**Abstract.** Twenty-first century snowfall changes over the European Alps are assessed based on high-resolution regional climate model (RCM) data made available through the EURO-CORDEX initiative. Fourteen different combinations of global and regional climate models with a target resolution of 12 km, and two different emission scenarios are considered. As raw snowfall amounts are not provided by all RCMs, a newly developed method to separate snowfall from total precipitation based on near-surface temperature conditions and accounting for subgrid-scale topographic variability is employed. The evaluation of the simulated snowfall amounts against an observation-based reference indicates the ability of RCMs to capture the main characteristics of the snowfall seasonal cycle and its elevation dependency, but also reveals considerable positive biases especially at high elevations. These biases can partly be removed by the application of a dedicated RCM bias adjustment that separately considers temperature and precipitation biases.

Snowfall projections reveal a robust signal of decreasing snowfall amounts over most parts of the Alps for both emission scenarios. Domain and multi-model mean decreases of mean September-May snowfall by the end of the century amount to -25% and -45% for RCP4.5 and RCP8.5, respectively. Snowfall in low-lying areas in the Alpine forelands could be reduced by more than -80%. These decreases are driven by the projected warming and are strongly connected to an important decrease of snowfall frequency and snowfall fraction and are also apparent for heavy snowfall events. In contrast, high-elevation regions could experience slight snowfall increases in mid-winter for both emission scenarios despite the general decrease of the snowfall fraction. These increases in mean and heavy snowfall can be explained by a general increase of winter precipitation and by the fact that, with increasing temperatures, climatologically cold areas are shifted into a temperature interval which favours higher snowfall intensities. In general, percentage changes of snowfall indices are robust with respect to the RCM postprocessing strategy employed: Similar results are obtained for raw, separated and separated + bias-adjusted snowfall amounts. Absolute changes, however, can differ among these three methods.

## 38 **1 Introduction**

39 Snow is an important resource for the Alpine regions, be it for tourism, hydropower generation, or  
40 water management (Abegg et al., 2007). According to the Swiss Federal Office of Energy (SFOE)  
41 hydropower generation accounts for approximately 55% of the Swiss electricity production (SFOE,  
42 2014). Consideration of changes in snow climatology needs to address aspects of both snow cover  
43 and snowfall. In the recent past, an important decrease of the mean snow cover depth and duration in  
44 the Alps was observed (e.g, Laternser and Schneebeli, 2003; Marty, 2008; Scherrer et al., 2004).  
45 Projections of future snow cover changes based on climate model simulations indicate a further  
46 substantial reduction (Schmucki et al., 2015a; Steger et al., 2013), strongly linked to the expected rise  
47 of temperatures (e.g., CH2011, 2011; Gobiet et al., 2014). On regional and local scales rising  
48 temperatures exert a direct influence on snow cover in two ways: First, total snowfall sums are  
49 expected to decrease as a result of a lower probability for precipitation to fall as snow, implying a  
50 decreasing overall snowfall fraction (ratio between solid and total precipitation). Second, snow on the  
51 ground is subject to faster and accelerated melt. These warming-induced trends might be modulated,  
52 for instance, by changes in atmospheric circulation patterns.

53 Although the snowfall fraction is expected to decrease during the 21st century (e.g., Räisänen, 2016)  
54 extraordinary snowfall events can still leave a trail of destruction. A recent example was the winter  
55 2013/2014 with record-breaking heavy snowfall events along the southern rim of the European Alps  
56 (e.g., Techel et al., 2015). The catastrophic effects of heavy snowfall range from avalanches and  
57 floods to road or rail damage. In extreme cases these events can even result in the weight-driven  
58 collapse of buildings or loss of human life (Marty and Blanchet, 2011). Also mean snowfall conditions,  
59 such as the mean number of snowfall days in a given period, can be of high relevance for road  
60 management (e.g. Zubler et al., 2015) or airport operation. Projections of future changes in snowfall,  
61 including mean and extreme conditions, are therefore highly relevant for long-term planning and  
62 adaptation purposes in order to assess and prevent related socio-economic impacts and costs.

63 21st century climate projections typically rely on comprehensive climate models. For large-scale  
64 projections, global climate models (GCMs) with a rather coarse spatial resolution of 100 km or more  
65 are used. To assess regional to local scale impacts, where typically a much higher spatial resolution is  
66 required, a GCM can be dynamically downscaled by nesting a regional climate model (RCM) over the  
67 specific domain of interest (Giorgi, 1990). In such a setup, the GCM provides the lateral and sea  
68 surface boundary conditions to the RCM. One advantage of climate models is their ability to estimate  
69 climate change in a physically based manner under different greenhouse gas (GHG) emission  
70 scenarios. With the Intergovernmental Panel on Climate Change's (IPCC) release of the Fifth  
71 Assessment Report (AR5; IPCC, 2013) the so-called representative concentration pathway (RCP)  
72 scenarios have been introduced (Moss et al., 2010). These specify GHG concentrations and  
73 corresponding emission pathways for several radiative forcing targets. To estimate inherent projection  
74 uncertainties, ensemble approaches employing different climate models, different greenhouse gas  
75 scenarios, and/or different initial conditions are being used (e.g., Deser et al., 2012; Hawkins and  
76 Sutton, 2009; Rummukainen, 2010).

77 Within the last few years several studies targeting the future global and European snowfall evolution  
78 based on climate model ensembles were carried out (e.g., de Vries et al., 2013; de Vries et al., 2014;  
79 Krasting et al., 2013; O’Gorman, 2014; Piazza et al., 2014; Räisänen, 2016; Soncini and Bocchiola,  
80 2011). Most of these analyses are based on GCM output or older generations of RCM ensembles at  
81 comparatively low spatial resolution, which are not able to properly resolve snowfall events over  
82 regions with complex topography. New generations of high resolution RCMs are a first step toward an  
83 improvement on this issue. This is in particular true for the most recent high-resolution regional climate  
84 change scenarios produced by the global CORDEX initiative (Giorgi et al., 2009) and its European  
85 branch EURO-CORDEX (Jacob et al., 2014). The present work aims to exploit this recently  
86 established multi-model archive with respect to future snowfall conditions over the area of the  
87 European Alps. It thereby complements the existing works of Piazza et al. (2014) and de Vries et al.  
88 (2014). These two works also exploit comparatively high-resolved RCM experiments but with a smaller  
89 focus domain in the case of Piazza et al. (2014; French Alps only) and based on a single-model  
90 ensemble with a comparatively small ensemble size (eight members) in the case of de Vries et al.  
91 (2014).

