduction of product uncertainty, the performance of RFB is inferior to that of SIT for SIV over WLS and ONSI, and only just superior for SIV over ESS.

Differences between target regions in the performance of the same product are the result of a complex interplay of the Jacobians $\mathbf{N}'$ for the target regions and the product's constraint on the control vector quantified by $\mathbf{C}(x)$ (see Equation (3)). For each of the target regions a different (combination) of control regions is most relevant: For WLS this is control region 5 (not shown), for ONSI control regions 5 and 6 (Figure 16 and enlarged in Figure 17) and for ESS on control regions 6 and 7 (not shown). The ability of a product to constrain a particular control region is determined by the combination of the observational Jacobian of the product and the product uncertainty (see Equation (1)).

It is tempting to explain regional performance differences simplistically by linking them to differences in observational coverage and uncertainty. Technically, such an explanation corresponds to replacing our observational Jacobian $\mathbf{M}'$ (that is based on model dynamics) with a drastically simplified representation. Such a simplistic approach would imply that only observations over a given control region constrain that same region (and none other), and that the observational Jacobian for each product and control variable is spatially uniform. The constraints of a product on a control region would then be proportional to the square root of the number of samples n of that region and to the reciprocal of the average observational uncertainty $\overline{\sigma}$ over the region. Table 2 shows both impact factors for the most relevant control regions, i.e. 5-7. For RFB and compared to region 6, the relevant quantity $\sqrt{n}/\overline{\sigma}$ is about 41% lower in region 5 and 12% lower in region 7. This is at least quantitatively in line with the performance decrease for RFB and SIV from ONSI (most relevant in region 6 and to smaller extent in 5) to ESS (most relevant in region 6 and to smaller extent in 7) to WLS (most relevant in region 5). But the performance ranking for RFB and SNV is different, i.e. the simplistic approach does not hold. Also for SIT, the differences in $\sqrt{n}/\overline{\sigma}$ between the three control regions are smaller and fail to explain the performance decrease from WLS to ONSI to ESS. Such calculations demonstrate the limits of a performance assessment that is only based on observational coverage and uncertainty, while neglecting the model dynamics.

The two hypothetical LFB products have a slightly better spatial coverage of the most relevant control regions than the products derived from CryoSat-2 and use uniform data uncertainties that span the range from 2 cm (high accuracy LFB) to 20 cm (low accuracy LFB). Recall that the specified data uncertainty combines the observational uncertainty (i.e. product

uncertainty) with the residual model uncertainty due to structural errors and uncertain contributions not accounted for in the control vector (Equation (2)). Only the high accuracy LFB can clearly outperform all CryoSat-2 products for both SIV and SNV and over all three regions, while the low accuracy LFB ~~is~~ falls in performance between that of SIFB and RFB.

Next we discuss the effect of combining either of these five products with the two hypothetical SND products. The difference in the respective product Jacobians shown in Figure 14 suggests complementarity of SND to the SIT and freeboard products. Indeed, the combination with SND considerably increases the performance of all SIT/freeboard products for SIV and SNV and over all regions. Most striking is the improved SIT performance for SNV. The combination with SND results in similar performance for SIT and SIFB, slightly better performance of low accuracy LFB, yet slightly better performance for RFB and the best performance for the high accuracy LFB. The assessment for SIV and in combination with low accuracy SND yields the same performance ranking of products, with slightly larger differences between products. Combining with the high accuracy SND product instead of the low accuracy SND product yields a performance gain for all products and for SIV and SNV over all regions.

Between the two LFB products, the increase in accuracy yields a considerable performance gain for SIV and SND over all regions, when assessed individually and in combination with SND. Over all regions the combination of the high accuracy LFB with the low accuracy SND performs better for SIV than the combination of the low accuracy LFB with the high accuracy SND. For SNV the two combinations are similar in performance.

Figure 14. The sensitivities of the respective EO product to the control vector ("observational Jacobians") for April means of LFB (orange bars), RFB (red bars), SIFB (green bars), SIT (black bars) and SND (cyan bars) over a single point indicated by the black dot (and by black cross on Figure 3). The observational Jacobians with respect to the process parameters are shown in the left middle panel. The other panels show the observational Jacobians with respect to the initial and forcing fields for each control region (see Table 1 for an explanation of the abbreviations).

