24 ABSTRACT

25 This study uses daily observations and modern reanalyses in order to evaluate
26 reanalysis products over Northern Eurasia regarding the spring snow albedo feedback
27 (SAF) during the period from 2000 to 2013. We used the state of the art reanalyses
28 ERA-Interim land and the Modern-Era Retrospective Analysis for Research and
29 Applications Version 2 (MERRA2) as well as an experimental setup of ERA-Interim
30 land with prescribed short grass as land cover to enhance the comparability with the
31 station data, while underlining the caveats of comparing in-situ observations with
32 gridded data. Snow depth statistics derived from daily station data are well reproduced
33 in all three reanalyses, however day-to-day albedo variability is notably higher in
34 stations compared to any reanalysis product. The ERA-Interim grass setup shows an
35 improved performance in representing albedo variability and generates comparable
36 estimates for the snow albedo in spring. We find that modern reanalyses show a
37 physically consistent representation of SAF, with realistic spatial patterns and area-
38 averaged sensitivity estimates. However, station-based SAF values are significantly
39 higher than in the reanalyses, which is mostly driven by the stronger contrast between
40 snow and snow-free albedo. Switching to grass-only vegetation in ERA-Interim land
41 increases the SAF values up to the level of station-based estimates. We found no
42 significant trend in the examined 14-year timeseries of SAF, but inter-annual changes
43 of about $0.5\% \text{ K}^{-1}$ in both station-based and reanalysis estimates were derived. This
44 inter-annual variability is primarily dominated by the variability in the snow melt
45 sensitivity, which is correctly captured in reanalysis products. Although modern
46 reanalyses perform well for snow variables, efforts should be made to improve the
47 representation of dynamic albedo changes.

53

54

55 **1. Introduction**

56 Global warming is enhanced at high northern latitudes, where the Arctic near-surface
57 air temperature has risen at twice the rate of the global average in recent decades – a
58 feature called Arctic amplification (**Serreze and Barry 2011**). Climate model
59 experiments for the 21st and 22nd centuries show that Arctic warming will continue
60 and intensify under all emission scenarios (**Collins et al. 2013**). Arctic amplification
61 results from several processes interacting with each other such as the albedo feedback
62 due to a reduction in snow and ice cover, enhanced poleward atmospheric and oceanic
63 heat transport, and changes in humidity (**Serreze and Barry 2011, Pithan and**
64 **Mauritsen 2014**).

65

66 Being one of the critical factors of the Arctic amplification, the surface albedo feedback
67 implies a decrease of reflected shortwave radiation at the top of the atmosphere in
68 conjunction with decreasing surface albedo and increasing near-surface temperature
69 (**Thackeray and Fletcher 2016**). It is considered to be a positive feedback in the sense
70 that an initial warming is strengthened over time, quantified through the change in
71 surface albedo per unit change of temperature (**Robock 1983, Cess et al. 1991, Qu and**
72 **Hall 2007**). Snow melt triggers this feedback via surface absorption of shortwave
73 radiation followed by conversion to longwave radiation, warming the lower layers of
74 the troposphere (**Curry et al. 1996**). Snow albedo feedback (SAF) and its impact on
75 climate have been studied for several decades (**Wexler et al. 1953, Budyko 1969,**
76 **Schneider and Dickinson 1974, Lian and Cess 1977**). It got further attention in the
77 wake of anthropogenic global warming accompanied by the reduction of snow and ice
78 cover over the Northern Hemisphere (NH) (**Bony et al. 2006, Qu and Hall 2007,**
79 **Fernandes et al. 2009, Flanner et al. 2011, Qu & Hall 2014, Fletcher et al. 2015,**
80 **Thackeray and Fletcher 2016**).

81

82 During 1979–2011, the Arctic snow cover extent in June decreased at a rate of -21%
83 per decade (**Derksen and Brown 2012**). Climate model projections for the end of the
84 21st century show an even more reduced Arctic cryosphere and, thus, the SAF will

85 continue to modulate Arctic warming (**Brutel-Vuilmet et al. 2013**). The SAF is
86 especially effective over the NH since most of it is covered by snow during boreal
87 wintertime (**Groisman et al. 1994**). **Hall (2004)** found that 50% of the total NH
88 extratropics SAF caused by global warming occurs during spring, while **Qu and Hall**
89 **(2014)** estimated that the SAF variability between models accounts for 40-50% of the
90 spread in the warming signal over the continents of the NH extratropics.

91

92 Several studies investigated spring NH extratropic SAF based on satellite, reanalysis
93 and model datasets (**Fernandes et al. 2009**, **Fletcher et al. 2012**, **Qu and Hall 2014**,
94 **Fletcher et al. 2015**). Satellite-based estimates of SAF vary within $\pm 10\%$ depending
95 on the analysed data set. **Hall et al. (2008)** used the International Satellite Cloud
96 Climatology Project (ISCCP) data (**Schiffer and Rossow 1983**) to calculate a SAF
97 strength of $-1.13\% \text{ K}^{-1}$, whereas **Fernandes et al. (2009)** using Advanced Very High
98 Resolution Radiometer (AVHRR) data (**Justice et al. 1985**) found a slightly weaker
99 SAF of $-0.93\% \text{ K}^{-1}$. **Qu and Hall (2014)** determined the SAF using Moderate
100 Resolution Imaging Spectroradiometer (MODIS) data (**Hall et al. 2002**) and found a
101 value of $-0.87\% \text{ K}^{-1}$ for springtime. Considering different spatial and temporal domains
102 as well as the variety of methods applied, the SAF estimates around $-1\% \text{ K}^{-1}$ from
103 satellite data can be considered as quantitatively consistent.

104

105 Model- and reanalysis-based estimates are somewhat higher compared to those derived
106 from satellite data. **Fletcher et al. (2015)** investigated Coupled Model Intercomparison
107 Project 3 and 5 (CMIP3/CMIP5) ensembles to estimate the SAF for an assortment of
108 Global Climate Models (GCMs). The authors found a SAF ensemble model mean of $-$
109 $1.2\% \text{ K}^{-1}$ for the NH extratropics, which is in fair agreement with MODIS values, but
110 is higher compared to ISCCP- and AVHRR-based estimates. Within this comparison
111 **Fletcher et al. (2015)** also investigated SAF computations based on ERA-Interim (**Dee**
112 **et al. 2011**), Modern-Era Retrospective Analysis for Research and Applications
113 (MERRA) (**Rienecker et al. 2011**) and NCEP-2 (**Kanamitsu et al. 2002**) reanalyses,
114 thus, providing the most up to date assessment of SAF in reanalysis datasets. While
115 MERRA data resulted in a slightly weaker SAF of $-1.17\% \text{ K}^{-1}$ compared to ERA-
116 Interim ($-1.23\% \text{ K}^{-1}$), both reanalyses show similar SAF values compared to MODIS.

117 That said, most studies use satellite derived albedo data in conjunction with temperature
118 and snow cover data from reanalyses.

119

120 Although satellite products of snow cover and albedo cover large parts of the NH, they
121 exhibit low temporal resolution and significant uncertainties for high solar zenith angles
122 as well as complex terrains (eg. **Wang et al. 2014**). **Thackeray and Fletcher (2016)**
123 compared CMIP3/CMIP5 model families and found that the models represent the SAF
124 process rather accurately. However, there are still inherent biases likely related to the
125 use of outdated parameterizations. In this respect the use of in-situ observations would
126 provide an opportunity for evaluating SAF estimates in different gridded datasets and
127 especially among reanalyses. However, estimating SAF in the Arctic using in-situ data
128 is challenging, mostly because of the lack of reliable, relevant observations, both in the
129 temporal and spatial domain. Furthermore, the lack of in-situ SAF estimates hampers
130 the understanding of SAF in high latitude climates (**Graversen and Wang 2009**,
131 **Gravesen et al. 2014**).