92 In general and on decadal to centennial time scales, two main drivers of future snowfall changes over  
93 the European Alps with competing effects on snowfall amounts are apparent from the available  
94 literature: (1) Mean winter precipitation is expected to increase over most parts of the European Alps  
95 and in most EURO-CORDEX experiments (e.g., Rajczak et al., 2017; Smiatek et al., 2016) which in  
96 principle could lead to higher snowfall amounts. (2) Temperatures are projected to considerably rise  
97 throughout the year (e.g., Gobiet et al., 2014; Smiatek et al., 2016; Steger et al., 2013) with the  
98 general effect of a decreasing snowfall frequency and fraction, thus potentially leading to a reduction  
99 in overall snowfall amounts. Separating the above two competing factors is one of the targets of the  
100 current study. A potential complication is that changes in daily precipitation frequency (events with  
101 precipitation > 1 mm/day) and precipitation intensity (average amount on wet days) can change in a  
102 counteracting manner (e.g., Fischer et al., 2015; Rajczak et al., 2013), and that relative changes are  
103 not uniform across the event category (e.g.; Fischer and Knutti, 2016; Rajczak et al., 2017).

104 We here try to shed more light on these issues by addressing the following main objectives:

105 **Snowfall separation on the RCM grid.** Raw snowfall outputs are not available for all members of the  
106 EURO-CORDEX RCM ensemble. Therefore, an adequate snowfall separation technique, i.e., the  
107 derivation of snowfall amounts based on readily available daily near-surface air temperature and  
108 precipitation data, is required. Furthermore, we seek for a snowfall separation method that accounts  
109 for the topographic subgrid-scale variability of snowfall on the RCM grid.

110 **Snowfall bias adjustment.** Even the latest generation of RCMs is known to suffer from systematic  
111 model biases (e.g., Kotlarski et al., 2014). In GCM-driven setups as employed within the present work  
112 these might partly be inherited from the driving GCM. To remove such systematic biases in  
113 temperature and precipitation, a dedicated bias adjustment method is developed and employed in the  
114 present work. To assess its performance and applicability, different snowfall indices in the bias-  
115 adjusted and not bias-adjusted output are compared against observation-based estimates.

116 **Snowfall projections for the late 21st century.** Climate change signals for various snowfall indices  
117 over the Alpine domain and for specific elevation intervals, derived by a comparison of 30-year control  
118 and scenario periods, are analysed under the assumption of the RCP8.5 emission scenario. In  
119 addition, we aim to identify and quantify the main drivers of future snowfall changes and, in order to  
120 assess emission scenario uncertainties, compare RCP8.5-based results with experiments assuming  
121 the more moderate RCP4.5 emission scenario. Snowfall projections are generally based on three  
122 different datasets: (1) raw RCM snowfall where available, (2) RCM snowfall separated from simulated  
123 temperature and precipitation, and (3) RCM snowfall separated from simulated temperature and  
124 precipitation and additionally bias-adjusted. While all three estimates are compared for the basic  
125 snowfall indices in order to assess the robustness of the projections, more detailed analyses are  
126 based on dataset (3) only.

127 In addition and as preparatory analysis, we carry out a basic evaluation of RCM-simulated snowfall  
128 amounts. This evaluation, however, is subject to considerable uncertainties as a high-quality  
129 observation-based reference at the required spatial scale is not available, and the focus of the present  
130 work is laid on snowfall projections.

131 The article is structured as follows: Section 2 describes the data used and methods employed. In  
132 Sections 3 and 4 results of the bias adjustment approach and snowfall projections for the late 21st  
133 century are shown, respectively. The latter are further discussed in Section 5 while overall conclusions  
134 and a brief outlook are provided in Section 6. Additional supporting figures are provided in the  
135 Supplementary Material (prefix 'S' in figure numbers).

## 136 **2 Data and methods**

### 137 **2.1 Observational data**

138 To estimate the reference fine-scale snowfall, two gridded data sets, one for precipitation and one for  
139 temperature, derived from station observations and covering the area of Switzerland are used. Both  
140 data sets are available on a daily basis with a horizontal resolution of 2 km for the entire evaluation  
141 period 1971-2005 (see Sec. 2.3).

142 The gridded precipitation data set (RhiresD) represents a daily analysis based on a high-resolution  
143 rain-gauge network (MeteoSwiss, 2013a) consisting of more than 400 stations that have a balanced  
144 distribution in the horizontal but under-represent high altitudes (Frei and Schär, 1998; Isotta et al.,  
145 2014; Konzelmann et al., 2007). Albeit the data set's resolution of 2 km, the effective grid resolution as  
146 represented by the mean inter-station distance is about 15 - 20 km and thus comparable to the  
147 nominal resolution of the available climate model data (see Sec. 2.2). The dataset has not been  
148 corrected for the systematic measurement bias of rain gauges (e.g., Neff, 1977; Sevruk, 1985; Yang et  
149 al., 1999).

150 The gridded near-surface air temperature (from now on simply referred to as *temperature*) data set  
151 (TabsD) utilises a set of approx. 90 homogeneous long-term station series (MeteoSwiss, 2013b).  
152 Despite the high quality of the underlying station series, errors might be introduced by unresolved

153 scales, an uneven spatial distribution and interpolation uncertainty (Frei, 2014). The unresolved effects  
154 of land cover or local topography, for instance, probably lead to an underestimation of spatial  
155 variability. Also note that, while RhiresD provides daily precipitation sums aggregated from 6 UTC to 6  
156 UTC of the following day, TabsD is a true daily temperature average from midnight UTC to midnight  
157 UTC. Due to a high temporal autocorrelation of daily mean temperature this slight inconsistency in the  
158 reference interval of the daily temperature and precipitation grids is expected to not systematically  
159 influence our analysis.

160 In addition to the gridded temperature and precipitation datasets and in order to validate simulated raw  
161 snowfall amounts station-based observations of fresh snow sums (snow depth) at daily resolution from  
162 29 stations in Switzerland with data available for at least 80% of the evaluation period 1971-2005 are  
163 employed.

