13 **Abstract.** Surface melting over the Antarctic Peninsula (AP) plays a crucial role for the stability of ice shelves and
14 dynamics of grounded ice, hence modulating the mass balance in a region of the world which is particularly
15 sensitive to increasing surface temperatures. Understanding the processes that drive melting using surface energy
16 and mass balance models is fundamental to improving estimates of current and future surface melting and associated
17 sea level rise through ice-shelf collapse. This is even more important in view of the specific challenges presented by
18 how circulation patterns over the topographically-complex Antarctic Peninsula, especially föhn winds, impact
19 surface melt. In this study, we evaluate the regional climate model Modèle Atmosphérique Régionale (MAR) over
20 the Antarctic Peninsula (AP) at a 10 km spatial resolution between 1999 and 2009, a period which coincides with
21 the availability of active microwave data from the QuikSCAT mission. This is the first time that this model, which
22 has been validated extensively over Greenland, has been applied to the Antarctic Peninsula at a high resolution. Our
23 primary regional focus is the northern East Antarctic Peninsula (East AP), where we define smaller sub-regions
24 according to divergent melt occurrence biases. Melting in the East AP can be initiated both by sporadic westerly
25 föhn flow over the AP and by northerly winds advecting warm air from lower latitudes. To assess MAR's ability to
26 simulate these physical processes, this study takes a unique approach, examining model biases for melt occurrence
27 on the Larsen Ice Shelf, as evaluated by satellite estimates from passive and active microwave data, with concurrent
28 temperature biases associated with wind direction biases as evaluated by three automatic weather stations (AWS).
29 Our results indicate that satellites estimates show greater melt frequency, a larger melt extent, and a quicker
30 expansion to peak melt extent than MAR in the center and east of the Larsen C ice shelf. The difference between the
31 remote sensing and modeled estimates reduces in the north and west of the East AP. Our results indicate that
32 although MAR shows an overall warm bias, it also shows fewer warm, strong westerly winds than reported by AWS
33 stations, which may lead to an underestimation of melt. The underestimation of föhn flow in the east of the Larsen C
34 may potentially be resolved by removing the hydrostatic assumption in MAR or increasing spatial resolution. The
35 underestimation of southwesterly flow in particular may be reduced by using higher-resolution topography.
36

1 Introduction

2 Increased meltwater production over the Antarctic Peninsula (AP) in the latter half of the 20th century has been
3 linked to a warming atmosphere, with potential implications for future sea-level rise (Barrand et al., 2013; Turner et
4 al., 2005; Vaughan, 2006). Surface melting has been implicated in the weakening and eventual collapse of ice
5 shelves as well as the subsequent acceleration of contributing glaciers, with the Larsen A (1995) and Larsen B
6 (2002) on the East AP as the most notable examples (Vaughan et al, 1996; Rott et al, 1998; Scambos, 2004). In July
7 2017, a rift on the Larsen C Ice Shelf, which had been expanding for several years, finally resulted in the calving of
8 the 5800 km² iceberg A68.

9 Surface melting influences ice shelf stability through the stress produced by melt ponding as well as
10 percolation through firn. One proposed mechanism for the disintegration of ice shelves hypothesizes that surface
11 meltwater infills and deepens pre-existent crevasses, through a process called hydrofracture (Scambos et al., 2000;
12 Weertman, 1973; van der Veen et al., 1997). In addition, a complementary mechanism proposes that when
13 supraglacial lakes drain (becoming dolines), an upward flexure is induced which can weaken an ice shelf, both at the
14 surface and at the base (MacAyeal and Sergienko, 2013). Large open-rift systems were observed over the Larsen B
15 ice shelf in the summer of 2002 which are consistent with substantial melt initiating both mechanisms and leading to
16 ice shelf disintegration (Glasser et al., 2008; MacAyeal and Sergienko, 2013). Alternatively, meltwater can affect ice
17 shelf dynamics by percolating into firn and increasing its density until no air remains. In the absence of pore space,
18 meltwater moves through the underlying ice sheet or collects on the surface in melt ponds. This process, operating
19 over decades, can therefore pre-condition the ice sheet for both hydrofracture and post-drainage flexure stress during
20 high-melt seasons (Kuipers Munneke et al., 2014). Meltwater can also form under blue ice surfaces, likely due to
21 smaller extinction coefficients and lowered albedo of ice (Brandt and Warren 1993) as well as under low-density
22 snow on clear days when temperatures are slightly below freezing (Koh and Jordan 1995). Modeling studies
23 suggested that the different sensitivities of blue-ice vs subsurface snow melt is a product of the radiative and heat
24 transfer interactions resulting from their differing albedo, grain size and density (Liston et al., 1999a; Liston et
25 al. 1999b). The net effects of melt over blue ice flowing downstream in subsurface layers (the ice-albedo feedback)
26 has recently been shown to be substantial in parts of East Antarctica (Lenaerts et al., 2016). Recent work has also
27 shown the lateral flow of meltwater (surface rivers) on the Larsen A Ice Shelf in 1979 (Kingslake et al., 2017) which
28 imply prolonged periods of lowered albedo. These surface rivers could be much more prevalent across Antarctica in
29 future warming scenarios than previously expected, and may provide a means of stabilizing ice shelves by routing
30 meltwater away (Bell et al., 2017).

31 Since the collapse of Larsen A and Larsen B ice shelves, ice velocities of several of their feeding glaciers
32 have increased, and seasonal variations in flow have suggested that both summer meltwater percolation (Zwally,
33 2002) and the removal of backstress played a role (Scambos, 2004; Rott et al., 2002). The remaining Larsen C ice
34 shelf to the south could prove to be similarly vulnerable to collapse due to atmospheric warming (Morris and
35 Vaughan, 2013). Radar analysis over a 15 year period has shown that Larsen C has been lowering from both firn air
36 depletion (due to either limited accumulation or high surface melt) and basal ice loss, although the latter term is
37 thought to be more substantial (Holland, 2015). While RCMs such as MAR do not account for englacial flow or

1 surface rivers, accurate models of surface meltwater production are a crucial step in assessing the potential effects
2 on the ice sheet, especially in the Larsen C ice shelf.

3 The East AP, where Larsen C Ice shelf is located, is on average 3-5°C cooler than the West AP at the same
4 latitude (Morris and Vaughan, 2013). This is primarily caused by more exposure to open water in combination with
5 prevailing westerly winds on the west AP and southerly winds on the east AP. Moreover, when strong westerly winds cross
6 the bisecting mountain range of the AP (Fig. 1), the resulting föhn winds can produce pulses of warming on the East
7 Antarctic Peninsula's ice shelves (Marshall, 2007). Föhn winds are a warm, dry air flow on the lee slopes of a
8 mountain range (Beran 1967). This resultant warming can be produced by four main mechanisms. Elvidge (2016)
9 uses a modeling approach to trace four physical processes that occur during föhn flow in the East AP, namely
10 *isentropic drawdown* (sourcing of föhn air from higher altitudes), *latent heating* and *precipitation* (where cooling
11 during uplift on the windward side promotes precipitation), *mechanical mixing* (turbulent sensible heating and
12 drying of low-level flow) and *radiative heating* (where cloudless conditions on the lee side increase the availability
13 of shortwave radiation for heating). The relative importance of each of these mechanisms for surface melt has been
14 shown to be related to the source of föhn flow in the East AP (Elvidge et al., 2015; Grosvenor et al., 2014). For
15 example, southwesterly föhn jets descending from gap flow (from lower-elevation passages in the mountain range)
16 have been shown to be cooler and moister than surrounding föhn flow descending from higher elevations (Elvidge et
17 al., 2015). Recent warming in the East AP has been linked to an increase in föhn winds during recent warming
18 (Cape et al., 2015), which were possibly related to an increase in the speed of warm northwesterly winds which have
19 been associated with positive phases of the Southern Annular Mode (SAM), (Van den Broeke and Van Lipzig,
20 2003). Because melt in the East AP is as vulnerable to wind dynamics as it is to regional temperature changes, an
21 accurate depiction of föhn flow is crucial for accurate estimates of meltwater production.

22 Models are limited by the parameterization of physics and our understanding of the physical processes
23 driving the observed changes. RCMs such as the Modèle Atmosphérique Régionale (MAR), evaluated here, can be
24 used for simulating the coupled atmosphere/surface system at a continental and decadal scale (Gallée and Schayes,
25 1994). The tradeoff, in this case, is that RCMs might not be able to capture physical processes with the required
26 accuracy and must be evaluated alongside observations. Several studies have used passive microwave estimates for
27 melt occurrence alongside *in-situ* temperature data, reporting an increase of surface melting over the AP (Torinesi
28 et al., 2003; Liu et al., 2003; Ridley, 1993; Tedesco et al., 2007; Tedesco et al 2009; Tedesco and Monaghan, 2009).
29 Melt occurrence over the AP has also been investigated using QuikSCAT satellite product at a ~2.225 km resolution
30 (Long and Hicks, 2010) in combination with model outputs from the RCM RACMO (Regional Atmospheric
31 Climate Model) and *in-situ* temperature estimates (Barrand et al., 2013). Raw backscatter values from QuikSCAT
32 have also been used to estimate melt flux over the AP (Trusel et al., 2013; Trusel et al., 2012). A recent study using
33 5.5km horizontal resolution run of RACMO 2.3 over the AP and focusing on overall surface mass balance (SMB)
34 suggested that a further increase in resolution would be required to properly resolve föhn winds, which would imply
35 the removal of the hydrostatic assumption (Van Wessem et al., 2015). We note, however, that where the hydrostatic
36 assumption is preserved (as with this model run), higher resolutions may inhibit flow in the model, resulting in
37 limited eastward föhn flow in the East AP (Hubert Gallée, personal communication). Observation-based studies on

1 the formation of melt ponds in the Cabinet Inlet portion of the Larsen C Ice Shelf have focused on the response to
2 föhn winds (Luckman et al., 2014) and the formation of subsurface ice (Hubbard et al., 2016). These last studies
3 taken together discuss both the atmospheric drivers for melt as well as the effects on the ice shelf within our region
4 of interest, but are necessarily limited to a small region where observations are available. By contrast, spaceborne
5 satellites allow us to estimate surface melt occurrence and meltwater production over the entire AP, complementing
6 *in-situ* data. The combination of satellite-based and *in situ* data provide an excellent toolset for model validation.