132

133 In this study we use a unique dataset of daily observations and modern reanalyses over
134 Northern Eurasia in order (1) to evaluate reanalysis products with respect to radiation
135 and snow properties and (2) to determine the SAF in spring between 2000–2013 based
136 on in-situ measurements. We compare different land-reanalysis products with modified
137 vegetation settings. Specific questions to be addressed in this study are the following:
138 How well do the modern reanalyses reproduce snow and radiation features on a daily
139 resolution? What are realistic estimates of the SAF from the station data over Northern
140 Eurasia and how well do they compare to the gridded reanalyses data? What are the
141 major characteristics of space-time variability of the SAF in station and reanalysis data?

142

143 The paper is organized as follows. After describing the different datasets and the
144 methods in sections 2 & 3, we evaluate the daily output for snow, radiation fluxes and
145 temperature within these datasets in section 4.1. In section 4.2 we assess the results of
146 the SAF computations and the differences between products including also an analysis
147 of the spatial and temporal variability. Section 5 discusses the results and considers
148 potential implications for future studies.

149

150 **2. Data**

151 2.1 Reanalysis Data

152 To investigate the SAF processes in reanalyses, we evaluated two products: the ERA-
153 Interim-land (ERA-Interim-L, **Balsamo et al. 2015**) and Modern-Era Retrospective analysis
154 for Research and Applications, Version 2 (MERRA2) (**Gelaro et al. 2017**). ERA-Interim-L is
155 a land-surface only simulation driven by the near-surface meteorology and fluxes from
156 the ERA-Interim atmospheric reanalyses (**Dee et al. 2011**). The land-surface model in
157 ERA-Interim-L (HTESSEL) has several enhancements compared with the land-surface model
158 used in ERA-Interim including the snowpack representation (**Dutra et al. 2010**). ERA-
159 Interim-L considers the prognostic evolution of snow mass and density, and for exposed areas
160 there is also a prognostic evolution of snow albedo. For shaded snow, i.e. snow under
161 high vegetation, the albedo is considered constant and dependent on vegetation type
162 (see **Dutra et al. 2010** for more details).

163 MERRA2 also includes a dedicated land module for surface variables. Furthermore, it
164 applies an updated Goddard Earth Observing System (GEOS) model and analysis
165 scheme and assimilates more observations than its predecessor MERRA (**Rienecker et
166 al. 2011**). Finally, MERRA2 uses observation-based precipitation data to force its land-
167 surface parameterizations, similar to what formerly was known as MERRA-land.
168 Unlike ERA-Interim-L, MERRA2 consists of a full land-atmosphere reanalysis. Its
169 incremental analysis update (IAU) scheme improves upon 3D-Var by dampening the
170 analysis increment. In IAU, a correction is applied to the forecast model gradually,
171 limiting precipitation spinup in particular.

172 For near-surface temperature we use 2m air temperature for both the reanalyses and
173 observations. Moreover, we do not use albedo computed by the reanalysis, but calculate
174 it from the radiative flux components consistent with the observed albedo. For this
175 purpose, we use upward and downward shortwave radiation at the surface as diagnosed
176 by ERA-Interim and MERRA2 as well as surface net and surface incoming radiation
177 from the station observations. Snow depth is used as inferred by reanalyses and, if
178 needed, converted to cm. More information about general characteristics of reanalysis
179 products in the Arctic can be found in **Lindsay et al. (2014)**, **Dufour et al. (2016)** and
180 **Wegmann et al. (2017)**.

181

182

183 **2.1.1 Idealized Reanalysis Experiment**

184

185 Since the in-situ measurements in this study are observed over clear cut vegetation,
186 idealized simulations prescribing grassland everywhere were carried out with the
187 ERAI-L configuration (hereafter ERA-Interim land grass only (ERAI-LG)). The ERAI-
188 LG simulation was carried out with the same model and setup as ERAI-L, differing
189 only in the land cover used. The land-surface model used in ERAI-L, HTESSEL,
190 accounts for sub-grid scale land cover variability by representing several land tiles,
191 namely: low vegetation, high vegetation, bare ground, exposed snow (snow on top of
192 bare ground or low vegetation), shaded snow (snow under high vegetation) and
193 interception. The land cover is prescribed with four maps: low and high vegetation
194 cover (cvl and cvh) and low and high vegetation types (tv1 and tvh). The bare ground
195 fraction is computed as $cvb = 1 - cvl - cvh$, the snow fraction is a function of the mean
196 grid-box snow depth and the interception fraction as a function of the mean interception
197 reservoir water content. For the ERAI-LG simulation, the high vegetation cover was
198 set to zero ($cvh=0$), the low vegetation cover to one ($cvl=1$) and the low vegetation type
199 to grassland. In this idealized simulation the entire globe was covered in grass land so
200 that only the low vegetation and exposed snow (when snow is present) tiles were
201 active. The main goal of this simulation is to evaluate the role of land cover when
202 comparing point observations with gridded reanalysis and to evaluate pathways to
203 improve reanalyses in representing albedo processes.