## 164 **2.2 Climate model data**

165 In terms of climate model data we exploit a recent ensemble of regional climate projections made  
166 available by EURO-CORDEX ([www.euro-cordex.net](http://www.euro-cordex.net)), the European branch of the World Climate  
167 Research Programme's CORDEX initiative ([www.cordex.org](http://www.cordex.org); Giorgi et al., 2009). RCM simulations for  
168 the European domain were run at a resolution of approximately 50 km (EUR-44) and 12 km (EUR-11)  
169 with both re-analysis boundary forcing (Kotlarski et al., 2014; Vautard et al., 2013) and GCM forcing  
170 (Jacob et al., 2014). We here disregard the reanalysis-driven experiments and employ the GCM-driven  
171 simulations only. These include historical control simulations and future projections based on RCP  
172 greenhouse gas and aerosol emission scenarios. We employ daily averaged model output of GCM-  
173 driven EUR-11 simulations that were available in December 2016 and for which control, RCP4.5 and  
174 RCP8.5 runs are provided. We hence exclusively focus on the higher resolved EUR-11 simulations  
175 and disregard the coarser EUR-44 ensemble due to the apparent added value of the EUR-11  
176 ensemble with respect to regional-scale climate features in the complex topographic setting of the  
177 European Alps (e.g., Giorgi et al., 2016; Torma et al., 2015). Out of the entire set of available EURO-  
178 CORDEX simulations, several GCM-RCM chains were either completely or partially removed from our  
179 analysis, resulting in a full set of 14 GCM-RCM combinations and a reduced set of 12 combinations  
180 only (Table 1). Reasons for removal are the existence of several realisations (MPI-ESM-REMO; only  
181 one realisation has been used) and simulation deficiencies that potentially affect our analysis  
182 (HadGEM2-RACMO, EC-EARTH-RACMO and IPSL-WRF). Further details on these issues are  
183 provided in the Supplementary Material, Part B.

184 It is important to note that each of the RCMs considered uses an individual topography field. Model  
185 topographies for a given grid cell might therefore considerably differ from each other, and also from the  
186 observation-based orography. It is therefore not meaningful to compare snowfall values at individual  
187 grid cells since the latter might be situated at different elevations. For this reason most analyses of the  
188 present work were carried out as a function of elevation, i.e., by averaging quantities over distinct  
189 elevation intervals.

## 190 **2.3 Analysis domain and periods**

191 The arc-shaped European Alps - with a West-East extent of roughly 1200 km , a total of area 190'000  
192 km<sup>2</sup> and a peak elevation of 4810 m a.s.l. (Mont Blanc) - are the highest and most prominent mountain  
193 range which is entirely situated in Europe. In the present work, two different analysis domains are  
194 used. The evaluation of the bias adjustment approach depends on the observational data sets  
195 RhiresD and TabsD (see Sec. 2.1). As these cover Switzerland only, the evaluation part of the study  
196 (Sec. 3) is constrained to the Swiss domain (Fig. 1, bold line). For the analysis of projected changes of  
197 different snowfall indices (Sec. 4 and 5) a larger domain covering the entire Alpine crest with its  
198 forelands is considered (Fig. 1, coloured region).

199 Our analysis is based on three different time intervals. The evaluation period (EVAL) 1971-2005 is  
200 used for the calibration and validation of the bias adjustment approach. Future changes of snowfall  
201 indices are computed by comparing a present-day control period (1981-2010, CTRL) to a future  
202 scenario period at the end of the 21<sup>st</sup> century (2070-2099, SCEN). For all periods (EVAL, CTRL and  
203 SCEN), the summer months June, July and August (JJA) are excluded from the analysis. In addition to  
204 seasonal mean snowfall conditions, i.e., averages over the nine-month period from September to May,  
205 we also analyse the seasonal cycle of individual snowfall indices at monthly resolution.

## 206 **2.4 Analysed snowfall indices and change signals**

207 A set of six different snowfall indices is considered (Tab. 2). Mean snowfall ( $S_{\text{mean}}$ ) refers to the  
208 (spatio-)temporally-averaged snowfall amount in mm SWE (note that from this point on we will use the  
209 term "mm" as a synonym for "mm SWE" as unit of several snowfall indices). The two indices heavy  
210 snowfall ( $S_{q99}$ ) and maximum 1-day snowfall ( $S_{1d}$ ) allow the assessment of projected changes in heavy  
211 snowfall events and amounts.  $S_{1d}$  is derived by averaging maximum 1-day snowfall amounts over all  
212 individual months/seasons of a given time period (i.e., by averaging 30 maximum values in the case of  
213 the CTRL and SCEN period), while  $S_{q99}$  is calculated from the grid point-based 99<sup>th</sup> all-day snowfall  
214 percentile of the daily probability density function (PDF) for the entire time period considered. We use  
215 all-day percentiles as the use of wet-day percentiles leads to conditional statements that are often  
216 misleading (see the analysis in Schär et al. 2016). Note that the underlying number of days differs for  
217 seasonal (September-May) and monthly analyses. Snowfall frequency ( $S_{\text{freq}}$ ) and mean snowfall  
218 intensity ( $S_{\text{int}}$ ) are based on a wet-day threshold of 1 mm/day and provide additional information about  
219 the distribution and magnitude of snowfall events, while the snowfall fraction ( $S_{\text{frac}}$ ) describes the ratio  
220 of solid precipitation to total precipitation. As climate models tend to suffer from too high occurrence of  
221 drizzle and as small precipitation amounts are difficult to measure, daily precipitation values smaller or  
222 equal to 0.1 mm were set to zero in both the observations and the simulations prior to the remaining  
223 analyses.

224 Projections are assessed by calculating two different types of changes between the CTRL and the  
225 SCEN period. The absolute change signal ( $\Delta$ ) of a particular snowfall index X (see Tab.2)

$$226 \Delta X = X_{SCEN} - X_{CTRL} \quad (1)$$

227 and the relative change signal ( $\delta$ ) which describes the change of the snowfall index as a percentage of  
 228 its CTRL period value

$$229 \quad \delta X = \left( \frac{X_{SCEN}}{X_{CTRL}} - 1 \right) \cdot 100 \quad (2)$$

230 To prevent erroneous data interpretation due to possibly large relative changes of small CTRL values,  
 231 certain grid boxes were masked out before calculating and averaging the signal of change. This  
 232 filtering was done by setting threshold values for individual indices and statistics (Tab. 2).