7 Here, we assess the MAR model at a 10 km horizontal spatial resolution over the Antarctic Peninsula, using
8 both satellite and *in-situ* data, aggregating meltwater production to drainage systems (basins) as described by Zwally
9 (2002). While previous studies have evaluated how surface melt is modelled using satellite data, or evaluated the
10 representation of the near-surface atmosphere with AWS data, we use both sources in conjunction (and co-
11 temporally) to understand MAR's ability to simulate specific physical processes, i.e. to assess melt and temperature
12 biases by wind direction. We evaluate surface melt occurrence from MAR at the sub-basin scale using satellite
13 estimates and link melt occurrence biases to temperature and wind biases at a point scale using automatic weather
14 station (AWS) data. We first compare meltwater occurrence derived from two satellite sources with MAR outputs
15 over the Antarctic Peninsula (Sect 3.1). We focus primarily on the NE basin in the East AP as it contains the former
16 Larsen A, Larsen B and current Larsen C Ice Shelf, where three AWS stations are located. In this basin, we define
17 sub-regions based on high and low melt occurrence estimated by three different passive microwave (PMW)
18 algorithms (Tedesco, 2009). We then compare climatologies of melt extent, as well as inter-annual trends, from both
19 passive and active microwave data with those computed from MAR outputs (Sect 3.2). Because melt on the Larsen
20 C Ice Shelf can potentially be initiated by northwesterly föhn flow sourced from over the AP or southwesterly flow
21 through gaps in the mountain range (even at sub-zero temperatures), we compare melt occurrence reported by
22 satellite estimates vs MAR (coinciding with the 2000-2009 QuikSCAT period) partitioned by temperature
23 differences and wind direction. Two additional stations (AWS14 and AWS15) are used to examine the persistence
24 of these wind bias trends to 2014 (Sect. 4). Discussion and conclusions follow in Sect. 5.

25 **2. Data and Methods**

26 This study takes a combined approach, using both model results and observations. The primary tool used to
27 understand the coupled atmosphere and snowpack is the Modèle Atmosphérique Régionale (MAR) RCM. We
28 employ *in-situ* data collected from 3 automatic weather stations (AWS) to evaluate the near-surface atmosphere
29 biases in MAR as well as to assess inter-annual trends. While *in-situ* observations of 2m air temperature are
30 frequently treated as a proxy for melt (Braithwaite 1981), this method is most effective when the energy budget is
31 dominated by the turbulent sensible heat flux and incoming longwave radiation and does not capture melt which can
32 occur due to shortwave radiative forcing when temperatures are below 0°C (Hock, 2005). Accordingly, we use
33 observations from the QuikSCAT (QS) and SSMR (Scanning Microwave Multichannel Radiometer, 1978-1987) /
34 SSM/I (Special Sensor Microwave/Imager, 1987 - to date) satellites to evaluate both melt occurrence and intensity
35 in MAR.

1 **2.1 The Modèle Atmosphérique Régionale (MAR) regional climate model**

2 The Modèle Atmosphérique Régionale (MAR) RCM is a modular atmospheric model coupled to the Soil Ice Snow
3 Vegetation Atmosphere Transfer scheme (SISVAT) surface model (De Ridder and Gallée, 1998), which includes
4 the multi-layer snow model Crocus (Brun et al., 1999). MAR was originally implemented to simulate energy and
5 mass balance processes over Antarctica (Gallée and Schayes, 1994). Within SISVAT, meltwater is calculated at the
6 surface when there is a surplus of energy (a deficit results in refreeze). The presence of meltwater alters the snow
7 history (for example, the type of snowgrains) and percolation through the snowpack is determined through a tipping
8 bucket method based on snow density. A diagram and description of the sequence of these specific processes in
9 MAR is provided in Supplemental Figure 1.

10 The model configuration used in this study is MAR version 3.5.2, with 23 sigma layers. The snowpack is
11 represented by 30 layers of variable thickness from the surface to a 20 m depth (below which ice is assumed
12 present). The snowpack is initialized at 300 kg/m³ at the surface and 600 kg/m³ at depth. Following 2 years of
13 spinup, MAR results are independent of the initial conditions ; this model run had a spin-up of 5 years for each final
14 model year.

15 For the purposes of this study, MAR outputs are generated at a horizontal spatial resolution of 10 km for the years
16 between 1999 and 2014. Lateral boundary conditions are specified from the European Centre for Medium-Range
17 Weather Forecasts, using the ERA-Interim reanalysis (Dee et al., 2011). We note that the mask used does not
18 include the Larsen A or Larsen B Ice Shelf in order to preserve consistency for comparison between years (most of
19 which post-date the collapse of these ice shelves).

20 We consider two conditions for identifying melting from MAR. Specifically, we assume melting in MAR either
21 when the daily-averaged integrated liquid water content (LWC) in the first meter of the snowpack exceeds 0.4%
22 (equivalent to 0.4 mmw in a 1 meter column) for at least three consecutive days or when total meltwater production
23 over the day exceeds 0.4 mm w.e. The threshold value in the first condition (denoted as $LWC_{0.4}$) of 0.4% has been
24 selected based on previous work comparing MAR outputs (version 3.2) and microwave melt estimates (Tedesco et
25 al., 2007). The second condition is denoted as $MF0.4$. This less-restrictive condition is intended to capture both
26 sporadic melt and melt which has percolated into the snowpack column below 1m.

27 **2.2 Microwave satellite estimates of melt extent, duration**

28 Spaceborne microwave satellites can detect the presence of melting over those regions where poor or no
29 observations exist at high temporal resolution, because unlike sensors in the visible range, microwave sensors are
30 weakly affected by the presence of clouds. In the case of active measurements (e.g., radar, scatterometer), the
31 presence of wet snow is associated with a sharp decline in backscatter (σ^0) (Ashcraft and Long, 2000) where in the
32 case of passive microwave data the detection is associated with an increase in brightness temperature (T_b) (Mote et
33 al., 1993; Tedesco et al., 2007). In either passive or active microwave estimates, even the presence of a relatively
34 small amount of liquid water (i.e. a few percent) triggers a substantial increase in the imaginary part of the dielectric
35 constant (Ashcraft and Long, 2006; Ulaby and Stiles, 1980).

1 **2.2.1 Active Microwave Data: QuikSCAT**

2 We employ a wet snow high-resolution product described in Steiner and Tedesco (2014) to derive melt occurrence
3 from active microwave data. Both melt occurrence and raw backscatter values used in this analysis use normalized
4 backscattering values as measured by the Seawinds sensor onboard the QuikSCAT satellite at Ku band (13.4 GHz),
5 with the enhanced resolution provided by the application of the Scatterometer Image Reconstruction (SIR)
6 algorithm. (Long and Hicks, 2010). Both Ku- and C-band scatterometers have been used extensively to detect melt
7 onset and freeze-up in Antarctica and Greenland (Drinkwater and Liu, 2000).

8 Threshold-based approaches with active microwave data, as used in this study, identify the point of melt
9 onset based on the departure in σ^0 from values in dry-snow with various thresholds (Ashcraft and Long, 2000;
10 Ashcraft and Long, 2006; Trusel et al., 2012). The approach used here derives melt occurrence from a threshold-
11 based method (ft3), which identifies melt when backscatter falls 3 dB below the preceding winter mean (Steiner and
12 Tedesco, 2014; Ashcraft and Long, 2006). This method, along with a wavelet approach have been evaluated over the
13 AP with AWS data at 5 locations estimating melt occurrence from AWS as when 2m air temperature exceeded 0°C
14 for more than 6 hours (Steiner and Tedesco, 2014).

15 In addition to the binary detection of melt, several methods have been proposed which relate seasonally-
16 integrated backscatter reduction to measures for melt intensity (Wismann, 2000; Smith, 2003; Trusel et al., 2013). As
17 these methods provide seasonally-cummulative values, we do not employ them in this study, although we do
18 examine raw backscatter values as a proxy for melt flux.