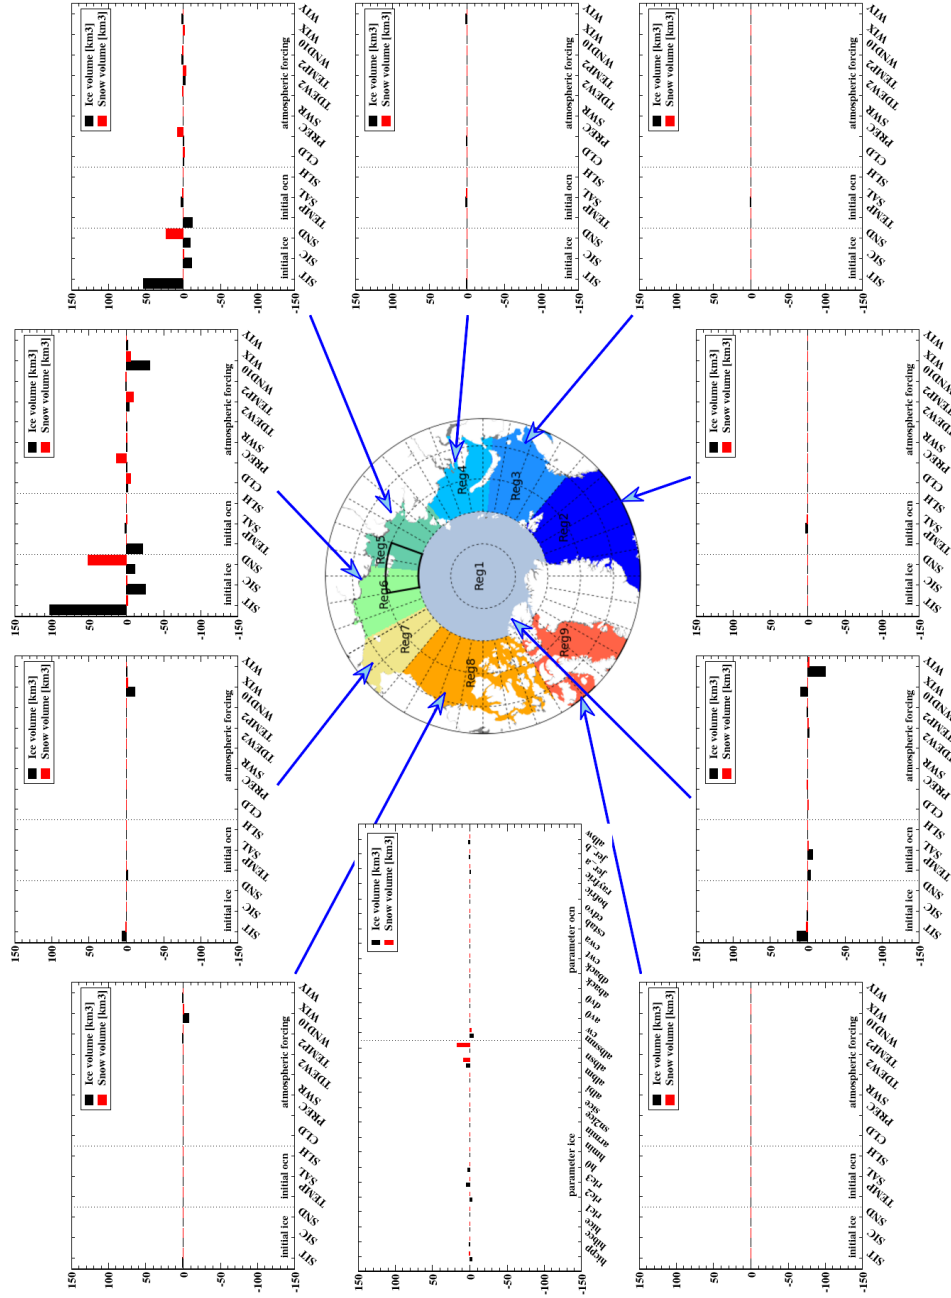
Figure 15. An excerpt of Figure 14 of the observational Jacobian (top) in target region 6 ("East Siberian Sea") and (bottom) for the model parameters.


Figure 16. As Figure 14 but for the sensitivities of the sea ice (SIV) and snow (SNV) volume over the target region Outer New Siberian Islands (ONSI) on the control vector ("target Jacobians").
Figure 17. An excerpt of Figure 16 for the target Jacobian (top) in target region 6 ("East Siberian Sea" - left) and region 5 ("Laptev Sea" - right) and (bottom) for the model parameters.
Figure 18. Uncertainty reduction for sea ice (SIV) and snow (SNV) volume over target regions when using observational constraints. The colour of the bars represents the different observational constraints. Yellowish: SIT and SIT in combination with a hypothetical snow depth product with two different uncertainties (15cm and 2cm), reddish: as SIT but for SIFB, greenish: as SIT but for RFB, bluish: as SIT but for hypothetical LFB with 20cm uncertainty, grayish: as SIT but for hypothetical LFB with 2cm uncertainty.