## 233 **2.5 Separating snowfall from total precipitation**

234 Due to (a) the lack of a gridded observational snowfall data set and (b) the fact that not all EURO-  
 235 CORDEX RCMs provide raw snowfall as an output variable, a method to separate solid from total  
 236 precipitation depending on near-surface temperature conditions is developed. The simplest approach  
 237 to separate snowfall from total precipitation is to fractionate the two phases binary by applying a  
 238 constant snow fractionation temperature (e.g., de Vries et al., 2014; Schmucki et al., 2015a; Zubler et  
 239 al., 2014). More sophisticated methods estimate the snow fraction  $f_s$  dependence on air temperature  
 240 with linear or logistic relations (e.g., Kienzle, 2008; McAfee et al., 2014). In our case, the different  
 241 horizontal resolutions of the observational (high resolution of 2 km) and simulated (coarser resolution  
 242 of 12 km) data sets further complicate a proper comparison of the respective snowfall amounts. Thus,  
 243 we explicitly analysed the snowfall amount dependency on the grid resolution and exploited  
 244 possibilities for including subgrid-scale variability in snowfall separation. This approach is important as  
 245 especially in Alpine terrain a strong subgrid-scale variability of near-surface temperatures due to  
 246 orographic variability has to be expected, with corresponding effects on the subgrid-scale snowfall  
 247 fraction.

248 For this preparatory analysis, which is entirely based on observational data, a reference snowfall is  
 249 derived. It is based on the approximation of snowfall by application of a fixed temperature threshold to  
 250 daily total precipitation amounts on the high resolution observational grid (2 km) and will be termed  
 251 *Subgrid method* thereafter: First, the daily snowfall  $S'$  at each grid point of the observational data set at  
 252 high resolution (2 km) is derived by applying a snow fractionation temperature  $T^*=2^\circ\text{C}$ . The whole  
 253 daily precipitation amount  $P'$  is accounted for as snow  $S'$  (i.e.,  $f_s=100\%$ ) for days with daily mean  
 254 temperature  $T \leq T^*$ . For days with  $T > T^*$ ,  $S'$  is set to zero and  $P'$  is attributed as rain (i.e.,  $f_s=0\%$ ). This  
 255 threshold approach with a fractionation temperature of  $2^\circ\text{C}$  corresponds to the one applied in previous  
 256 works and results appear to be in good agreement with station-based snowfall measurements (e.g.,  
 257 Zubler et al., 2014). The coarse grid (12 km) reference snowfall  $S_{SG}$  is determined by averaging the  
 258 sum of separated daily high resolution  $S'$  over all  $n$  high-resolution grid points  $i$  located within a specific  
 259 coarse grid point  $k$ . I.e., at each coarse grid point  $k$

$$260 \quad S_{SG} = \frac{1}{n} \cdot \sum_{i=1}^n P'_i [T'_i \leq T^*] = \frac{1}{n} \sum_{i=1}^n S'_i \quad (3)$$

261 For comparison, the same binary fractionation method with a temperature threshold of  $T^*=2^\circ\text{C}$  is  
 262 directly applied on the coarse 12 km grid (*Binary method*). For this purpose, total precipitation  $P'$  and  
 263 daily mean temperature  $T'$  of the high-resolution data are conservatively remapped to the coarse grid

264 leading to  $P$  and  $T$ , respectively. Compared to the *Subgrid method*, the *Binary method* neglects any  
 265 subgrid-scale variability of the snowfall fraction. As a result, the *Binary method* underestimates  $S_{\text{mean}}$   
 266 and overestimates  $S_{\text{q99}}$  for most elevation intervals (Fig. 2). The underestimation of  $S_{\text{mean}}$  can be  
 267 explained by the fact that even for a coarse grid temperature above  $T^*$  individual high-elevation  
 268 subgrid cells (at which  $T \leq T^*$ ) can receive substantial snowfall amounts. As positive precipitation-  
 269 elevation gradients can be assumed for most parts of the domain (larger total precipitation at high  
 270 elevations; see e.g. Kotlarski et al., 2012 and Kotlarski et al., 2015 for an Alpine-scale assessment)  
 271 the neglect of subgrid-scale snowfall variation in the *Binary method* hence leads to a systematic  
 272 underestimation of mean snowfall compared to the *Subgrid method*. Furthermore, following O’Gorman  
 273 (2014), heavy snowfall events are expected to occur in a narrow temperature range below the rain-  
 274 snow transition. As the *Binary method* in these temperature ranges always leads to a snowfall fraction  
 275 of 100%, too large  $S_{\text{q99}}$  values would result.

276 To take into account these subgrid-scale effects, a more sophisticated approach – referred to as the  
 277 *Richards method* – is developed here. This method is based upon a generalised logistic regression  
 278 (Richards, 1959). Here, we apply this regression to relate the surface temperature  $T$  to the snow  
 279 fraction  $f_s$  by accounting for the topographic subgrid-scale variability. At each coarse grid-point  $k$ , the  
 280 *Richards method*-based snowfall fraction  $f_{s,RI}$  for a given day is hence computed as follows:

$$281 \quad f_{s,RI}(T_k) = \frac{1}{[1 + C_k \cdot e^{D_k \cdot (T_k - T^*)}]^{C_k}} \quad (4)$$

282 with  $C$  as the point of inflexion (denoting the point with largest slope), and  $D$  the growth rate (reflecting  
 283 the mean slope).  $T_k$  is the daily mean temperature of the corresponding coarse grid box  $k$  and  $T^*=2^\circ\text{C}$   
 284 the snow fractionation temperature. First, we estimate the two parameters  $C$  and  $D$  of Equation 4 for  
 285 each single coarse grid point  $k$  by minimizing the least-square distance to the  $f_s$  values derived by the  
 286 *Subgrid method* via the reference snowfall  $S_{SG}$  (local fit). Second,  $C$  and  $D$  are expressed as a function  
 287 of the topographic standard deviation  $\sigma_h$  of the corresponding coarse resolution grid point only (Fig.  
 288 S1; global fit). This makes it possible to define empirical functions for both  $C$  and  $D$  that can be used  
 289 for all grid points  $k$  in the Alpine domain and that depend on  $\sigma_h$  only.