19 **2.2.2 Passive Microwave Data**

20 We complement the assessment of MAR with estimates of melt extent and duration obtained from passive
21 microwave observations which have been used in the past to assess melt occurrence in Antarctica and Greenland
22 using brightness temperature from at 19.35 GHz with a horizontal polarization (Tedesco, 2007). One of the major
23 disadvantages of passive microwave is the relatively coarse horizontal spatial resolution (25 km) with respect to the
24 fine-scale topography characterizing the AP. However, the historical record for passive microwave data extends as
25 far back as 1972. Threshold-based methods for melt detection from passive microwave data range from a
26 combination of multiple frequencies and polarizations (Abdalati and Steffen, 1995) to using a single frequency,
27 single polarization (e.g., Mote et al. 1993, Tedesco 2009), as is used in this study. Three algorithms are used here
28 which are described in detail in (Tedesco, 2009). These include the 240-algorithm where the threshold was
29 determined as the value above which an increase in liquid water content above 1% no longer produces an increase in
30 T_b , based on output of an electromagnetic model. The original threshold of 245K was found to be insufficiently
31 sensitive and reduced to 240K for this study (Tedesco, 2007) (M. Tedesco, personal communication). The second
32 algorithm uses the winter mean threshold-based method ALA:

$$33 T_c = T_{winter} * \alpha + T_{wet_{snow}} * (1 - \alpha)$$

34 (1)

1 where T_{winter} is mean winter (JJA) brightness temperature (T_b), $T_{\text{wet_snow}}$ is wet snow brightness temperature (equal
2 to 273K) and α is the mixing coefficient (equal to 0.47). Ashcraft and Long (2006) here presume a wet layer of 4.7
3 cm and a Liquid Water Content of 1%. Finally, the third algorithm (zwa) is based on the winter mean threshold.

$$4 \quad T_c = T_{\text{winter}} + \Delta T$$

5 (2)

6 where ΔT is a threshold value, in this case 30K (Zwally and Fiegles, 1994).

7 **2.3 AWS measurements**

8 We assess MAR simulation of the near-surface atmosphere using temperature and wind speed data collected by
9 three automatic weather stations (AWS) on the AP (Fig 1). Data from the Larsen Ice Shelf station is obtained from
10 the University of Wisconsin Madison (AMRC, SSEC, UW-Madison) at a 3-hourly temporal resolution. AWS data
11 from two additional sites on the Larsen Ice Shelf (AWS14 and AWS15) are obtained from the Institute for Marine
12 and Atmospheric Research at Utrecht University (IMAU) at an hourly resolution. These also include values for the
13 surface energy budget (Kuipers Munneke et al., 2012). We note that the Larsen IS station (-67.00 °S, -61.60°W)
14 and the AWS14 station (-67.00°S, -61.5°W) are co-located to the same MAR grid cell.

15 AWS values are temporally averaged to obtain mean daily values for the comparison with the MAR
16 outputs. Metrics are computed for December-January-February (DJF, summer). We did not compute a seasonal
17 average when more than 5 consecutive days of data were missing. The five-day period was chosen as an upper limit
18 for the length of a synoptic event, corresponding spatially to approximately 145 MAR grid cells (or half the model
19 domain) of continuous flow in a single direction for an average windspeed of 3.4 m/s, i.e. the expected value for
20 Larsen IS AWS station in DJF from 1999-2014 (Fig. 5c). Near-surface (2m) air temperature values are corrected for
21 a difference between AWS station elevation and the elevation averaged by the corresponding MAR gridcell by
22 calculating the elevation gradient from surrounding MAR gridcells and interpolating the final value for the AWS
23 location's recorded elevation using the bedmap2 DEM (Fretwell et al., 2013). Differences in elevation values
24 between MAR at the 10km resolution and those recorded at AWS stations were as large as 23 m. Maximum daily
25 2m air temperature (MaxT2m) is calculated as well because this measure may better indicate sporadic melt than
26 values averaged to the daily scale. MaxT2m temperatures are extracted from available 3-hourly values and are used
27 only when no more than one 3-hour measurement is missing during the day. Pressure values from AWS stations are
28 also estimated at a approximately 2m above the surface, and compared to MAR values at the first atmospheric layer
29 in MAR. Because the height of this layer is generally between 2 and 3 m above the surface, this is treated as an
30 acceptable proxy for 2m pressure values. Pressure values from MAR are corrected for elevation using the
31 hypsometric equation (Wallace and Hobbs, 1977).

32 **2.4 Statistical Methods**

33 To evaluate and quantify the agreement between MAR outputs and AWS data for temperature and wind speed we
34 use a mean bias. Additional statistical measures used in supplemental data include the coefficient of determination
35 (R^2), root mean squared error (RMSE) and mean error (ME) (Wilks, 1995). Also included in supplemental data, we

1 assess the extent to which each station is representative of larger scale climate variability by constructing correlation
2 (R^2) maps between MAR values co-located with AWS stations vs all other gridpoints in the full MAR domain. We
3 ignore all R^2 statistics where the p-value (indicating the probability that the underlying R value would exceed the
4 result reported) exceeds 0.05.

5 To capture wind speed frequency distributions, we fit available data for each season for MAR (for the full
6 2000-2009 period), AWS (when AWS data is available) and MAR-R (MAR values collected only when AWS data
7 is available) with a Weibull distribution. The shape (β) parameter roughly captures the degree of skew, with higher
8 values being closer to an even normal distribution. The scale (λ) parameter approximates the peak frequency (we
9 note that this is not equivalent to the mean). We report expected values for each windspeed distribution using the
10 best Weibull fit.

11 3. Results: Melt Occurrence and Meltwater Production

12 In this section, we compare melt occurrence estimated by MAR with estimates from three passive microwave
13 algorithms as well as QuikSCAT ft3 over the Antarctic Peninsula. We first identify spatial biases for melt
14 occurrence at the domain scale, finding substantial differences in the center of the Larsen C Ice Shelf (the “CL”
15 region, where PMW melt occurrence is highest) as well as to the north and west of the NE basin, a region which
16 includes the former Larsens A and B ice shelves as well as the northernmost portions of the Larsen C ice shelf (the
17 “NL” region, where MAR and QuikSCAT ft3 melt occurrence is highest) (Sect. 3.1). These differences could result
18 from either weaknesses in the MAR representation of wind dynamics (discussed in Sect. 4) or from limitations of
19 the satellite sensor or algorithm. Additionally, we compare climatology and inter-annual variability of melt extent
20 (calculated by multiple algorithms) over the CL and NL region (Sect. 3.2).

21 3.1 Melt occurrence over the AP

22 Fig. 2 shows average annual melt occurrence (in days) over the model domain, estimated from the satellite-based
23 algorithms QuikSCAT ft3 (Sect. 2.2.1) and three passive microwave algorithms (Sect. 2.2.2) as well as two metrics
24 for melt derived from MAR outputs (Sect. 2.1). Because the MAR $MF_{0.4}$ melt metric shows more sensitivity to melt
25 occurrence than the $LWC_{0.4}$ metric, it is used for comparison to QuikSCAT ft3 and PMW zwa (the most sensitive
26 satellite-based algorithms). We use the term “PMWAll” to define the condition when all PMW algorithms report
27 melt occurrence. Our primary focus is on the NE basin in the AP (shown in Fig. 1)

28 QuikSCAT ft3 generally estimates higher average yearly melt occurrence than either of the MAR melt
29 metrics over the full domain. In the NE basin, the difference is on the order of 25 more days than the MAR $MF_{0.4}$
30 melt metric (Fig. 2f). Differences between QuikSCAT ft3 and $MF_{0.4}$ also show a strong latitudinal dependence in
31 the NE basin, shifting from near agreement in the northern regions of the Larsen C Ice Shelf to QuikSCAT ft3
32 reporting over 500% of the melt days reported by MAR towards the southern edge. Melt onset is on the order of 22
33 days earlier in QuikSCAT ft3 than in $MF_{0.4}$ in the NE basin, except at the northern edge of the Larsen C ice shelf,
34 where $MF_{0.4}$ reports average yearly melt onset as much as 25 days earlier than QuikSCAT ft3 (Supplemental Fig. 2).

1 A comparison between the two MAR melt metrics shows that $MF_{0.4}$ reports as much as 40 more days of melt than
2 $LWC_{0.4}$ at the northern tip of the Larsen C Ice Shelf (Fig 2b vs Fig 2a). The portion of the Larsen C ice shelf which
3 experiences an average of 25 days of melt or more extends as far south as 80.0°S on the eastern side of the Larsen C
4 ice shelf according to the $MF_{0.4}$ metric but extends only to 70.50°S according to $LWC_{0.4}$. Towards the very south of
5 the Larsen C Ice Shelf, the two MAR metrics show similar values, although $LWC_{0.4}$ reports melt onset as late as
6 early January (Supplemental Fig. 2a) while $MF_{0.4}$ reports melt onset in December (Supplemental Fig 2b). The
7 formulation for the $MF_{0.4}$ metric (considering melt at any time of the day for the full depth of the snowpack)
8 suggests that the early season melt observed only by $MF_{0.4}$ is either sporadic (i.e. can refreeze, even immediately)
9 and/or percolates below 1m in the snowpack in the south of the Larsen C Ice Shelf, i.e. below the depth range at
10 which $LWC_{0.4}$ is calculated. Whereas QuikSCAT ft3 and MAR melt metrics report maximum melt occurrence in the
11 north and west of the Larsen C Ice Shelf ($MF_{0.4}$ reporting > 60 days, Fig. 2b), PMW algorithms report maximum
12 melt occurrence in the center-east of the Larsen C Ice Shelf, specifically 43 days (240, Fig. 2c), 57 days (ALA, Fig.
13 2d) and 69 days (zwa, Fig. 2e).