204

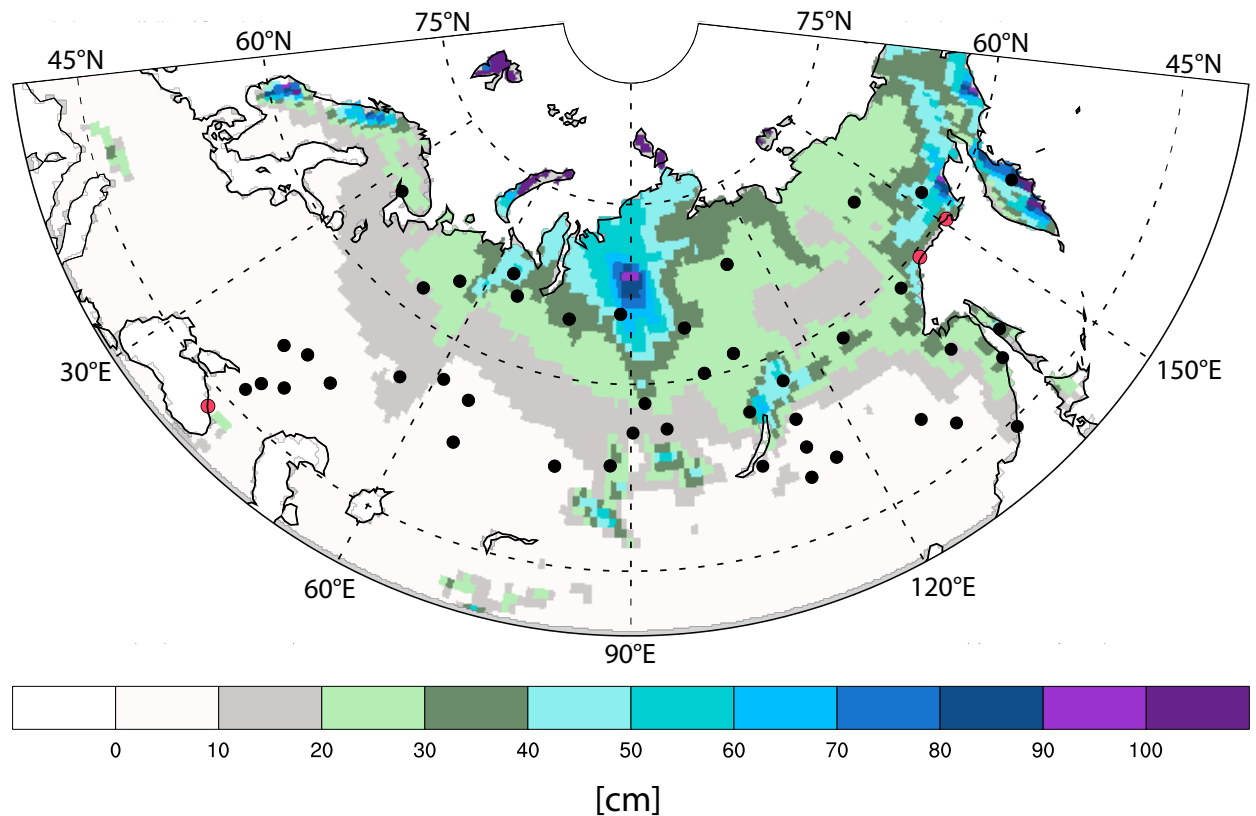

205

206 **2.2 Observational in-situ data**

207 To evaluate reanalysis performance, we used newly assembled in-situ radiation
208 observations from Russian meteorological stations. This dataset includes 4-hourly solar
209 radiation and radiation balance data from the World Meteorological Organisation
210 (WMO) World Radiation Network of the World Radiation Data Center (WRDC) at the
211 Voeikov Main Geophysical Observatory, Saint Petersburg, Russia. The original
212 WRDC data contains time series from 65 locations. We selected 47 stations for this
213 study because they overlap with daily snow depth and 2m temperature observations
214 (see Supplement Table 1). Of these 47 stations three were attributed by ERAI-L to

215 ocean gridpoints and we decided to remove the three coastal stations from the initial
216 dataset, so that the final dataset consists of 44 stations. Temperature and snow depth
217 observations were taken from the All-Russian Research Institute of
218 Hydrometeorological Information World Data Centre (RIHMI-WDC), Obninsk, Russia.
219 A detailed description of this dataset is provided by **Bulygina et al. (2010)**. This dataset
220 includes snow depth as well as snow cover fraction around meteorological stations.
221 Snow cover information in this data set is not stored in percentages, but rather in a scale
222 of integers from 0 to 10 (for example, 50% is assigned a value of 5, but so is 53%). This
223 makes these data hardly applicable for precise SAF calculations. Snow depth
224 information is measured in centimeters with the precision of 1 cm. This might lead to
225 an underestimation of snow depth in case of shallow snow (between 0 and 1 cm). All
226 variables (temperature, snow depth and snow cover, surface LW radiation budget and
227 surface SW radiation, the sum of the surface short-wave and long-wave radiation
228 budgets) were represented as daily time series for the period 2000–2013, which is the
229 time period available for the radiation observations by the Voeikov Main Geophysical
230 Observatory.

231 Figure 1 shows the location of the stations together with the climatological 2000–2013
232 MAMJ snow depth as computed by ERAI-L. The distribution of stations is quite
233 heterogeneous, with very few stations located in Eastern Siberia and in the Far East.
234 Moreover, some stations have prolonged periods of missing values; six stations have
235 more than 50% missing values in the daily timeseries for MAMJ. For monthly means,
236 the total number of missing values generally decreases from 2000 to 2013 (see
237 Supplementary Figure 1). However, data for the year 2009 are missing at 44 out of 47
238 stations during MAM period and at 3 stations in June. Nevertheless, spatial and
239 temporal coverage of this data set is exceptional for the analysis of albedo in this region.
240 It is also important to note that neither snow nor radiation from these stations were
241 assimilated in the reanalysis datasets and, therefore, our inter-comparisons are
242 completely independent.

243

244 Figure 1: Station location and snowdepth [cm] for the 2000–2013 MAMJ average taken
 245 from ERAI-L. Red colored stations are excluded by the land-sea mask of ERAI-L.

246 3. Methods

247 To evaluate the climatic variables needed for the SAF computation, we first compared
 248 daily values of snow depth, albedo and 2m temperature from the meteorological
 249 stations with those from the reanalyses. To co-locate observations with reanalyses, we
 250 extracted the information of the gridcell from the reanalysis, in which the station is
 251 located. In case of ERA-Interim land, horizontal resolution is $0.75^\circ \times 0.75^\circ$ degrees,
 252 whereas MERRA2 has a horizontal resolution of $0.5^\circ \times 0.625^\circ$ degrees. That said, the
 253 extracted values of the gridcell are expected show less variability and lower peak values,
 254 since they are integrated over a larger spatial domain, which dampens extreme values.
 255 We then derived long-term differences, performed a correlation analysis and also
 256 compared the variability among the datasets for the MAMJ period.

257 Since the SAF signals for the seasonal cycle and under long-term climate change are
 258 highly correlated (Hall and Qu 2006), we focus here on the evaluation of the seasonal
 259 cycle. Snow cover is converted from snow depth following a logarithmic equation

260 according to which 2.5 cm of snow depth was defined as equivalent to 100% snow
 261 cover (Fletcher et al. 2015). We split SAF into a snow cover component (SNC) and a
 262 temperature/metamorphosis component (TEM). SNC relates to the decrease of the
 263 albedo linked to the earlier melting of snow. TEM concerns the reduction of snow
 264 albedo due to enhanced metamorphism and larger grain sizes at warmer temperatures.
 265 In this study we focus on these two components of the feedback process, rather than
 266 the general classic term for net SAF ($\Delta\alpha/\Delta T$), since our goal is to evaluate differences
 267 in the more intricate terms of SAF. In the following, we assume that SAF=SNC+TEM,
 268 which was shown to be true in nearly all cases for the NH (Fletcher et al. 2012,
 269 Fletcher et al. 2015). Therefore, we compute the two terms as

270

$$271 \quad \mathbf{SNC} = (\overline{\alpha_{snow}} - \alpha_{land}) \Delta S_c / \Delta T_{2m} \quad (1)$$

272 and

$$273 \quad \mathbf{TEM} = \overline{S_c} \Delta \alpha_{snow} / \Delta T_{2m} \quad , \quad (2)$$

274 where α_{snow} is the snow-covered surface albedo, α_{land} is the snow-free surface albedo,
 275 S_c is the snow cover fraction and T_{2m} is the 2 m temperature. The first term of SNC
 276 $(\overline{\alpha_{snow}} - \alpha_{land})$ is also known as albedo contrast, whereas the second term
 277 $(\Delta S_c / \Delta T_{2m})$ will be referred to as snow melt sensitivity. In (1) and (2) deltas indicate
 278 month-to-month changes and the overbars indicate means over the two adjacent months.
 279 Note that ΔT_{2m} does not represent a hemispheric mean but rather the difference at an
 280 individual location. It was found that the contribution of SNC and TEM to the overall
 281 SAF is between 60 to 70% and 30 to 40 % for the NH (Fletcher et al. 2015).

282 In our SAF assessment, we use 2 m temperature as a surrogate for near surface air
 283 temperature, since the latter variable is not represented by stations. Using 2m
 284 temperature introduces some uncertainty to the results since atmospheric temperature
 285 advection can play a role in local temperature evolution. However, by now multiple
 286 studies (Fletcher et al. 2015, Xiao et al. 2017, Kevin et al. 2017) deal with 2 m
 287 temperature in their SAF assessment, mainly also due to the same comparability issues.

288 Since daily data are available, we define α_{snow} as the monthly mean over all daily
 289 estimates during the specific month when $S_c = 100\%$. Moreover, we define α_{land} as
 290 the mean over all daily estimates during MAMJ (in some stations this might only occur

291 in June) when $S_c = 0\%$. This allows for a less artificial estimation of α_{land} than
292 conventionally using summer (e.g. August) albedo.