$$290 \quad \sigma_{h,k} = \sqrt{\frac{\sum_i^n (h_i - \bar{h}_k)^2}{n-1}} \quad (5)$$

$$291 \quad C_k = \frac{1}{(E - \sigma_{h,k} \cdot F)} \quad (6)$$

$$292 \quad D_k = G \cdot \sigma_{h,k}^{-H} \quad (7)$$

293 Through a minimisation of the least square differences the constant parameters in Equations 6 and 7  
 294 are calibrated over the domain of Switzerland and using daily data from the period September to May  
 295 1971-2005 leading to values of  $E=1.148336$ ,  $F=0.000966 \text{ m}^{-1}$ ,  $G=143.84113 \text{ }^\circ\text{C}^{-1}$  and  $H=0.8769335$ .  
 296 Note that  $\sigma_h$  is sensitive to the resolution of the two grids to be compared (cf. Eq. 5). It is a measure for  
 297 the uniformity of the underlying topography and has been computed based on the high-resolution  
 298 GTOPO30 digital elevation model (<https://lta.cr.usgs.gov/GTOPO30>) aggregated to a regular grid of

299 1.25 arc seconds (about 2 km) which reflects the spatial resolution of the observed temperature and  
300 precipitation grids (cf. Sec. 2.1). Small values of  $\sigma_h$  indicate a low subgrid-scale topographic variability,  
301 such as in the Swiss low-lands, while high values result from non-uniform elevation distributions, such  
302 as in areas of inner Alpine valleys.  $\sigma_h$  as derived from GTOPO30 might be different from the subgrid-  
303 scale topographic variance employed by the climate models themselves, which is however not  
304 relevant here as only grid cell-averaged model output is analysed while  $\sigma_h$  is regarded as a proper  
305 estimate of subgrid-scale variability.

306 Figure S1 (panel c) provides an example of the relation between daily mean temperature and daily  
307 snow fraction  $f_s$  for grid cells with topographical standard deviations of 50 m and 500 m, respectively.  
308 The snowfall amount  $S_{RI}$  for a particular day and a particular coarse grid box is finally obtained by  
309 multiplying the corresponding  $f_{s,RI}$  and  $P$  values. A comparison with the *Subgrid method* yields very  
310 similar results. For both indices  $S_{\text{mean}}$  and  $S_{\text{q99}}$ , mean ratios across all elevation intervals are close to 1  
311 (Fig. 2). At single grid points, maximum deviations are not larger than  $1 \pm 0.1$ . Note that for this  
312 comparison calibration and validation period are identical (EVAL period). Based on this analysis, it has  
313 been decided to separate snowfall according to the *Richards method* throughout this work in both the  
314 observations and in the RCMs. The observation-based snowfall estimate obtained by applying the  
315 *Richards method* to the observational temperature and precipitation grids after spatial aggregation to  
316 the  $0.11^\circ$  RCM resolution will serve as reference for the RCM bias adjustment and will be termed  
317 *reference* hereafter. One needs to bear in mind that the parameters  $C$  and  $D$  of the Richards method  
318 were fitted for the Swiss domain only and were later on applied to the entire Alpine domain (cf. Fig. 1).

## 319 **2.6 Bias adjustment approach**

320 Previous work has revealed partly substantial temperature and precipitation biases of the EURO-  
321 CORDEX RCMs over the Alps (e.g. Kotlarski et al., 2014; Smiatek et al., 2016), and one has to expect  
322 that the separated snowfall amounts are biased too. This would especially hamper the interpretation of  
323 absolute climate change signals of the considered snow indices. We therefore explore possibilities to  
324 bias-adjust the simulated snowfall amounts and to directly integrate this bias adjustment into the  
325 snowfall separation framework of Section 2.5. Note that we deliberately employ the term *bias*  
326 *adjustment* as opposed to *bias correction* to make clear that only certain aspects of the snowfall  
327 climate are adjusted and that the resulting dataset might be subject to remaining inaccuracies.

328 A simple two-step approach that separately accounts for precipitation and temperature biases and  
329 their respective influence on snowfall is chosen. The separate consideration of temperature and  
330 precipitation biases allows for a more physically-based bias adjustment of snowfall amounts: Due to  
331 the temperature dependency of snowfall occurrence, snowfall biases of a given climate model cannot  
332 be expected to remain constant under changing climate conditions. For instance, a climate model with  
333 a given temperature bias might pass the snow-rain temperature threshold earlier or later than reality  
334 during the general warming process. Hence, traditional bias adjustment approaches based only on a  
335 comparison of observed and simulated snowfall amounts in the historical climate would possibly fail  
336 due to a non-stationary bias structure. The bias adjustment is calibrated in the EVAL period for each  
337 individual GCM-RCM chain and over the region of Switzerland, and is then applied to both the CTRL

338 and SCEN period of each chain and for the entire Alpine domain. To be consistent in terms of  
339 horizontal grid spacing, the observational data sets RhiresD and TabsD (see Sec. 2.1) are  
340 conservatively regridded to the RCM resolution beforehand.

341 In a first step, total simulated precipitation is adjusted by introducing an elevation-dependent  
342 adjustment factor which adjusts precipitation biases regardless of temperature. For this purpose, mean  
343 precipitation ratios (RCM simulation divided by observational analysis) for 250 m elevation intervals  
344 are calculated (Fig. S3). An almost linear relationship of these ratios with elevation is found. Thus, a  
345 linear regression between the intervals from 250 m a.s.l. to 2750 m a.s.l. is used for each model chain  
346 separately to estimate a robust adjustment factor. As the number of both RCM grid points and  
347 measurement stations at very high elevations (>2750 m a.s.l.) is small (Sec. 2.1; Fig. S2) and biases  
348 are subject to a considerable sampling uncertainty, these elevations are not considered in the  
349 regression. Overall the fits are surprisingly precise except for the altitude bins above 2000 m (Fig. S3).  
350 The precipitation adjustment factors ( $P_{AF}$ ) for a given elevation are then obtained as the inverse of the  
351 fitted precipitation ratios. Multiplying simulated precipitation  $P$  with  $P_{AF}$  for the respective model chain  
352 and elevation results in the adjusted precipitation:

$$353 \quad P_{adj} = P \cdot P_{AF} \quad (8)$$

354 For a given GCM-RCM chain and for each elevation interval, the spatially and temporally averaged  
355 corrected total precipitation  $P_{adj}$  approximately corresponds to the observation-based estimate in the  
356 EVAL period.