6 Discussion

There are a number of factors in the setup of our ArcMBA system that impact our assessments. One of them is the model that is required to realistically compute the sensitivities (Jacobians) of the target quantities and of the observation equivalents to changes in the control vector. As detailed in Section 2.3, the MPIOM has a state of the art representation of processes, compares

5 reasonably with a range of observations (Notz et al., 2013; Kaminski et al., 2017), and the setup of MPIOM we are using has a spatial resolution below the grid size of the observations and well below the size of the target regions. The model thus appears appropriate for our study and the ArcMBA system in general. Nevertheless, through the Jacobians the results depend on the model, and it would be useful to confirm the robustness of the assessments through the use of a second model, or even an ensemble of models.

10 The study has investigated the performance of four-week forecasts in May 2015. The impact of an observation is likely to depend on the state of the Arctic ~~sea-ice ocean~~ sea ice-ocean system. The robustness of the ArcMBA assessments can thus be increased through extension of the system for an ensemble of ice and ocean conditions representing different forecasting times (for example 2, 7-10, and 90 days and also 0 days, i.e. an analysis), different seasons, different typical years (potentially also including conditions of very low ice cover), and different target regions and variables, e.g. SIC.

15 In our setup, the control vector has 157 components. In particular within any of our 9 control regions we do not resolve changes in the spatial patterns of the initial conditions nor in the spatio-temporal patterns of the forcing data. This means that we are ignoring uncertain aspects in the inputs that determine our simulation, which results in so-called aggregation errors (Trampert and Snieder, 1996; Kaminski et al., 2001) and renders the ArcMBA assessments of the product impacts too optimistic. As the target quantities are integrals over large regions, we expect, however, that our control regions can capture

20 most of the uncertainty. Also the set of reasonable surface forcings is in practise limited by physical relations between variables, in space and in time. Similar restrictions apply to the initial state. Further, we use the same control vector for all cases, so that the relative performance with respect to the prior (uncertainty reduction) and among products is more reliable. Nevertheless it appears useful to explore extended control vectors, for example with decreased sizes of the control regions, in particular in areas with high impact on observations or target quantities.

25 Another factor that impacts our assessments are correlations in the data uncertainty. These uncertainty correlations are difficult to estimate. We used zero uncertainty correlation for each of the products, which is certainly the most optimistic assumption and yields the best performance. As we made this assumption consistently for all products, the relative performance between the products is less affected. To illustrate the implications of uncorrelated uncertainty in the products, we have computed the resulting uncertainty in the respective average of each observable over all sampled grid cells (last column of Table 2). This

30 yields for the April 2015 mean of SIT about 2 cm, of SIFB about 2 mm, of RFB about 0.4 mm and (using the respective high-accuracy versions) of LFB and SND about 0.1 mm.

The effect of uncertainty correlation on the assessments can be demonstrated also by the following simplified calculation: If we partition our product grid into groups of n by n pixels, and assume perfect uncertainty correlation and the same Jacobian for each observation within a given group, then we decrease the first term in Equation (1) by a factor of n^2. This case then

yields the same results as a case with an uncertainty that is uncorrelated and increased by a factor of n. This means we can interpret the impact of the low resolution LFB product (uncorrelated uncertainty of 20 cm) as the impact of a high resolution LFB product (with 10 times lower uncertainty, i.e. 2 cm) in which the uncertainty within each 10 by 10 group of pixels is completely correlated. Likewise for the SND product and (roughly) 6 by 9 groups of pixels, because $(15 \text{ cm}/2 \text{ cm})^2$ is about

5 6×9. One reason for spatial uncertainty correlation would be a sensor footprint that exceeds the size of a 25km EASE grid cell. Likewise, for sensors with footprints considerably smaller than a 25km EASE grid cell, the procedure for upscaling from the sampled fraction of a grid cell to a grid-cell average could suffer from systematic errors that affect large scales in the same way, which would result in large-scale uncertainty correlations.