293

294 **4 Results**

295 **4.1 Daily data evaluation**

296 Since 2m air temperature in reanalyses has been comprehensively evaluated in previous
297 studies (eg. **Schubert et al. 2014, Lindsay et al. 2014**), we only perform a general
298 comparative assessment of the daily values of albedo and snow depth in the SAF
299 computations. That said, **Lindsay et. al 2014** found that 2m temperatures show slight
300 negative biases over Russia in Winter for both ERA-Interim and MERRA1, whereas in
301 summer ERA-Interim shows basically no bias and MERRA1 shows slight positive
302 biases. Improvements in this regard from MERRA1 to MERRA2 are to be expected.

303 Figure 2 shows an overall comparison between station data and reanalyses in terms of
304 correlations, differences and magnitude of variability quantified by the standard
305 deviation for the albedo and snow depths. On a day-to-day basis MERRA2 and ERAI-
306 L are underestimating average albedo values compared to observations by about 0.1
307 during MAMJ (Figure 2a). On the other hand, ERAI-LG shows a much smaller average
308 deviation from the station data with differences close to zero. However, the overall
309 range of the boxplot for ERAI-LG is similar to the other two reanalyses resulting in
310 only slightly less absolute deviations from the observations.

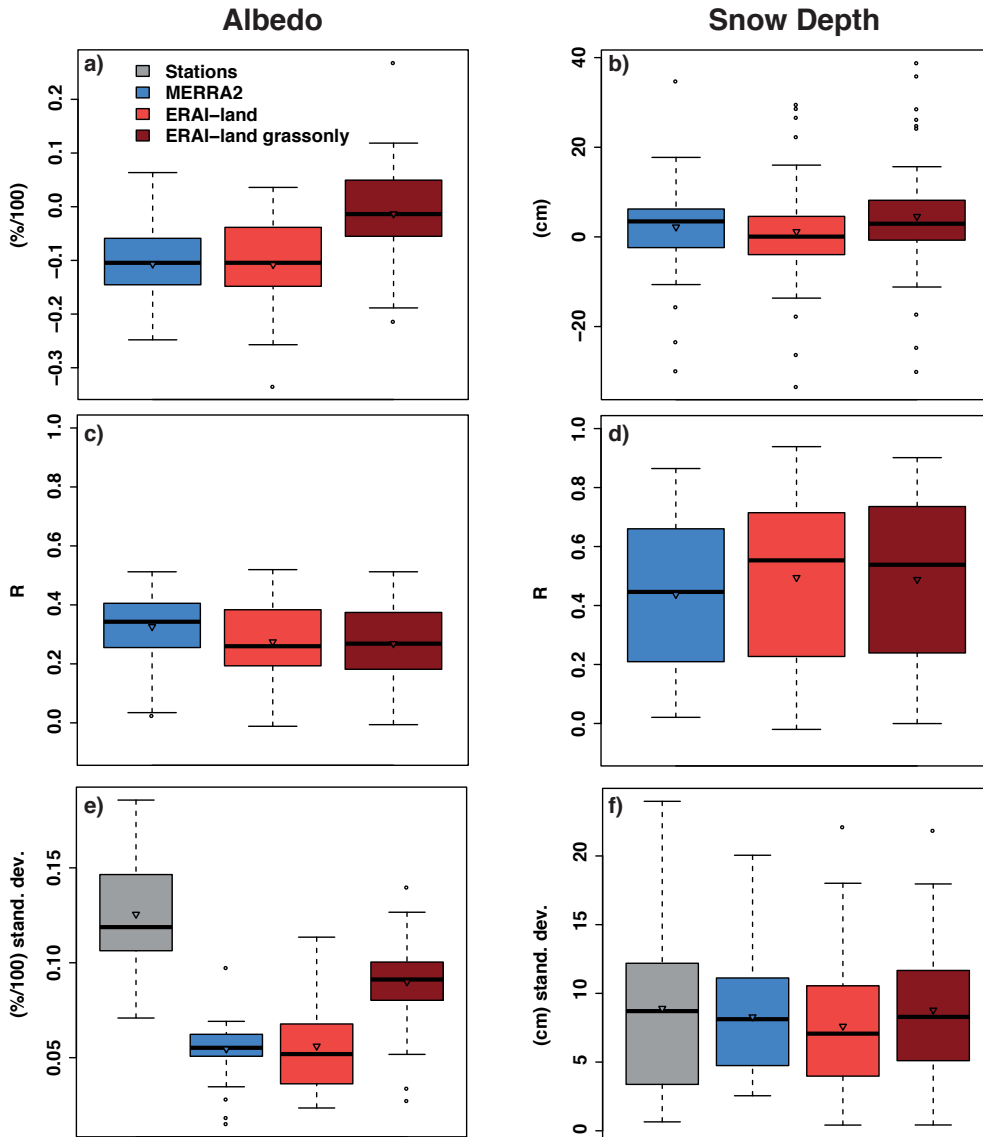

311 For snow depth (Figure 2b), all three reanalysis datasets show an overestimation of
312 daily values for MAMJ. Interestingly, ERAI-LG shows the largest deviations from
313 observed values, although the grass better represents the conditions at the observational
314 sites. This can be caused by biases in the observations due to surrounding higher
315 vegetation creating a snowfall shadow or negative instrumental biases (**Rasmussen et**
316 **al. 2012**). Moreover, positive biases in particular for precipitation can occur in
317 reanalysis products (**Brun et al. 2013**).

318 The analysis of daily correlations (Figure 2 c and d) demonstrates that the correlations
319 for the albedo are generally low among all three experiments, whereas for some stations
320 they can reach correlation coefficients higher than 0.8. Surprisingly, the correlations

321 between MERRA2 and station data are the highest for albedo and the lowest for snow
322 depth. The observed difference between MERRA2 and the ECMWF experiments
323 regarding the correlation for albedo can likely be explained by the introduction of
324 aerosols (and their respective deposition) in MERRA2 (see the Supplement for a initial
325 investigation). For snow depth, the correlation values are dominated by snowfall and
326 melting events. Also in this case, the grass-only experiment shows no increased
327 performance compared to the classic ERAI setup.

328 All reanalyses severely underestimate the day-to-day variability of the albedo (Figure
329 2 e and f). MERRA2 and ERAI-L show similar means, but reach the overall station
330 level only in specific grid cells. A clear improvement is observed in ERAI-LG, which
331 shows the smallest deviation from station estimates. Nevertheless, all modern
332 reanalyses fail to adequately reproduce daily variability in the observed albedo. On the
333 other hand, for snow depth the agreement is very good. The means of all four products
334 are around the values of 8 to 10 cm, with the grass-only experiment being the closest
335 to the average station variability.

336 In summary, the boxplot analysis (Figures 2) reveals that there is a general
337 improvement in agreement between stations and ERAI-L if vegetation is set to grass
338 only. However, none of the reanalysis products can accurately reproduce day-to-day
339 albedo variability. This is likely explained by the comparison of grid versus point
340 observations, where small-scale variations are averaged out.