357 In the second step of the bias adjustment procedure, temperature biases are accounted for. For this  
358 purpose the initial snow fractionation temperature  $T^*=2^\circ\text{C}$  of the Richards separation method (see Sec  
359 2.5) is shifted to the value  $T_a^*$  for which the spatially (Swiss domain) and temporally (September to  
360 May) averaged simulated snowfall amounts for elevations below 2750 m a.s.l. match the respective  
361 observation-based reference (see above). Compared to the adjustment of total precipitation,  $T_a^*$  is  
362 chosen independent of elevation but separately for each GCM-RCM chain, in order to avoid over-  
363 parameterization and to not over-interpret the elevation dependency of mean snowfall in the snowfall  
364 reference grid. After this second step of the bias adjustment, the spatially and temporally averaged  
365 simulated snowfall amounts below 2750 m a.s.l. match the reference by definition. Hence, the  
366 employed simple bias adjustment procedure adjusts domain-mean snowfall biases averaged over the  
367 entire season from September to May. It does, however, not correct for biases in the spatial snowfall  
368 pattern, in the seasonal cycle, or in the temporal distribution of daily values. Note that, as the  
369 underlying high-resolution data sets are available over Switzerland only, the calibration of the bias  
370 adjustment methodology is correspondingly restricted, but the adjustment is then applied to the whole  
371 Alpine domain. This approach is justified as elevation-dependent mean winter precipitation and  
372 temperature biases of the RCMs employed - assessed by comparison against the coarser-resolved  
373 EOBS reference dataset (Haylock et al., 2008) - are very similar for Switzerland and for the entire  
374 Alpine analysis domain (Figs. S4 and S5).

### 375 **3 Evaluation**

#### 376 **3.1 RCM raw snowfall**

377 We first carry out an illustrative comparison of RCM raw snowfall amounts (for those simulations only  
378 that directly provide snowfall flux) against station observations of snowfall in order to determine  
379 whether the simulated RCM snowfall climate contains valid information despite systematic biases. To  
380 this end, simulated raw snowfall amounts of seven EURO-CORDEX simulations of the reduced set  
381 (Tab. 1) averaged over 250 m-elevation intervals and over the range 950 – 1650 m a.s.l. are  
382 compared against observations of measured fresh snow sums from 29 MeteoSwiss stations (Sec.  
383 2.1).. For this purpose a mean snow density of  $100 \text{ kg/m}^3$  for the conversion from measured snow  
384 depth to water equivalent is assumed. Note that this simple validation is subject to considerable  
385 uncertainties as it does not explicitly correct for the scale and elevation gap between grid-cell based  
386 RCM output and single-site observations. Especially in complex terrain and for exposed sites, point  
387 measurements of snow depth might be non-representative for larger-scale conditions (e.g., Grünewald  
388 and Lehning, 2015). Also, the conversion from snow depth to snow water equivalent is of approximate  
389 nature only, and fresh snow sums might furthermore misrepresent true snowfall in case that snow melt  
390 or snow drift occurs between two snow depth readings.

391 At low elevations simulated mean September-May raw snowfall sums match the observations well  
392 while differences are larger aloft (Fig. 3a). The positive bias at high elevations might arise from the fact  
393 that (the very few) observations were made at specific locations while simulated grid point values of  
394 the corresponding elevation interval might be located in different areas of Switzerland. It might also be  
395 explained by positive RCM precipitation and negative RCM temperature biases at high elevations of  
396 the Alps (e.g., Kotlarski et al., 2015). Also note that, in general, the total high-elevation area of the  
397 Alpine analysis domain is small and elevations above 2500 m represent less than 5% of the total area  
398 (Fig. S2). Both model-based and observation-based estimates for high-elevations are hence subject to  
399 a considerable sampling uncertainty and are likely to be less robust than estimates for lower  
400 elevations.

401 At lower elevations, the station network is geographically more balanced and the observations are  
402 probably more representative of the respective elevation interval. Despite a clear positive snowfall bias  
403 in mid-winter, the RCMs are generally able to reproduce the mean seasonal cycle of snowfall for  
404 elevations between 950 m a.s.l. - 1650 m a.s.l. (Fig. 3b). The fact that the major patterns of both the  
405 snowfall-elevation relationship and the mean seasonal snowfall cycle are well represented indicates  
406 the general and physically consistent applicability of RCM output to assess future changes in mean  
407 and heavy Alpine snowfall. However, substantial biases in snowfall amounts are apparent and a bias  
408 adjustment of simulated snowfall seems to be required prior to the analysis of climate change signals  
409 of individual snowfall indices.

#### 410 **3.2 Evaluation of the reference snowfall**

411 The snowfall separation employing the *Richards method* (Sec. 2.5) and, as a consequence, also the  
412 bias adjustment (Sec. 2.6) make use of the 2 km reference snowfall grid derived by employing the

413 *Subgrid method* on the observed temperature and precipitation grids. Hence, the final results of this  
414 study could to some extent be influenced by inaccuracies and uncertainties of the reference snowfall  
415 grid itself. In order to assess the quality of the latter and in absence of a further observation-based  
416 reference we here present an approximate evaluation.

417 First, the reference snowfall grid is evaluated against fresh snow sums at the 29 Swiss stations that  
418 are also used for evaluating RCM raw snowfall. Note the limitations of such a comparison as outlined  
419 in Chapter 3.1. The comparison of black and red markers and lines in Figure 3 indicates a good  
420 agreement of mean snowfall at individual elevation intervals (left panel) as well for the mean annual  
421 cycle of snowfall at medium elevations (right panel). The reference snowfall grid is obviously a good  
422 approximation of site-scale fresh snow sums. Note that similarly to the RCM raw snowfall evaluation,  
423 all 2 km reference snowfall grid cells in the respective elevation interval are considered. The good  
424 agreement, however, still holds if only those 2 km grid cells covering the 29 site locations are  
425 considered (not shown here).