14 In summary, a comparison between observed and modeled data sources show two distinct spatial patterns
15 for maximum melt occurrence. QuikSCAT ft3 as well as both MAR melt metrics show the highest range of melt
16 days in the northern and western edges of the Larsen C Ice Shelf (including both high and low elevation regions)
17 while PMW algorithms show the highest number of melt days in the center of the Larsen C Ice Shelf, where
18 elevations are lower and topography is less complex. We hypothesize that the major difference in spatial patterns
19 between algorithms/melt metrics are primarily related to the different resolutions of the data sources and secondarily
20 to the depths presumed for the calculation of meltwater content. This is true for both the MAR metrics and for the
21 three PMW algorithms; the “ALA” algorithm, for example, presumes a 4.7cm depth and a 1% liquid water content.
22 (see Sect. 2). To confirm this, we find the maximum depth to which meltwater percolates (according to MAR)
23 associated with the number of days when melt occurs (according to PMW algorithms). Histograms for total PMW
24 melt days in Supplemental Fig. 3 show three peaks (two major inflection points) for each algorithm which are used
25 to create three classes for meltwater occurrence (“low”, “medium” and “high”). For these classes, the maximum
26 depth to which meltwater percolates (in MAR) is shown in Supplemental Fig. 5 and the associated elevation and
27 MAR meltwater production is shown in Supplemental Table 1.

28 Spatial regions defined as having “low” melt occurrence are highly heterogeneous. Bedmap2 (Fretwell et
29 al., 2013) reports a large range of elevations while MAR reports low coincident meltwater production and a
30 relatively shallow meltwater depth. Both the ALA and zwa algorithms report melt at higher elevations (above
31 approximately 1300m and 1900m, respectively) than the 240 algorithm, which neither reports any melt occurrence
32 above 1100m in the NE basin nor at lower elevations to the north and south. (Supplemental Material Table 1, rows
33 1,4,7 and Fig. 5). Where melt occurrence is low, the 240 and ALA algorithms generally detect melt only where
34 MAR reports a maximum meltwater percolation depth below 0.4 m, (Supplemental Fig 5a,b), whereas the zwa
35 algorithm can detect melt at a substantially shallower depth of 0.1 m (Supplemental Fig 5c). Although generally
36 meltwater in MAR rarely percolates below 3m, in low melt-occurrence regions, modeled meltwater occasionally
37 percolates below 10m in the beginning of the melt season (Supplemental Fig. 5 a,b,c, N column). We remind the

1 reader that melt occurrence within the firm layer (as calculated by MAR $MF_{0.4}$) will capture melt that can refreeze
2 immediately, so this does not necessarily correspond to melt which is retained in the snowpack. Rather, the
3 snowpack layer depth represents the deepest layer which is affected by the melt process according to MAR.

4 By contrast, in high PMW melt occurrence regions in the NE basin, MAR consistently reports high coincident
5 meltwater production, low elevations and the deepest average meltwater percolation in the region. In the month of
6 January, we find that where PMW algorithms report melt, coincident MAR meltwater percolates to 2 meters into the
7 snowpack for 35-47% of the total day-pixels in the NE basin which report any melt, and as deep as 3 meters for
8 more than 30% of total day-pixels (Supplemental Table 1, 240-H, ALA-H, zwa-H, Fig 5 g,h,i).

9 To quantify the two major spatial trends for maximum melt occurrence, i.e. (a) PMW in the center-east of
10 the Larsen C ice shelf and (b) QuikSCAT ft3 and MAR in the northwest of the NE basin, we (a) explicitly calculate
11 concurrent melt occurrence in all PMW algorithms (PMWAll) for the first region and (b) define the latter
12 geographically in order to include most of the Northern NE basin, but deliberately exclude center-east of the Larsen
13 C ice shelf region where PMW melt is highest. The first region “CL” (Center Larsen), where all PMW algorithms
14 agree on high melt occurrence, is defined where PMWAll reports average yearly total melt days exceeding one
15 standard deviation from the mean for the NE basin. Mean elevation for the CL region is $42.70 \pm 17.70\sigma$ m (where σ
16 is one standard deviation) . PMWAll reports a mean annual 36 days of melt occurrence (vs 21 days derived from
17 $MF_{0.4}$) and a mean PMWAll-coincident annual MAR meltwater production of 96 mmwe/100km² (vs 143
18 mmwe/100km² when $MF_{0.4}$ reports melt)(Supplemental Table 1, row 11,12).

19 The “NL” (Northern Larsen) mask is defined by finding the mean latitude of the CL region and including
20 all portions of the NE basin above this latitude, but excluding the CL region (Fig. 4c, inset). In the NL region,
21 elevation is highly-variable, with a mean value ~600m and MAR and QS detect melt both earlier and more often
22 than for PMW algorithms. Both masks are shown in the inset in Fig. 3a and Fig. 4c and are used for subsequent
23 analysis of inter-annual meltwater production in MAR.

24 3.2 Climatology and inter-annual trends for melt extent at the sub-basin scale

25 We compare the seasonal cycle and interannual variability of melt as modeled by MAR vs observations for both the
26 CL and NL regions by computing regional melt extent over the period (total melt extent area for each day in NDJF),
27 both yearly and as a climatological average. The PMWAll algorithm is typically treated as the most restrictive
28 condition while the PMW zwa and QuikSCAT ft3 are the most sensitive. Melt extent is defined as the total area
29 reporting melt daily between Nov 1st and February 28th (austral summer, including November to show early
30 melt)(Fig. 3).

31 The melt extent climatology for PMWAll in the CL region shows an early pulse of melt around Dec 15th
32 with melt extent peaking in January, followed by a series of increasingly smaller melt pulses ending with refreeze at
33 the end of February. While MAR shows peak melt extent at the same point in the season, the progression from melt
34 onset is more gradual, average peak melt extent is generally smaller and interannual variability (indicated by the
35 grey envelope) during peak melt extent is larger (Fig. 3c vs Fig. 3a). In the CL region, the PMWAll metric is
36 generally restricted by the low sensitivity of the 240 algorithm. Interannual variability for melt extent is substantial,

1 with PMWAll reporting a larger melt extent than MAR towards the middle of the melt season in most years (Fig.
2 3b,d), but not necessarily during melt onset or its ending. In the CL region, PMWAll reports a larger melt extent
3 throughout the melt season during 2000-2001 and 2001-2002 (Fig. 3d). During three periods, MAR reports a larger
4 melt extent than PMWAll, including 1999-2000, the latter half of the 2002-2003 season and the 2003-2004 season.
5 While the highly-sensitive PMW zwa algorithm (Fig. 3e,f) reports sporadic periods where MAR melt extent is larger
6 (during the 1999-2000 and 2003-2004 melt seasons, for example), zwa generally reports either a larger melt extent
7 or general agreement with MAR. Similarly, melt extent derived from the QuikSCAT ft3 algorithm consistently
8 shows a larger melt extent than MAR, except for a few short periods towards the end of the season in 1999-2000 and
9 2003-2004 (Fig. 3 g,h). We note that for several years, both QuikSCAT ft3 and PMW zwa report substantial melt
10 occurrence early in the season (~Nov 15th) and that the QuikSCAT ft3 climatology frequently reports melt
11 occurrence in the CL region well after February (Fig 3g).

12 Note that the NL region includes areas which reported low melt occurrence in all PMW algorithms,
13 variable meltwater percolation depth in MAR, and a large range of elevations (Sect 3.1), implying that the mask
14 defined by the combined PMWAll algorithm is less clearly linked to specific modeled physical properties in this
15 region. Here, the MAR melt extent climatology (Fig. 4a,b) is consistently larger than PMWAll throughout the
16 season (Fig. 4c,d). In comparison to the zwa (Fig. 4c) and QuikSCAT ft3 (Fig. 4g) algorithms, MAR reports less
17 melt extent in the middle of the season (with peak melt extent in January), but larger melt extent at the beginning
18 and end of the melt season. As compared with the CL region, the MAR climatological melt extent shows less inter-
19 annual variability (grey envelope, Fig. 4a). During the 2000-2001 and 2001-2002 melt seasons, MAR shows a larger
20 melt extent than PMWAll (Fig. 4d), but less than the PMW zwa (Fig 4f) or QuikSCAT ft3 (Fig. 4h) algorithms. We
21 find that during the 2005-2006 season, MAR shows greater melt extent than PMWAll, consistently less than
22 QuikSCAT ft3, but reports a greater melt extent than zwa only towards the end of the season. We consider the
23 condition where only QuikSCAT ft3 or PMW zwa show a greater melt extent than MAR to likely be indicative of
24 sporadic surface melt.

25 In summary, we conclude that in the CL region, MAR reports a larger melt extent during that period than
26 PMWAll (which is highly-restrictive), but a smaller melt extent than either the PMW zwa or QuikSCAT ft3
27 algorithms, which are more sensitive. Notably, MAR melt occurrence is comparatively low during the peak melt
28 period. By contrast, in the NL region, MAR reports greater melt occurrence than the most restrictive measure
29 (PMWAll) during peak melt, but far less than the highly-sensitive QuikSCAT ft3 algorithm. The interannual
30 comparison suggests that MAR shows substantially less melt occurrence than observations during the 2000-2001
31 and 2001-2002 seasons in the CL region, but not the NL region.