347

348

349

350

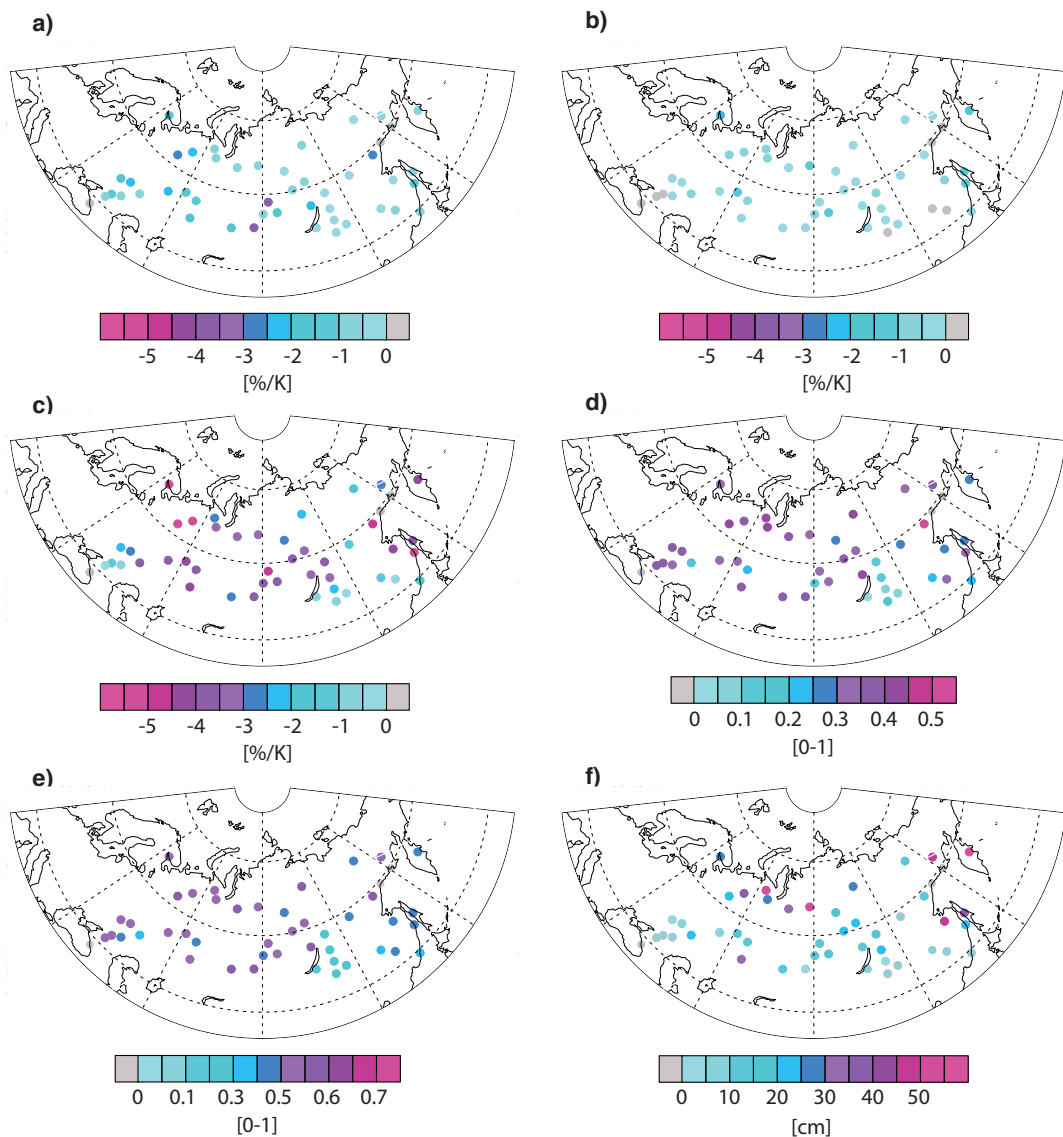

351 4.2 Analysis of feedback components

352 To assess regional patterns of key SAF components, we show their spatial distribution
353 over Russia as revealed by the observations in Figure 3 (See Supplement Figures 2-4
354 for the respective distribution from the reanalyses data).

355 Strong SNC (Figure 3a) responses in the station data are observed in Southern European
356 Russia and Western Siberia as well as over the Far East. The weaker responses are
357 observed in Southern Eastern Siberia. TEM (Figure 3b) follows a similar distribution
358 but is more homogeneously distributed with most negative values in Central Siberia
359 and towards the Arctic coastline. Snow melt sensitivity (Figure 3c) is strongest in the
360 mid-latitude and subpolar regions north of 50° N, such as Finland to the southeast,
361 west and north of Lake Baikal and along the Pacific Coast. Here the temperatures react
362 most strongly to seasonal snow melt. While there is a broad agreement between the
363 stations and ERAI-LG in this region, stations show a somewhat stronger snow melt
364 sensitivity (not shown). Snow melt sensitivity is a key factor for the SNC calculations
365 and, thus, shapes the spatial variability of SNC.

366 The other key factor in the SNC calculations is the contrast in albedo between snow-
367 covered and snow-free periods (Figure 3d). The observed albedo contrast is
368 characterized by a relatively homogeneous pattern with somewhat smaller values in
369 the southern regions, especially over Southern Eastern Siberia east of the Lake Baikal.
370 In general, a north-south gradient is visible with similar patterns as in SNC. Mean
371 albedo for spring (Figure 3e) shows that highest values are found closer to the Arctic
372 coastline, in Central Siberia and towards the western border. Lower mean albedo values
373 are mostly located east of Lake Baikal. This distribution is in general agreement with
374 the reanalyses datasets, especially for the lower values in the south east.

375 Finally, since TEM follows closely the general MAMJ snow distribution, we show
376 average snow depth in Figure 3f. A clear north-south gradient is visible with hotspots
377 at the Pacific coast and towards the Barents-Kara sea. Moreover, snow depths from
378 stations follow closely the ERA-L snowdepth distribution shown in Figure 1.

379

380 **Figure 3: Mean SAF components in station data for 2000–2013 MAMJ. a) SNC,**