426 Second, both the 2 km reference snowfall grid and the 0.11° reference snowfall grid obtained by  
427 employing the Richards method to aggregated temperature and precipitation values (Sec. 2.5) are  
428 compared against the gridded HISTALP dataset of solid precipitation (Chimani et al., 2011). The latter  
429 is provided at a monthly resolution on a 5' grid covering the Greater Alpine Region. It is based on  
430 monthly snowfall fraction estimates that are used to scale a gridded dataset of total precipitation. The  
431 comparison of the three datasets for the region of Switzerland (for which the 2 km reference snowfall  
432 is available) in the EVAL period 1971-2005 yields an approximate agreement of both the magnitude of  
433 mean winter snowfall and its spatial pattern (Fig. S6). The three data sets differ with respect to their  
434 spatial resolution but all show a clear dependency of snowfall on topography and mean September-  
435 May snowfall sums above 1000 mm over most parts of the Alpine ridge. Climatologically warm and dry  
436 valleys, on the other hand, are represented by minor snowfall amounts of less than 400 mm only.

437 As mentioned before these evaluations of the reference snowfall grid are subject to uncertainties and,  
438 furthermore, they only cover mean snowfall amounts. However, they provide basic confidence in the  
439 applicability of the reference snowfall grid for the purposes of snowfall separation and bias adjustment  
440 in the frame of the present study.

441

### 442 **3.3 Calibration of bias adjustment**

443 The analysis of total precipitation ratios (RCM simulations with respect to observations) for the EVAL  
444 period, which are computed to carry out the first step of the bias adjustment procedure, reveals  
445 substantial elevation dependencies. All simulations tend to overestimate total precipitation at high  
446 elevations (Fig. S3). This fact might ultimately be connected to an overestimation of surface snow  
447 amount in several EURO-CORDEX RCMs as reported by Terzago et al. (2017). As the precipitation  
448 ratio between simulations and observations depends approximately linearly on elevation, the  
449 calculation of  $P_{AF}$  via a linear regression of the ratios against elevation (see Sec. 2.6) seems  
450 reasonable. By taking the inverse of this linear relation,  $P_{AF}$  for every model and elevation can be

451 derived. For the CCLM simulations, these correction factors do not vary much with height, while  $P_{AF}$   
452 for MPI-ESM - REMO and EC-EARTH - HIRHAM is much larger than 1 in low lying areas, indicating a  
453 substantial underestimation of observed precipitation sums (Fig. 4a). However, for most elevations  
454 and simulations,  $P_{AF}$  is generally smaller than 1, i.e., total precipitation is overestimated by the models.  
455 Similar model biases in the winter and spring seasons have already been reported in previous works  
456 (e.g., Rajczak et al., 2017; Smiatek et al., 2016). Especially at high elevations, these apparent positive  
457 precipitation biases could be related to observational undercatch, i.e., an underestimation of true  
458 precipitation sums by the observational analysis. Frei et al. (2003) estimated seasonal Alpine  
459 precipitation undercatch for three elevation intervals. Results show that measurement biases are  
460 largest in winter and increase with altitude. However, a potential undercatch (with a maximum of  
461 around 40% at high elevations in winter; Frei et al., 2003) can only partly explain the often substantial  
462 overestimation of precipitation found in the present work.

463 After applying  $P_{AF}$  to the daily precipitation fields, a snowfall fractionation at the initial  $T^*$  of 2 °C (see  
464 Eq. (4)) would lead to a snowfall excess in all 12 simulations as models typically experience a cold  
465 winter temperature bias. To match the observation-based and spatio-temporally averaged reference  
466 snowfall below 2750 m a.s.l.,  $T^*$  for all models needs to be decreased during the second step of the  
467 bias adjustment (Fig. 4b). The adjusted  $T_a^*$  values indicate a clear positive relation with the mean  
468 temperature bias in the EVAL period. This feature is expected since the stronger a particular model's  
469 cold bias the stronger the required adjustment of the snow fractionation temperature  $T^*$  towards lower  
470 values in order to avoid a positive snowfall bias. Various reasons for the scatter around a simple linear  
471 relation in Figure 4b can be thought of. These include remaining spatial inaccuracies of the corrected  
472 precipitation grid, elevation-dependent temperature biases and misrepresented temperature-  
473 precipitation relationships at daily scale. Note that precipitation and temperature biases heavily  
474 depend on the GCM-RCM chain and seem to be rather independent from each other. Concerning the  
475 partly substantial temperature biases of the EURO-CORDEX models shown in Figure 4b, their  
476 magnitude largely agrees with Kotlarski et al. (2014; in reanalysis-driven simulations) and Smiatek et  
477 al. (2016).

### 478 **3.4 Evaluation of snowfall indices**

479 We next assess the performance of the bias adjustment procedure by comparing snowfall indices  
480 derived from separated and bias-adjusted RCM snowfall amounts against the observation-based  
481 reference. The period for which this comparison is carried out is EVAL, i.e., it is identical to the  
482 calibration period of the bias adjustment. We hence do not intend a classical cross validation exercise  
483 with separate calibration and validation periods, but try to answer the following two questions: (a)  
484 Which aspects of the Alpine snowfall climate are adjusted, and (b) for which aspects do biases remain  
485 even after application of the bias adjustment procedure.

486 Figure 5 shows the evaluation results of the six snowfall indices based on the separated and not bias-  
487 adjusted simulated snowfall ( $RCM_{sep+nba}$ ), and the separated and bias-adjusted simulated snowfall  
488 ( $RCM_{sep+ba}$ ). In the first case the snowfall separation of raw precipitation is performed with  $T^*=2^\circ\text{C}$ ,  
489 while in the second case precipitation is adjusted and the separation is performed with a bias-adjusted

490 temperature  $T^*_a$ . The first column represents the mean September to May statistics, while columns 2-4  
491 depict the seasonal cycle at monthly resolution for three distinct elevation intervals.