32 4. Results: Wind and Temperature Biases at the Larsen Ice Shelf station

33 The East AP is substantially colder than the West AP, and temperature-driven melt primarily results from either
34 warm northerly flow from lower latitudes or from westerly föhn flow over the spine of the AP. Here, we assess the
35 bias in temperature and melt occurrence associated with wind direction at three AWS stations located on the Larsen
36 C Ice Shelf (shown in Fig. 1). We first discuss wind direction and wind speed biases during the summer season at all

1 three locations (without regard to melt occurrence) (Sect. 4.1). We then find temperature/wind direction biases
2 specifically associated with melt occurrence in MAR, PMWAll and QuikSCAT ft3, in order to capture which wind
3 direction/temperature biases lead to a disproportionate amount of observed melt which is not captured by MAR
4 (Sect. 4.2). All MAR and satellite data used are co-located to the grid cell associated with the AWS station (Fig. 1),
5 and we remind the reader that all three stations, at the eastern edge of the CL region (Fig. 2 inset), are located where
6 MAR reported substantially less melt occurrence than PMW algorithms or QuikSCAT ft3.

7 **4.1 Aggregate wind direction biases**

8 Fig. 5 shows wind frequency distributions during the summer season (AWS, MAR-R, MAR from left to right
9 columns, Larsen IS station, AWS 14 and AWS 15 from top to bottom), color-coded for wind direction as
10 represented by the pie graph at the top. We note that AWS data uses 3-hourly data for wind speed and direction
11 without daily-averaging, while MAR produced daily-averaged outputs. For this reason, a direct comparison between
12 Weibull parameters derived from MAR vs AWS data is not meaningful, although we show comparisons between
13 different stations (for the same data source). The Larsen IS station has full temporal coverage during the QuikSCAT
14 period while AWS14 and AWS15 were installed after termination of the QuikSCAT mission. These last two stations
15 are used in this study to demonstrate the consistency of wind biases at multiple locations, as well as how wind biases
16 vary by latitude (AWS15 being located slightly to the south). Whereas MAR is dominated northerly winds at its
17 lower range of windspeeds (in yellow and blue), AWS data shows a greater frequency of southwesterly winds at the
18 higher range of windspeeds (> 8 m/s). In general, even at lower wind speeds (2-5 m/s), AWS data shows more
19 southwesterly winds than either MAR-R or MAR. This is especially relevant at the southern AWS15 station, where
20 modeled temperature correlates with a larger region of the Larsen IS than temperatures modeled by MAR for the
21 AWS14 station (Supplemental Fig. 6). Observed wind direction (without consideration for wind speed) at AWS15
22 shows more southwesterly flow (Fig. 5g) than either MAR-R or MAR (Fig. 5 h,i), which show a substantially higher
23 percentage of southeasterly and northerly flow instead.

24 Specifically, while both MAR and AWS show a higher proportion of northerly (vs southerly) winds, the
25 proportion of northerly winds in MAR is slightly higher (Table 1). While both MAR and AWS report a larger
26 proportion of easterly (vs westerly) flow, MAR reports 64% of flow to be easterly where AWS reports only 55%
27 easterly flow. We show that MAR melt occurrence at the Larsen Ice Shelf station is concurrent with both increased
28 northerly and westerly flows. On days when MAR reports melt (compared to days with no melt), northerly winds
29 are more frequent (according to both MAR and AWS estimates), and the proportion of westerly winds increases
30 slightly in MAR but decreases slightly in AWS data (Table 1).

31 When daily-averaged temperature (AvgT2m) values are high, it is more likely that melt is sustained, while high
32 maximum daily temperatures (MaxT2m) can also occur during sporadic melt. Melt occurrence is strongly influenced
33 by the temperature of the snow column as well as at the surface; internal melting can occur even when the surface is
34 frozen due to net outgoing longwave radiation (Holmgren 1971)(Hock 2005) In general, we find a small, but
35 consistent warm MAR bias for AvgT2m, and a consistent cold MaxT2m bias. However, when we restrict the dataset
36 to days when AWS 2m-temperature estimates exceed 0°C , (a condition where melt is most likely), MAR indicates a

1 cold bias for AvgT2m and an enhanced cold bias for MaxT2m, i.e. while MAR shows an overall warm bias, this
2 bias is reversed at the temperature ranges where melt is likely (although melt is still possible due to other elements
3 in the energy balance). On days when MAR meltwater production meets the $MF_{0.4}$ criteria, we find that the
4 magnitude of all biases is greatly reduced. In particular, we note that the MaxT2m bias for westerly winds (for the
5 ALL condition) is substantial, showing a -2.42°C cool bias in MAR for all available data and -3.04°C when data
6 is restricted to days when $\text{MaxT2m} > 0^{\circ}\text{C}$.

7 **4.2 Wind and temperature biases concurrent with observed melt occurrence**

8 Three wind direction biases are dominant on days when observed sources (either PMW All or QuikSCAT ft3) report
9 melt, but MAR does not. We refer to the condition where PMWAll reports melt (but MAR does not) as “PMWEx”
10 (i.e. PMW exclusive-or), with the equivalent condition for QuikSCAT ft3 called “QSEx”. We focus on these
11 specific wind biases and find the associated temperature biases. Supplemental tables 2-7 include R^2 , RMSE and
12 mean bias values for both surface pressure and daily AvgT2m at all three stations.

13 **4.2.1 Observed northeasterly flow**

14 The largest proportion of melt occurrence for either MAR, PMWEx or QSEx is reported when northeasterly winds
15 are dominant, specifically when winds are recorded by the Larsen Ice Shelf AWS station as northeasterly (0° - 90°).
16 Northeasterly AWS flow accounts for a large proportion of general flow and an even larger proportion of flow when
17 either MAR or PMWEx report melt, i.e. 36% of general flow, 39% of days where MAR reports melt, 42% of days
18 where PMWEx reports melt and 36% of days where QSEx reports melt. On days when AWS reports northeasterly
19 winds, MAR primarily reports northeasterly flow (0° - 90° , case 1), but also reports a substantial bias for
20 northwesterly flow (270° - 360° , case 2). In case 2, associated temperature biases may be influenced by the inclusion
21 of warmer westerly winds in MAR. We add that the majority of northeasterly AWS flow is actually captured in a
22 narrower northeasterly band in MAR from 0 - 45° , accounting for 13.4% of ALL days. We examine these two cases
23 separately to quantify how a modeled westerly wind bias affects temperature and melt (in comparison to the case
24 when wind direction matches observed estimates). Supplemental tables 8-10 contain relative proportions of each
25 case (flow bias) divided by the general melt restriction (i.e. MAR, QSEx or PMWEx), as well as the timeseries mean
26 and biases for AvgT2m, $\text{AvgT2m} > 0^{\circ}\text{C}$ (excluding days when AvgT2m values from AWS are below 0°C), MaxT2m
27 and $\text{MaxT2m} > 0^{\circ}\text{C}$.

28 In the instance where northeasterly flow is modeled accurately (case 1, Fig. 6a), modeled temperature
29 values are clustered around 0°C , whereas AWS-observed temperatures (especially when only satellite-observed melt
30 occurs) are higher. When MAR reports melt, MAR AvgT2m values cluster near 0°C , with a small overall warm bias
31 (0.69°C). Under omission conditions (PMWEx and QSEx), AvgT2m values are lower, and MAR bias is slightly
32 cold, although standard deviation is high. As with all flow cases, only QuikSCAT ft3 shows melt at very low
33 observed AvgT2m values. By contrast, AWS MaxT2m values are substantially higher than MAR values (the latter
34 clustering around 0°C) (Fig. 6b). We find that where QuikSCAT ft3 uniquely reports melt (QSEx), AvgT2m values
35 at the lower range of temperatures report a stronger cool MAR bias for MaxT2m.

1 In case 2, AvgT2m values show a small warm MAR bias in all melt conditions, i.e. for ALL data points
2 (0.79°C), for when MAR shows melt (0.82°C), and finally for both the PMWEx (0.44°C) and QSEx(0.65°C)
3 conditions (Supplemental Table 8). However, when MAR reports melt and AWS AvgT2m values exceed 0°C, there
4 is a substantial cold bias (-1.13°C)(Fig 6c), which may lead to reduced meltwater production. In contrast to case 1,
5 modeled MaxT2m values in case 2 do not cluster around 0°C (Fig. 6b,d) and MAR melt days report larger MaxT2m
6 values.

7 In summary, when MAR reports westerly flow, Avg T_s values are higher (as is melt occurrence). As with the
8 comparison with case 1 and case 2, we find that in all instances when MAR reports northeasterly flow (with all
9 AWS-observed wind directions considered), AvgT2m and MaxT2m temperatures cluster near 0°C (Fig. 6e,f),
10 whereas when MAR reports northwesterly flow (with all AWS wind directions taken into consideration), MaxT2m
11 values are, on average, higher, and the temperature bias is narrowed (Fig. 6 g,h). Expected values for windspeeds for
12 each condition based on a Weibull fit show comparable expected values, but larger standard deviations for AWS-
13 estimated windspeeds when MAR reports northwesterly flow (Fig. 6 c,d g,h).