 382 **depth.**

383

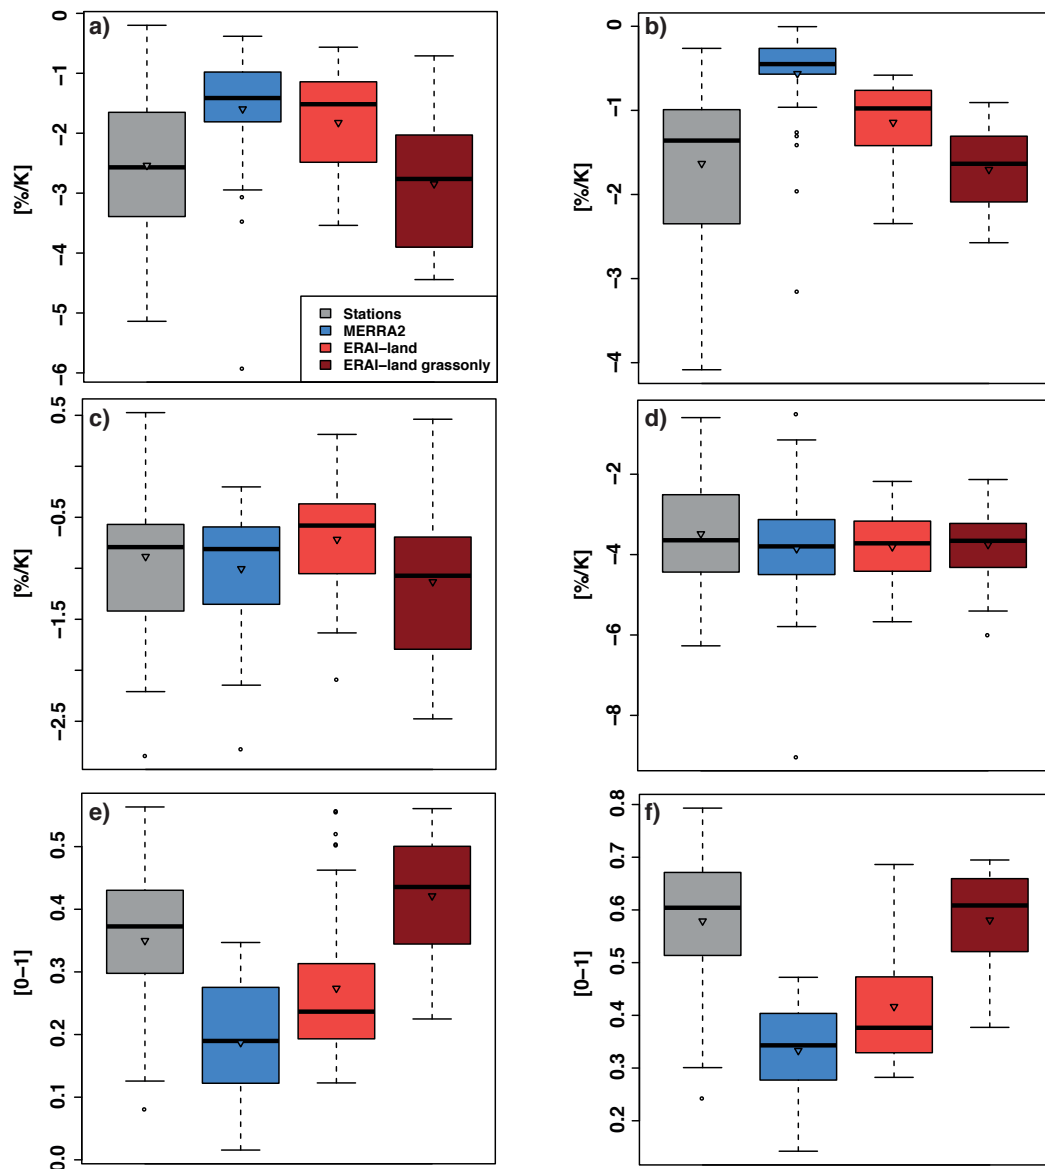

384 To analyse the differences between the datasets and to put the station data in context,
 385 Figure 4a shows the response for SAF computed for the entire period 2000-2013 and
 386 all 44 locations. Stations show much stronger SAF ($-2.5\% \text{ K}^{-1}$) compared to MERRA
 387 ($-1.6\% \text{ K}^{-1}$) and ERAI-L ($-1.8\% \text{ K}^{-1}$). At the same time ERAI-LG shows SAF estimate
 388 close to that derived from the station data ($-2.8\% \text{ K}^{-1}$). Thus, changing the vegetation
 389 to short grass adds an additional 1% albedo decrease per degree of warming to the
 390 feedback process. The further analysis of the two components of SAF (SNC and TEM,

391 Figure 4 b and c) shows that ERAI-LG reproduces well the SNC signal derived from
392 the station data ($-1.6\% \text{ K}^{-1}$ mean for stations and $-1.7\% \text{ K}^{-1}$ mean for ERAI-LG),
393 whereas the other two reanalyses show much weaker SNC values. The lowest value of
394 $-0.56\% \text{ K}^{-1}$ was obtained from the MERRA2 data. In general, SNC responses largely
395 explain differences in SAF (Figure 4a).

396 For TEM values (Figure 4c), all three reanalyses are in a good agreement with the
397 observations with MERRA2 showing the best agreement. Changing the vegetation to
398 grass in ERA-Interim results in a TEM component, which is $0.4\text{-}0.5\% \text{ K}^{-1}$ stronger
399 compared to the standard version of ERA-Interim. Given that TEM represents the
400 response to snow metamorphosis, good performance of MERRA2 is in agreement with
401 findings implied by Figure 2. However it is worth noting that for the station network as
402 well as for the ECMWF experiments, locations with positive TEM are calculated. This
403 is due to snow albedo changes being positive in some instances (Figure 4c).

404 To further investigate the nature of the SNC and TEM responses we show in Figure 4d
405 the results for snow melt sensitivity, which is one of the two key components in the
406 SNC response (1). This component is barely influenced by the underlying vegetation.
407 All three reanalysis datasets agree very well with the station network, with ERAI-LG
408 showing the closest agreement for both mean and median. This indicates an accurate
409 representation of this relationship in both NASA and ECMWF land surface modules.

410 Figure 4d implies that the changes in the SNC should stem from the albedo contrast,
411 the second key component expressed as the average difference between albedo values
412 for a complete snowcover and snow-free conditions (Figure 4e). Indeed, MERRA2
413 shows the lowest albedo contrast among all datasets, resulting in very low SNC values.
414 Albedo contrast in ERAI-L is higher than MERRA2, but is on average still lower
415 compared to the observations, which show average values around 0.35. ERAI-LG
416 shows the strongest albedo contrast, which is twice as large compared to the experiment
417 with classic vegetation cover. These striking differences among the datasets mainly
418 drive the SNC results.

419

420 **Figure 4: Boxplot analysis for MAMJ 2000–2013 a) SNC+TEM, b) SNC, c) TEM,**
 421 **d) snow melt sensitivity, e) albedo contrast and f) snow albedo. Triangle indicates**
 422 **the mean value.**

423

424 Snow albedo is well captured by the grass-only experiment showing the same average
 425 value around 0.6 as determined from the observations (Figure 4f). The standard
 426 vegetation schemes used in MERRA2 and ERAI-L reduce the snow albedo in the
 427 analyzed grid cells to 0.33 and 0.37. The differences in snow albedo between the
 428 products is the main driver for the differences in the albedo contrast since the snow-

429 free albedo values are remarkably similar for all reanalysis products (Figure 5a).
430 Nevertheless, they strongly deviate from the snow-free albedo determined from the
431 observations, which is roughly twice as large compared to the reanalyses with a mean
432 value of about 0.21 and which is very close to albedo values for grass (see e.g. **Betts**
433 **and Ball 1997, Wei et al. 2001**).

434 To explore the impact of different factors on the TEM estimates, we show in Figure 5
435 mean values of temperature, snow cover and albedo, as well as the average change of
436 snow albedo during spring. Also, to underline the crucial role of in-situ snow depth
437 information, mean snow depth is shown. Mean station snow depth lies within the range
438 of reanalyses values, with higher values reported by ERAI-LG. Moreover, stations have
439 the lowest snow cover among all datasets (Figure 5 b and c). This difference is likely
440 due to the conversion of snow depth to snow cover as well as from the precision (in
441 centimeters) of the Russian snow depth measurement. Precision of snow depth
442 diagnosed by reanalysis is much finer and the logarithmic conversion here can be
443 performed more accurately. As a result, TEM values diagnosed by stations are probably
444 too low. If we consider instead in-situ snow cover information from stations, the
445 average snow cover is quite similar to reanalyses (ca. 55%), and the average TEM value
446 gets stronger. However, replacing converted snow cover with observed snow cover in
447 Eq. (2) is a questionable procedure, as the remaining terms were computed using snow
448 depth conversion. Thus, for consistency we show lower values of TEM in Figure 4.