Our hypothetical products (LFB and SND) observe every pixel with SIC above 0.7. This is optimistic but, at least for snow,

10 not totally unrealistic, depending on the mission concept. Recalling that the data uncertainty has to include also an uncertainty from model error, the value of 0.02 m for the high accuracy products (without spatial correlation) is extreme and unrealistic (as it is already a challenging requirement on the observational uncertainty) but still useful as a sanity check for the methodology. We note that, even for the assessment of an individual product, the posterior uncertainty on the target quantities is not a simple linear function of the product uncertainty, because of the contribution from the prior term in Equation (1). This means, for

15 example, the posterior uncertainties achieved by a hypothetical LFB product with 0.11 cm uncertainty will not be the average of the posterior uncertainties achieved by our two hypothetical SND products with respective uncertainties of 0.02 m and 0.20 m. For combined assessment of multiple products the relation between the uncertainty of a single product and the posterior target uncertainty is yet more complex.

The uncertainty specified with the SIT product is higher than the uncertainty specified with the SIFB products derived from

20 CryoSat-2. This increase reflects the inclusion of uncertainty in the input quantities for the application of Archimedes' principle, in particular of climatological snow depth. In the assessment of SIFB, Archimedes' principle is applied in the observation operator, where the input quantities including snow depth are taken from the model. The fact that the impact of SIFB on SIV is lower than that of SIT indicates that the assumptions on the uncertainty of input quantities for the application of Archimedes' principle is more conservative on the modelling branch than those that were made on the retrieval branch (yielding

25 the respective product uncertainties). More conservative assumptions on the retrieval branch would yield higher uncertainty in the SIT product. We also note that biases may be reduced when using the RFB product instead, as it does not rely on an external snow depth climatology but uses a consistently simulated snow depth.

7 Summary and conclusions

The ArcMBA tool was used to assess the impact of a series of EO products on the quality of four-week forecasts of SIV and SNV over three regions along the NSR in May 2015. The tool is built around the MPIOM, a coupled model of the sea ice-ocean system extended by observation operators that link the simulated variables to equivalents of SIT, SIFB, RFB, LFB, and SND products.

On the basis of the per-pixel uncertainty ranges that are provided with the CryoSat-2 SIT, SIFB, and RFB products, the SIT and RFB products achieve the best performance for the target SIV. For the SNV target, the performance of SIT is only low, the performance of SIFB higher and the performance of RFB yet higher. A hypothetical LFB product with low accuracy (20 cm uncertainty) lies in performance between SIFB and RFB for both SIV and SNV. A reduction in the uncertainty of the LFB product to 2 cm yields a significant increase in performance.

Combining either of the SIT/freeboard products with a hypothetical SND product achieves a significant performance increase. The uncertainty in the SND product matters: A higher accuracy product achieves an extra performance gain.

The provision of spatial and temporal uncertainty correlations with the EO products would be beneficial not only for assessments within systems like the ArcMBA, but also for assimilation of the products. For example, complete uncertainty correlation within each group of 10 by 10 pixels (with uniform Jacobians within each group) is equivalent to an uncertainty increase by a factor of 10.

The ArcMBA can be extended to cover further EO products and further target variables. In the setup used here the model can simulate a range of sea ice-ocean variables in addition to those considered in the present study (e.g. ice drift, mixed layer depth, freshwater, sea surface salinity, sea surface temperature, or circulation). Switching to a more comprehensive model configuration would enable the investigation of yet further variables. For example the ~~model~~ MPIOM can be operated with its biogeochemistry module HAMOCC (Ilyina et al., 2013) or in a mode coupled to an atmospheric general circulation model.

The study has investigated the performance of four-week forecasts in May 2015. It would be interesting to analyse how the relative performance of the products varies from year to year, with the length of the forecasting period, for other target regions, and with a different sea ice-ocean model.

As the QND approach can evaluate a (group of) hypothetical product(s) - characterised by their space-time coverage and uncertainty ranges - it is generally suited to assess the benefit of filling a given observational gap. It provides answers to hypothetical questions such as: *"Provided we could derive a product of a given variable with a given accuracy, at a given sampling frequency and spatial coverage. What is the added value of this additional observation for the quality of sea ice forecasts (as quantified by uncertainty reduction in a set of predicted target quantities)?"* ArcMBA assessments of a set of such products (each filling an observational gap) can help to establish a priority list.

The ArcMBA system is an ideal framework to assist the formulation of mission requirements or the development of EO products. In an end-to-end simulation it can translate product specifications in terms of spatio-temporal resolution and coverage, accuracy, and precision into a range of performance metrics. Alternatively, it can translate requirements on forecast performance into requirements on the respective observables. As demonstrated in the present study, the joint assessment of

products from (constellations of) multiple satellites is one of the particular strengths of the ArcMBA approach. This type of assessment can be performed for higher-level products (e.g. SIT or SIC) but also for rawer products (e.g. freeboard or brightness temperature).