14 **4.2.2 Observed southwesterly flow**

15 For all days in the summer season (“ALL”, i.e. without regard for melt occurrence), we find that MAR reports 15%
16 of winds to be southwesterly at the Larsen Ice Shelf station location while AWS reports ~ 30% southwesterly flow.
17 We note that the relative proportions of southwesterly/southeasterly flow in AWS is approximately reversed in
18 MAR, with AWS reporting 18.3% of flow to be southwesterly and MAR reporting 29.2% southwesterly flow. We
19 focus specifically on the condition where both MAR and AWS report southwesterly flow (between 180° and 270°),
20 which accounts for 5.7% of total flow and only 4.9% of MAR melt days, but a larger proportion of days where only
21 observed sources report melt, i.e. 5.6% for the PMWEx condition and 8% for the QSEx condition.

22 As with case 2 for northwesterly winds in section 4.2.1, MAR captures higher AvgT2m values which
23 frequently exceed 0°C, with a slight cool MAR bias when AvgT2m > 0°C (Fig 7a). The PMWEx and QSEx
24 conditions report melt at lower temperature values, where the MAR bias is slightly warmer. Although a cold MAR
25 bias persists, MaxT2m values are, in general, higher with AWS and MAR values showing greater agreement (Fig
26 7b). Expected windspeeds for southwesterly winds are substantially higher (with a greater standard deviation) than
27 the base condition when wind direction is not considered, with AWS reporting an even higher standard deviation
28 (i.e. high-speed sporadic winds).

29 **5. Discussion and Conclusions**

30 In the aggregate, we conclude that MAR shows lower melt occurrence than satellite estimates in the center and east
31 of the Larsen C ice shelf (i.e. the CL region, where eastward föhn flow is likely limited in MAR), while in the north
32 and west of the NE basin (i.e. the NL region which is most immediately affected by föhn flow), MAR reports melt
33 occurrence largely concurrent with satellite estimates. For example, within the CL region, there are periods during
34 the 2001-2002 season when MAR reports no meltwater production, but raw QuikSCAT backscatter values report
35 periods where over 300 km² of surface area show backscatter values dipping below -15 dB (Supplemental Fig.

1 8e). We remind the reader that raw backscatter values from QuikSCAT have previously been used to estimate melt
2 flux over the AP (Trusel et al., 2013; Trusel et al., 2012).

3 In comparison to AWS estimates, MAR displays a general warm bias in the East AP at lower temperatures
4 where melt is less likely to occur, but which may still impact the refreeze process. However, when maximum daily
5 temperatures (MaxT2m) and average daily temperatures (AvgT2m) exceed 0°C, MAR shows a substantial cold bias
6 which may limit melting. We note a smaller proportion of westerly winds in MAR compared to observed values at
7 the Larsen Ice Shelf AWS station, especially an absence of southwesterly flow, which tends to have higher observed
8 windspeeds. The general cold bias in MAR is partially closed when observed northeasterly winds are reported by
9 MAR as northwesterly, i.e. MAR reports both higher AvgT2m and MaxT2m values as well as greater melt
10 occurrence. Similar biases are shown for southwesterly flow, which accounts for a disproportionate amount of
11 satellite-observed melt which is not captured by MAR. The importance of westerly winds is demonstrated during
12 mid-December in the 2001-2002 season, at which point satellite-based melt extent in the CL region increases
13 substantially, while MAR melt extent declines (Supplemental Fig. 8a). This period is concurrent with an increase in
14 westerly winds at the Larsen IS AWS station which are not modeled MAR (Supplemental Fig 9b vs f). Additionally,
15 we note that shortly after this point, AWS AvgT2m temperatures consistently exceed MAR AvgT2m values until the
16 end of the season (Supplementary Fig. 10).

17 Previous work has suggested that southwesterly föhn winds can result from gap flow (Elvidge et al. 2015),
18 although we note that the southwesterly jets studied in this single campaign were typically cooler and moister than
19 surrounding air (i.e. föhn flow produced from isentropic drawdown). We note that the low windspeed bias in MAR
20 may have a minor impact overall, but could strongly impact melt in the East AP if southwesterly flow is more
21 accurately captured in future versions of MAR. We hypothesize that the underestimation of westerly flow at the
22 eastern reaches of the Larsen C ice shelf is likely due to the hydrostatic assumption (allowing for no vertical
23 acceleration of air mass) preventing eastward, downward flow in the near-surface atmosphere. The implementation
24 of a non-hydrostatic model will likely be required to fully capture föhn flow in the East AP (Hubert Gallée, personal
25 communication). We conclude that the relative absence of fast, warm westerly and southwesterly winds contributes
26 to a lack of MAR melt in the CL region as compared to satellite estimates.

27 Previous literature has pointed to several limitations in the remote sensing data sources used here which are
28 either intrinsic to the satellite data itself or a product of the algorithm selected for melt detection. Products derived
29 from QuikSCAT are limited in temporal resolution because the satellite passes at a twice-daily scale, and may
30 therefore ignore sporadic melt occurring at other times of day. However, previous studies have compared total melt
31 days from the QuikSCAT ft3 algorithm with a measure derived from surface temperature at seven automatic
32 weather stations and shown a positive QuikSCAT ft3 bias compared to AWS (Steiner and Tedesco, 2014).
33 Similarly, all PMW algorithms are limited by a relatively low resolution (25km) and twice-daily passes. Periods of
34 melt occurrence have also been shown to be highly sensitive to the choice of algorithm (Tedesco 2009). Because of
35 the high topographic variability of the NL region (especially near the spine of the AP), it is possible that PMW
36 algorithms are under-reporting melt occurrence due to low horizontal spatial resolution. A higher-resolution passive
37 microwave product may better resolve this issue.

1 In the northernmost portions of the NL region, sporadic MAR-modeled meltwater percolates deeply into the
2 snowpack in November (as deep as 10m early in the season in some years), which is consistent with MAR $MF_{0.4}$,
3 PMW zwa and QuikSCAT ft3 reporting melt occurrence at this point while other algorithms/melt metrics do not.
4 The deep percolation of meltwater is potentially enabled by low density snow early in the season. This early-season
5 melt is frequently followed by a near-complete refreeze. Future work will focus on the interannual variability of
6 early-season melt as this may have a substantial impact on the density of the firm layer in the Larsen C ice shelf.

7 In light of the biases reviewed here, we report MAR meltwater production over the 1999-2009 period (Fig.
8 8) and consider the potential implications of the wind/temperature biases found in this analysis on regional
9 meltwater production. Over the full study domain, the total annual meltwater production estimated by MAR shows
10 substantial inter-annual variation with the NE basin accounting for the highest aggregate meltwater production,
11 closely followed by the SW basin (in green). The NE basin is divided into three regions: the NL and CL masks and
12 the remainder of the basin. We note that the SW basin does not covary with the NE basin (with all subregions taken
13 together) and the subregions of the NE basin do not consistently covary with one another. The meltwater production
14 shown here does not account for refreeze and we note that the effects of refrozen melt on the snowpack will vary
15 regionally depending on local properties. The NL region dominates meltwater production in the NE basin in most
16 years except for 1999-2000, 2002-2003 and 2003-2004. The 2001-2002 melt season shows the second lowest overall
17 melt production during the study period (only the preceding year is lower). Declining aggregate meltwater
18 production across the AP does not necessarily correspond to declining meltwater production in the most vulnerable
19 regions of the northeastern AP (including the Larsen C ice shelf). Because melt in the NL region is particularly
20 sensitive to föhn-induced melt, we note that changes in circulation patterns may affect the northwest regions
21 differently than the southern regions. The strong relationship between wind direction and temperature bias points to
22 the need for isolating dominant inter-annual patterns of melt in the Northern Larsen C Ice Shelf and associating
23 them with large-scale atmospheric drivers.