449 Temperature is well represented by all datasets with MERRA2 being about 1 K colder
450 compared to stations, which is quite notable for such a robust variable. However,
451 absolute values of temperature do not have a strong impact on the computation of TEM,
452 since month-to-month changes in temperature affect both TEM and SNC computations.
453 For ERAI-LG albedo contrast, the effect of the underestimated snow-free albedo and
454 overestimated snow albedo cancel each other out. Finally, the snow albedo change
455 during spring (Figure 5f) is very similar in station data and in MERRA2 (-0.09 average
456 in both datasets), which points towards an adequate representation of snow
457 metamorphosis and aerosol deposition in MERRA2. The ERAI-LG experiment shows
458 a stronger change of snow albedo during spring than the standard version. ERAI-L
459 potentially keeps the temperature and therefore snow metamorphosis more constant
460 throughout spring due to a more stable local temperature climate induced by the

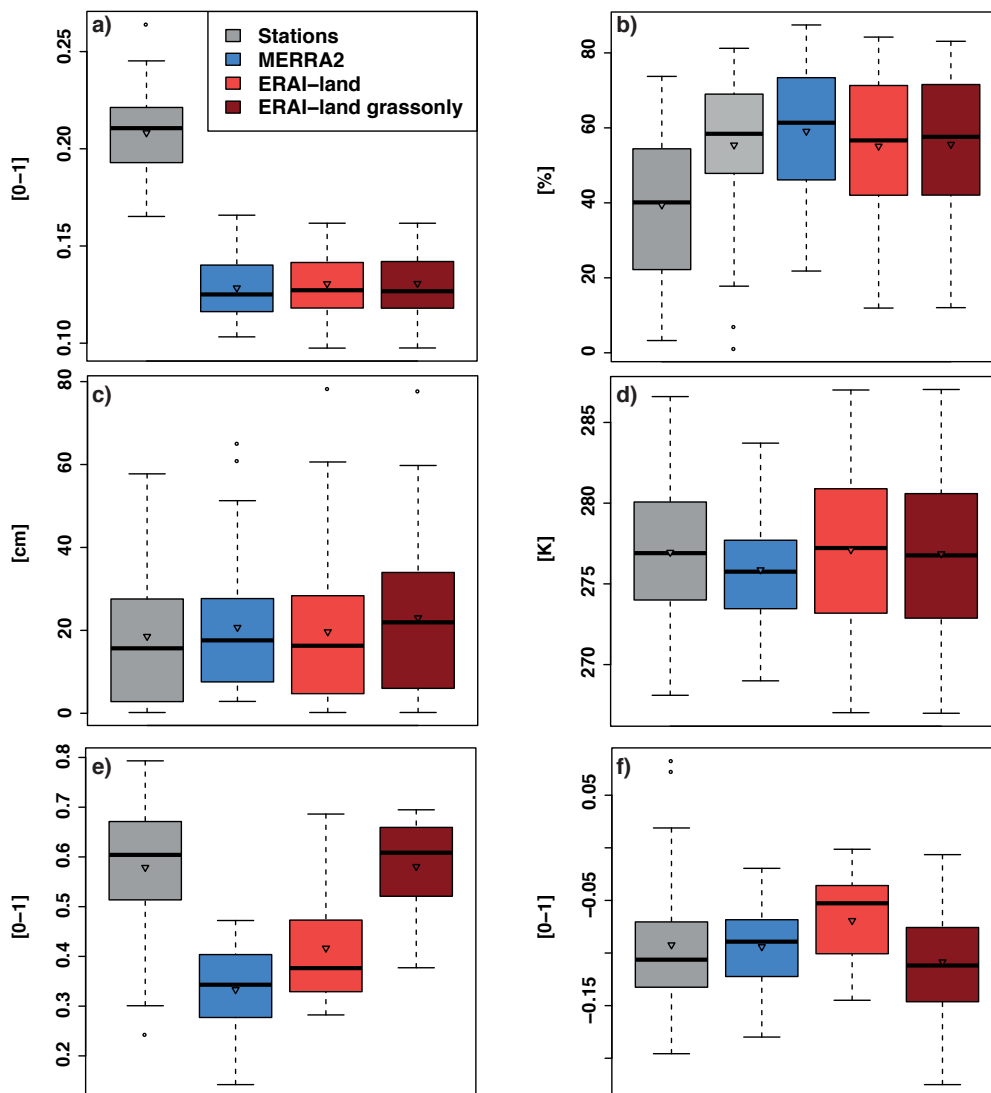

461 vegetaiton. Note also, that some stations show an increase of snow albedo during spring.

462 This can be caused by fresh snow accumulation in late spring in some locations.

463

464

470 **albedo change within the season. Triangle indicates the mean value.**

471

472 Figure 6 shows timeseries (2000–2013) for the mean values for SAF-related variables.
473 Timeseries for SNC (Figure 6a) and TEM (Figure 6b) show that inter-annual variations
474 of up to $0.5\% \text{ K}^{-1}$ are possible for both stations and reanalyses. Moreover, for both SNC
475 and TEM, ERAI-LG seems to reproduce well the overall baseline and the magnitude
476 of variability.

477 For snow melt sensitivity (Figure 6c) the agreement among the datasets is very good
478 when it comes to magnitude and interannual variability, with MERRA2 showing an
479 amplified inter-annual variability (up to $1.5\% \text{ K}^{-1}$), which is beyond the magnitudes
480 observed at stations. As already noted above, snow melt sensitivity seems to be a rather
481 well reproduced process in modern reanalyses. Since snow-free albedo is quite constant
482 over time in the reanalyses, the albedo contrast is dominated by the snow albedo (Figure
483 6d). ERAI-LG and the station network agree very well on the magnitude of snow albedo,
484 whereas ERAI-L and MERRA2 fail to reproduce such high values. Magnitudes of inter-
485 annual variability can reach up to ± 0.05 in stations, with slightly weaker response in
486 reanalyses. Correlation between stations and reanalyses is rather low, only individual
487 years are captured correctly by ERAI-LG (see Supplement for correlation values).

488 Snow albedo change within spring (Figure 6e) is well captured by MERRA2 and ERAI-
489 LG. Furthermore, ERAI-LG captures well the inter-annual variability for this metric.
490 Specifically, variability during 2001–2004 and 2005–2008 periods is quite well
491 represented. On the other hand, ERAI-L seems to lack the consistency with
492 observations. Finally, as it was mentioned in section 4.1, snow depth variability (Figure
493 6f) is very well captured by all reanalyses. Again, ERAI-LG overestimates snow depth
494 by up to 5 cm, with the other two reanalyses being on average 1-2 cm above the station
495 values.

496

497 **Figure 6: Yearly timeseries of selected MAMJ SAF components averaged over all**

500

501 To further demonstrate the effect of the vegetation changes in the ERA-Interim land
502 reanalysis, Figure 7 shows anomalies between ERAI-L and ERAI-LG. The structure
503 follows Figure 6, with SNC and TEM shown in Figure 7a&b. As is clearly visible both
504 variables are generally less negative in ERAI-L, a fact already known from timeseries
505 and boxplot analysis. The largest impact of the vegetation changes is found for Northern
506 Russia, the Pacific coast and the western region between Black and Caspian Sea.
507 Interestingly, but as expected, snow melt sensitivity (Figure 6c) is not the key driver
508 behind this distribution. Since snow melt sensitivity is not directly linked to vegetation
509 changes, the anomaly distribution is very heterogenous, with positive and negative
510 anomalies over the whole domain. As known from the timeseries plot, snow sensitivity
511 in ERAI-LG is overall slightly weaker than in ERAI-L, probably due to positive
512 feedbacks such as reduction of nighttime cooling over higher vegetation types. The
513 main driver behind the distribution of SNC is albedo contrast (Figure 7d). Albedo
514 contrast is overall higher in ERAI-LG, especially along the borders of the domain,
515 highlighted already for SNC.

516

521

522

523 **5. Discussion**

524 We compared spring SAF and its components determined from in-situ measurements
 525 over Russia for the period 2000–2013 with data derived from three modern reanalysis
 526 products restricted to the grid cells including the observational sites. This was achieved
 527 by using a unique collection of station measurements of radiation and snow

528 characteristics investigating for the first time observed SAF over this broad spatial and
529 temporal domain. Besides ERAI-L we also used a customized version of ERAI-L
530 (ERAI-LG), in which vegetation was set to grass in all concerned grid cells.

531 All three reanalysis datasets are completely independent from the analyzed station data.
532 While a direct comparison of point measurements with grid cell output always
533 introduces uncertainties due to the spatial variability of the surface, this is for now the
534 only way to evaluate reanalyses data using in-situ observations. An alternative option
535 would be satellite data, which come with their own uncertainties (e.g. **Romanov et al.**
536 **2002, Foster et al. 2005, Wang et al. 2014**).

537 Snow depth statistics derived from daily station data are reasonably well reproduced in
538 all three modern reanalyses, which is in agreement with **Wegmann et al. (2017)** who
539 investigated April snow depth in ERAI-L. While snow depth differences between
540 ERAI-L and ERAI-LG are small, ERAI-LG shows slightly higher deviations from the
541 station data than ERAI-L that might be caused by the higher vegetation in station
542 surroundings and by underestimation of snowfall due to instrumentation used at the
543 Russian station network (**Rasmussen et al. 2012**).

544 Day-to-day variability of albedo is notably higher in station data compared to any
545 reanalysis product. Besides spatial averaging over the reanalyses grid cells, this is
546 potentially caused by land surface changes due to weather (e.g. soil moisture change,
547 aerosol deposition), which are not represented in the reanalyses. However, ERAI-LG
548 demonstrates increasing albedo variability, nearly doubling the standard deviations
549 diagnosed by ERAI-L with the standard vegetation scheme.

550 The limitations of the station data imply some constraints for comparisons with
551 reanalysed data. As near-surface temperature is unavailable in station data, we used for
552 both stations and reanalyses 2m air temperature, which reduces the strength of the SAF
553 feedback. Moreover, using local 2m air temperature first and then average over our
554 domain later leads to lower SAF values than if we would have used NH averaged 2m
555 air temperature. Since albedo changes in our stations are much more dramatic (due to
556 the WMO conditions) than in model or satellite grid cells, using geographically
557 “smoothed” temperature data would eventually lead to a much stronger impact of
558 albedo changes on temperature changes. Thus, our results are not to be seen as a

559 Northern Hemisphere impact analysis but rather as a contribution to reanalysis
560 improvement and the investigation of SAF evolution.

561

562 Secondly, snow cover is underestimated in station data due to the measurement
563 precision of 1cm, which reduces the strength of the TEM component. The snow albedo
564 and the snow-free albedo are substantially higher in station data than in the reanalyses
565 with classic vegetation boundary conditions (MERRA2 and ERAI-L). Compared to
566 other observation-based studies, spring snow albedo and grass albedo derived from our
567 station network is quite realistic (**Roesch et al. 2009, Stroeve et al. 2006**). Thus, the
568 difference revealed by reanalyses is likely due to averaging over grid cells.

569 Results from ERAI-LG clearly demonstrate that SAF and its components are very close
570 to those in the station data. The largest improvement was found for albedo contrast and
571 for snow albedo, which both are more realistic in ERAI-LG. At the same time snow-
572 free albedo in all three reanalyses (including ERAI-LG) was found to be lower than in
573 the station data, because snow-free albedo in all reanalysis data sets is prescribed as a
574 monthly climatology from MODIS data. As MODIS mostly registers albedo from
575 Taiga and Tundra vegetation, a stark difference to the grass albedo from the stations
576 occurs.

577 MERRA2 shows the lowest SAF values resulting from a very low albedo contrast,
578 which is probably a consequence of the vegetation scheme in the MERRA2 land
579 module. On the other hand, MERRA2 represents TEM reasonably well most likely due
580 to the accurate representation of the intra-seasonal snow albedo changes. Thus, relative
581 snowpack changes appear to be well represented in MERRA2, probably also due to a
582 more accurate representation of aerosols.

583 In general, we found higher SAF values in ERAI-L than in the recent CMIP3/CMIP5
584 analyses of NH SAF by **Fletcher et al. (2015)**. This disagreement results from a variety
585 of factors. First, our domain is limited to Russia only, thus excluding considerable parts
586 of Eurasia as well as North America. In this respect our domain is set within a high
587 SAF region, which may explain higher SAF values compared to the NH average by
588 **Fletcher et al. (2015)**. On the other hand, MERRA2 shows good agreements with the
589 NH CMIP4/5 SAF results, however mostly because the albedo contrast is very low.
590 Furthermore, as we pointed out above, in-situ observations used here tend to slightly

591 overestimate SAF, mainly due to higher snow albedo values. This is because in-situ
592 snow albedo is typically measured by a sensor installed over a vegetation-free snow
593 pack. The vegetation scheme used in reanalyses gives lower snow albedo values
594 implying realistic vegetation cover such as taiga or tundra. However, our MERRA2
595 results agree fairly well with the findings of **Fletcher et al. (2015)**. Moreover, mean
596 values of the albedo independent variable snow melt sensitivity are very close to the
597 "observational" snow melt sensitivity computed by **Fletcher et al. (2015)**.

598 We also found agreements with **Fletcher et al. (2015)** in the representation of the
599 spatial pattern of the SAF components. **Fletcher et al. (2015)** as well as **Fernandes et**
600 **al. (2009)** have shown maxima in SAF over northern Canada, northern Siberia and
601 southwestern Eurasia. The relation of 60:40 between SNC and TEM, which is found in
602 modeled, satellite and reanalysis data, was replicated by our station network. We found
603 similar spatial patterns for SAF and its components in both stations and gridded data
604 specifically for Southern Russia, while the pattern of station responses is less
605 homogenous compared to the gridded data. Also consistent with **Fletcher et al. (2015)**,
606 we found higher snow melt sensitivity north of 50° N. Finally, albedo contrast
607 distribution, which closely follows the snow albedo pattern, is in very good agreement
608 with the gridded analysis of snow albedo by **Fletcher et al. (2015)**.

609 **6. Conclusions**

610 Reanalyses including land surface modules show a physically consistent representation
611 of SAF with realistic spatial patterns and area-averaged sensitivity estimates. ERAI-LG
612 shows a better performance in representing station-based estimates considering the
613 uncertainty associated with "point to grid cell" comparisons. Accounting for aerosol-
614 related processes would likely improve this performance in future reanalysis releases.
615 Thus, for the analysis and validation of large-scale temporal and spatial averages of
616 SAF modern reanalyses seem to be an appropriate tool.

617 However, for analysing processes on smaller scales and high temporal resolution
618 studies, a healthy dense station network is required. The idealized ERAI-LG simulation
619 also highlights the caveats of comparing in-situ observations with gridded model data.
620 In this study, we show these discrepancies in terms of albedo and snow depth. Other
621 variables, in particular 2m temperature, can be expected to have a similar signal arising
622 from the differences between the model's gridcell land cover and the actual station

623 conditions. Our findings show that the experimental approach in ERAI-LG allows for
624 an enhanced use of in-situ observations to diagnose the SAF in not-forested areas.

625 Considering future studies, the extension to other regions and use of other regional in-
626 situ data might give further insights into regional hotspots of SAF. Cross-validation
627 efforts employing model, reanalysis, satellite and station data may help to generate
628 blended products to investigate radiation and albedo feedbacks in the changing Arctic,
629 a region where SAF is especially strong. Regional modelling, including a variety of
630 multi-layer land surface models over areas with a relatively dense observation network
631 can provide a quantitative estimation of uncertainties among complex variables such as
632 snow depth, albedo or SAF.