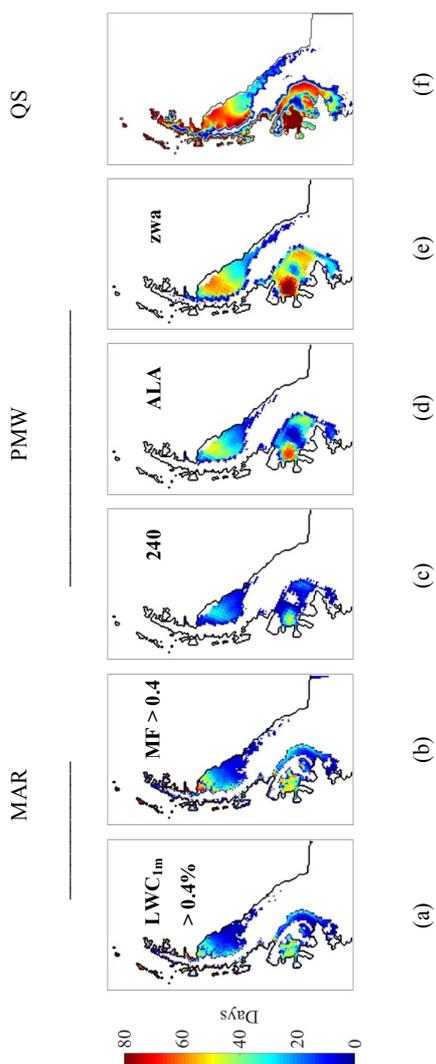

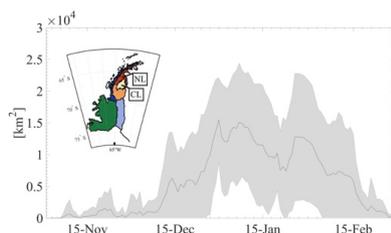

Figure 2: Average number of melt days from multiple sources (a) MAR, Liquid Water Content > 0.4% for three consecutive days. (b) MAR Total Melt Flux > 0.4 mmwe for 1 day or more. Satellite-based: (c) PMW 240 algorithm (d) PMW ALA (e) PMW Zwa (f) QuikSCAT. All satellite-based estimates include a melt day only when part of a sustained three-day period of melt. All averages are taken from the 2000-2009 period to retain consistency with the availability of QuikSCAT data

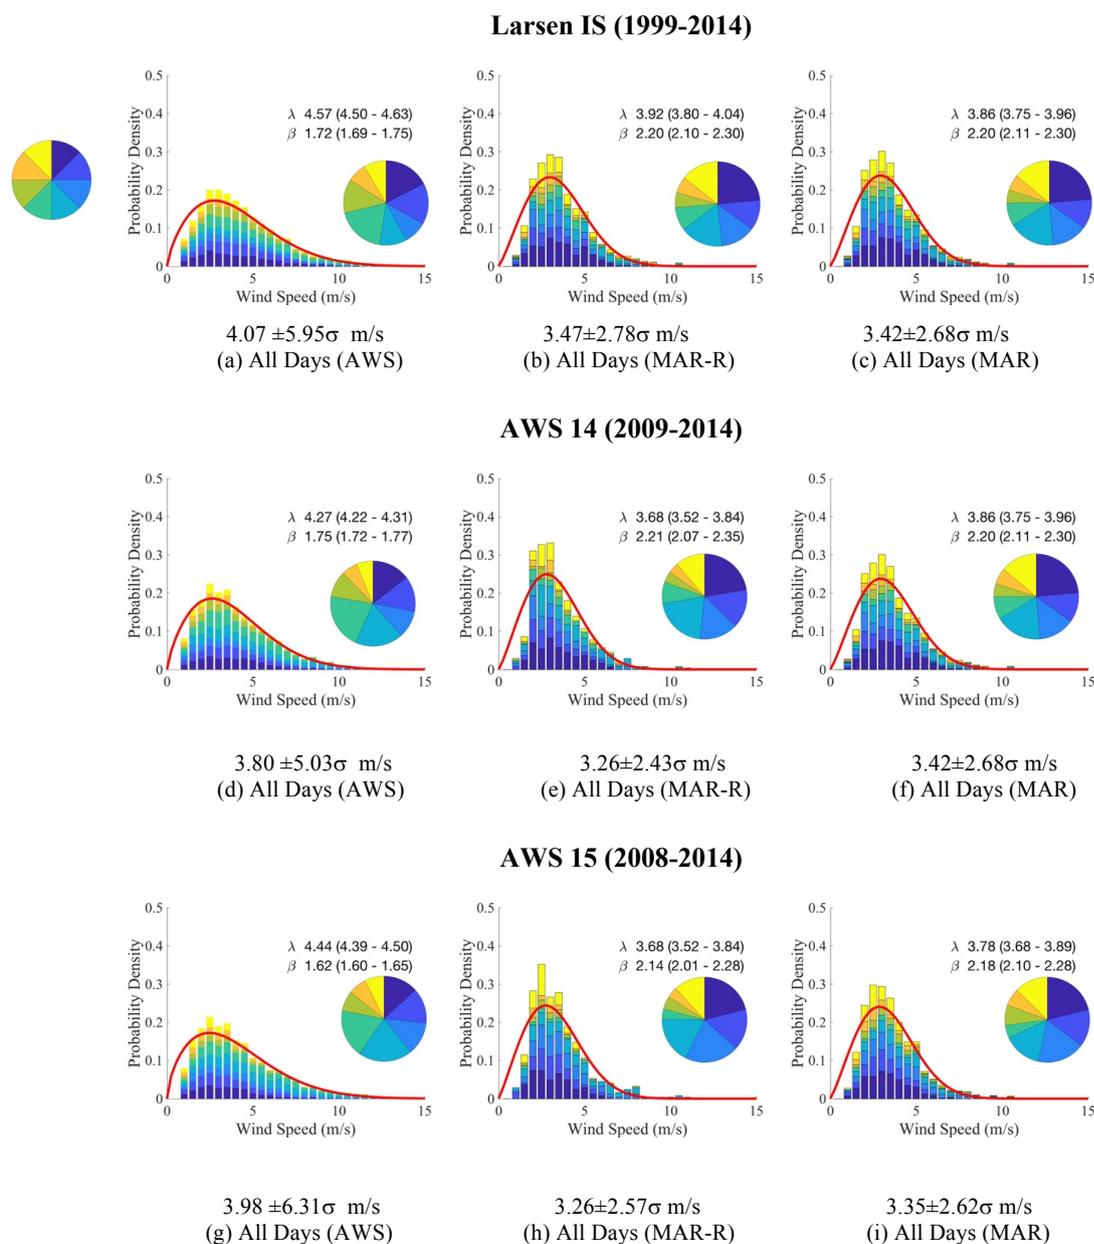

Figure 5: Probability distribution (y-axis) of summer (DJF) wind speeds (x-axis) with wind speed direction proportions shown in each inset. Wind directions corresponding to instet colors shown in 45° increments in inset left of (a). Curve shows best-fit Weibull curve with parameters for shape (β) and scale (λ , m/s). Datasets are for AWS data (left column), MAR outputs restricted to AWS availability (middle column) and MAR data for the 2001-2014 period (right column). Shown for (a) Larsen, AWS (b) Larsen, MAR at AWS availability (c) Larsen, MAR full period (d) AWS 14, (e) AWS 14, MAR at AWS availability (f) AWS 14, MAR full period (g) AWS 15, AWS (h) AWS 15, MAR at AWS availability (i) AWS 15, MAR full period. Values shown below figures are expected values from the Weibull distribution

	Northerly	Southerly	Easterly	Westerly
DJF All Days				
Where MAR shows wind direction				
MAR wind direction percentage	55.6%	44.4%	63.9%	36.3%
MAR expected wind speed [m/s]	3.49(±3.12)	4.21(±4.83)	3.75(±3.09)	4.04(±5.69)
AWS expected wind speed [m/s]	3.82(±5.23)	5.10(±9.14)	4.41(±6.87)	4.44(±8.73)
Where AWS shows wind direction				
AWS wind direction percentage	51.2%	48.8%	54.5%	45.5%
MAR expected wind speed [m/s]	4.04(±5.31)	3.72(±3.07)	3.48(±2.37)	4.43(±6.26)
AWS expected wind speed [m/s]	4.52(±8.33)	4.39(±6.98)	3.90(±4.77)	5.22(±11.03)
Temperature biases				
Avg T2m Bias (MAR - AWS)	0.58°C	0.77°C	0.43°C	0.76°C
Max T2m Bias (MAR - AWS)	-2.21°C	-1.11°C	-1.75°C	-2.42°C
Temperature bias where Ts > 0°C				
Avg T2m Bias (MAR - AWS)	-1.25°C	-1.42°C	-1.32°C	-1.29°C
Max T2m Bias (MAR - AWS)	-2.80°C	-2.40°C	-2.84°C	-3.04°C
DJF, MAR reports melt				
MAR wind direction	59.5%	40.5%	62.8%	37.2%
AWS wind direction	55%	45%	56.7%	43.3%
Temperature biases				
Avg T2m Bias (MAR - AWS)	0.28°C	0.18°C	0.25°C	0.24°C
Max T2m Bias (MAR - AWS)	-0.78°C	-0.41°C	-0.73°C	-0.43°C
Temperature bias where Ts > 0°C				
Avg T2m Bias (MAR - AWS)	-0.69°C	-0.76°C	-0.47°C	-0.63°C
Max T2m Bias (MAR - AWS)	-1.06°C	-0.92°C	-1.31°C	-0.64°C

Table 1: Proportions for wind direction and associated temperature biases at the Larsen Ice Shelf AWS station from 2000-2009 restricted to the summer season (DJF)

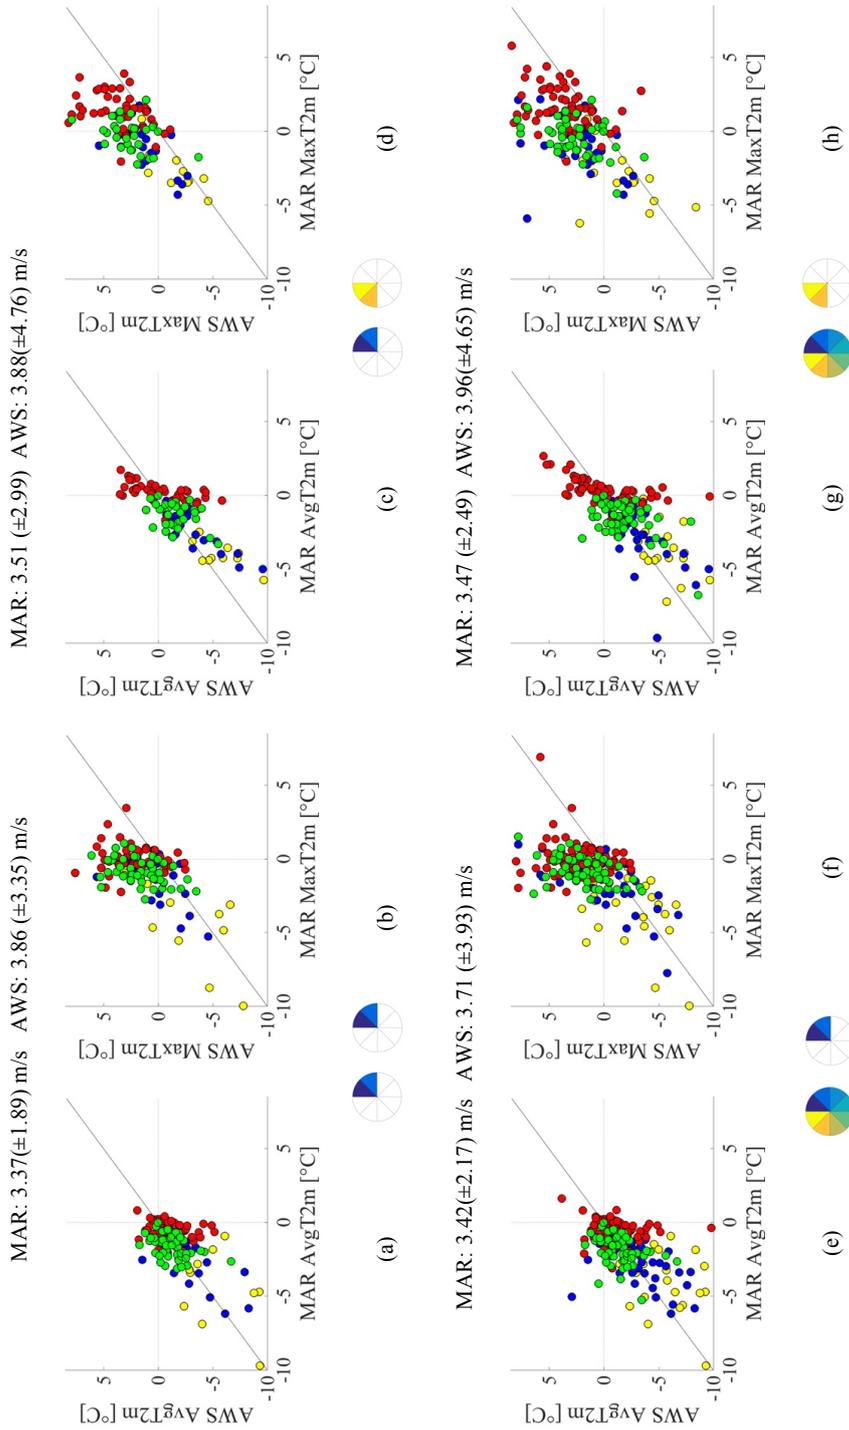

Figure 6: MAR vs AWS temperatures at the Larsen Ice Shelf AWS station for DJF from 2001-2009 for wind biases AWS \rightarrow MAR shown by pie charts (when AWS data is available). Red shows days where MAR shows melt. Blue shows “QSEx” days, i.e. when QuikSCAT reports melt (and MAR does not), Cyan indicates “PMWEx” when PMWAll shows melt and MAR does not. Green indicates when PMWEx an QSEx both report melt (and MAR does not). Yellow (only shown for g,h) indicates all other days for completeness. Northeasterly agreement (case 1) (a) AvgTs (b) MaxTs, Northeasterly AWS winds reported as northwesterly in MAR (case 2) (c) AvgTs (d)MaxTs, All wind directions in AWS reported as northeasterly in MAR (e) AvgTs (f) MaxTs

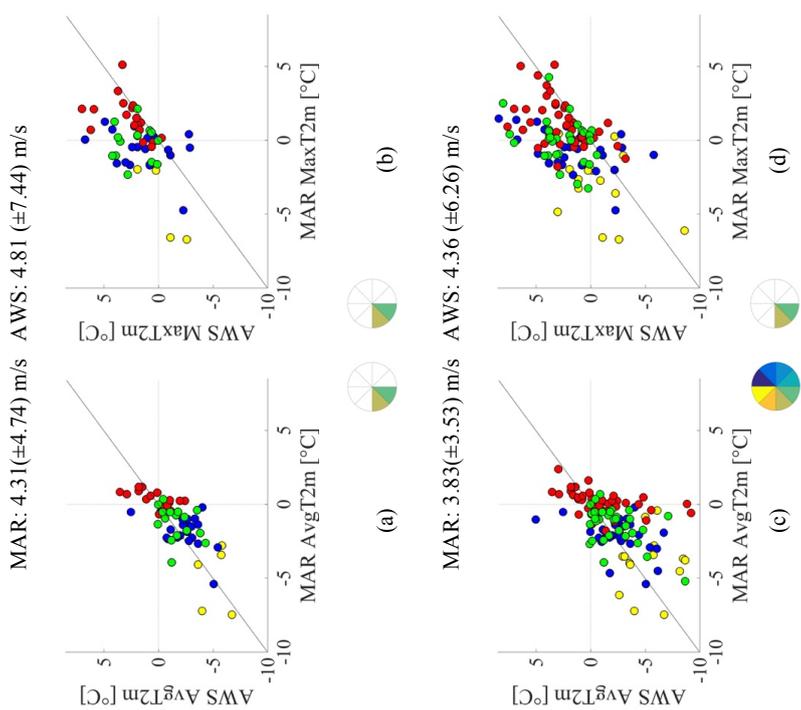

Figure 7: MAR vs AWS temperatures at the Larsen Ice Shelf AWS station for DJF from 2001-2009 for wind biases AWS \rightarrow MAR shown by pie charts (when AWS data is available). Red shows days where MAR shows melt. Blue shows “QSEx” days, i.e. when QuikSCAT reports melt (and MAR does not), Cyan indicates “PMWEx” when PMWAll shows melt and MAR does not. Green indicates when PMWEx an QSEx both report melt (and MAR does not). Yellow (only shown for g,h) indicates all other days for completeness. Southwesterly wind direction agreement (a) AvgTs (b) MaxTs, All wind directions in AWS which are reported as southwesterly in MAR (c) AvgTs (d)MaxTs,

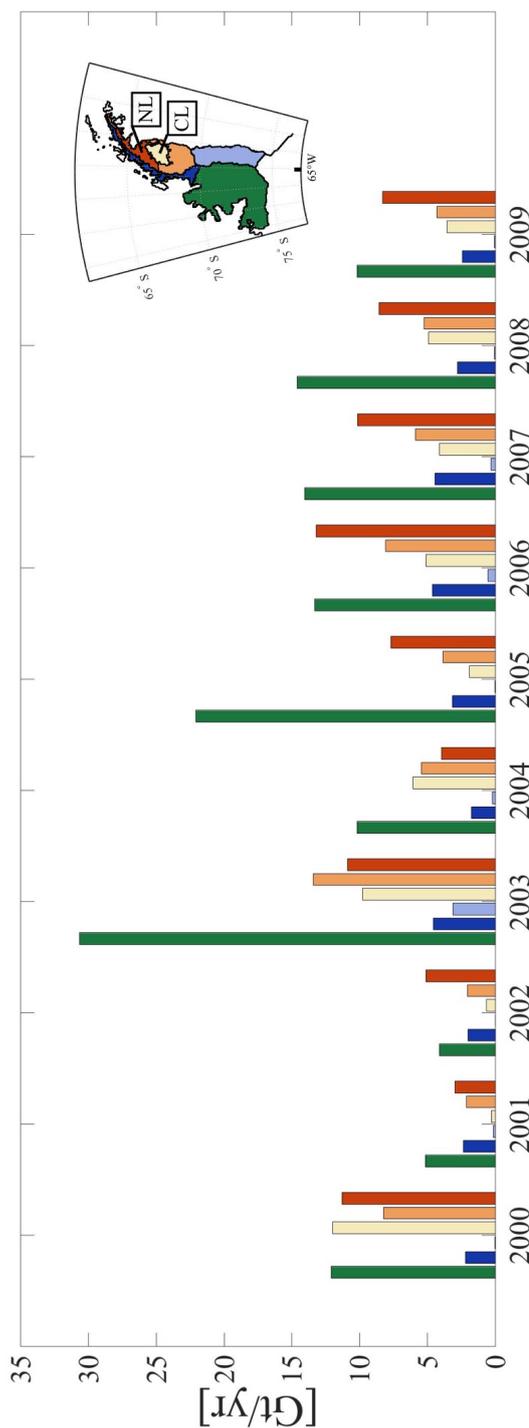

Figure 8: Annual meltwater production from MAR [Gt/yr] shown for masks shown in inset ('2001' corresponds to the meltwater from July, 2000-June, 2001). NW, SW, SE basins are kept intact as in Fig. 1. NE basin is divided into the NL mask, the CL mask and the remaining portion of the NE basin (NE - (CL+NL)). The CL and NL masks are described in text