492 The analysis of  $S_{\text{mean}}$  confirms that  $\text{RCM}_{\text{sep+ba}}$  is able to reproduce the observation-based reference in  
493 the domain mean as well as in most individual elevation intervals. The domain-mean agreement is a  
494 direct consequence of the design of the bias adjustment procedure (see above).  $\text{RCM}_{\text{sep+nba}}$ , on the  
495 other hand, consistently overestimates  $S_{\text{mean}}$  by up to a factor of 2.5 as a consequence of positive  
496 precipitation and negative temperature biases (cf. Fig. 4). Also the seasonal cycle of  $S_{\text{mean}}$  for  
497  $\text{RCM}_{\text{sep+ba}}$  yields a satisfying performance across all three elevation intervals, while  $\text{RCM}_{\text{sep+nba}}$  tends  
498 to produce too much snowfall over all months and reveals an increasing model spread with elevation.

499 For the full domain and elevations around 1000 m, the observation-based reference indicates a mean  
500  $S_{\text{freq}}$  of 20% between September and May. Up to 1000 m a.s.l.  $\text{RCM}_{\text{sep+ba}}$  reflects the increase of this  
501 index with elevation adequately. However, towards higher elevations the approximately constant  $S_{\text{freq}}$   
502 of 30% in the reference is not captured by the simulation-derived snowfall. Notably during wintertime,  
503 both  $\text{RCM}_{\text{sep+ba}}$  and  $\text{RCM}_{\text{sep+nba}}$  produce too many snowfall days, i.e., overestimate snowfall frequency.  
504 This feature is related to the fact that climate models typically tend to overestimate the wet day  
505 frequency over the Alps especially in wintertime (Rajczak et al., 2013) and that the bias adjustment  
506 procedure employed does not explicitly correct for potential biases in precipitation frequency. Due to  
507 the link between mean snowfall on one side and snowfall frequency and mean intensity on the other  
508 side, opposite results are obtained for the mean snowfall intensity  $S_{\text{int}}$ .  $\text{RCM}_{\text{sep+ba}}$  largely  
509 underestimates mean intensities during snowfall days while  $\text{RCM}_{\text{sep+nba}}$  typically better reflects the  
510 reference. Nevertheless, deviations during winter months at mid-elevations are not negligible. Mean  
511 September-May  $S_{\text{frac}}$  in the reference exponentially increases with elevation. This behaviour is  
512 reproduced by both  $\text{RCM}_{\text{sep+ba}}$  and  $\text{RCM}_{\text{sep+nba}}$ . Notwithstanding,  $\text{RCM}_{\text{sep+ba}}$  results are more accurate  
513 compared to  $\text{RCM}_{\text{sep+nba}}$ , which turns out to be biased towards too large snowfall fractions.

514 For the two heavy snowfall indices  $S_{\text{q99}}$  and  $S_{\text{1d}}$ ,  $\text{RCM}_{\text{sep+nba}}$  appears to typically match the reference  
515 better than  $\text{RCM}_{\text{sep+ba}}$ . Especially at high elevations,  $\text{RCM}_{\text{sep+ba}}$  produces too low snowfall amounts.  
516 This again illustrates the fact that the bias adjustment procedure is designed to adjust biases in mean  
517 snowfall, but does not necessarily improve further aspects of the simulated snowfall climate.

518 The spatial patterns of  $S_{\text{mean}}$  for the 12  $\text{RCM}_{\text{sep+ba}}$  simulations from September to May are presented in  
519 Figure 6. The observational-based reference (lower-right panel) reveals a snowfall distribution with  
520 highest values along the Alpine main ridge, whereas the Swiss plateau, Southern Ticino and main  
521 valleys such as the Rhône and Rhine valley experience less snowfall. Almost all bias-adjusted models  
522 are able to represent the overall picture with snow-poor lowlands and snow-rich Alpine regions.  
523 Nevertheless substantial differences to the observations concerning the spatial snowfall pattern can  
524 arise. EC-EARTH - HIRHAM, for example, is subject to a noisy structure. This could be the result of  
525 frequent grid-cell storms connected to parameterisations struggling with complex topographies. Such  
526 inaccuracies in the spatial pattern are not corrected for by our simple bias adjustment approach which  
527 only targets domain-mean snowfall amounts at elevations below 2750 m a.s.l. and that does not  
528 considerably modify the simulated spatial snowfall patterns.. Note that these patterns are obviously

529 strongly determined by the RCM itself and only slightly depend on the driving GCM (see, for instance,  
530 the good agreement among the CCLM and the RCA simulations).

531 In summary, after applying the bias adjustment to the simulations most snowfall indices are fairly well  
532 represented at elevations below 1000 m a.s.l.. With increasing altitude and smaller sample sizes in  
533 terms of number of grid cells, reference and RCM<sub>sep+ba</sub> diverge. This might be caused by the remaining  
534 simulated overestimation of  $S_{\text{freq}}$  and an underestimation of  $S_{\text{int}}$ . While the bias adjustment approach  
535 leads to a reduction of  $S_{\text{int}}$  due to the total precipitation adjustment,  $S_{\text{freq}}$  is only slightly modified by this  
536 correction and by the adjustment of  $T^*$ . Nevertheless, these two parameters strongly influence other  
537 snowfall indices. The counteracting effects of overestimated  $S_{\text{freq}}$  and underestimated  $S_{\text{int}}$  result in  
538 appropriate amounts of  $S_{\text{mean}}$  whereas discrepancies for  $S_{\text{q99}}$  and  $S_{\text{1d}}$  are mainly driven by the  
539 underestimation of  $S_{\text{int}}$ .

#### 540 **4 Snowfall projections for the late 21<sup>st</sup> century**

541 For the study of climate change signals, the analysis domain is extended to the entire Alps (see Sec.  
542 2.3). Due to the identified difficulties of bias-adjusting certain snowfall indices (see Sec 3.4), emphasis  
543 is laid on relative signals of change (see Eq. 2). This type of change can be expected to be less  
544 dependent on the remaining inaccuracies after the adjustment. If not stated otherwise, all results in  
545 this Section are based on the RCM<sub>sep+ba</sub> data, i.e., on separated and bias-adjusted RCM snowfall, and  
546 on the RCP8.5 emission scenario. Depending on the type of analysis, either the full or the reduced  
547 model set is used (see Tab. 1 and Supplementary Material, Part B).

548 Projections for seasonal  $S_{\text{mean}}$  show a considerable decrease over the entire Alpine domain (Fig. 7).  
549 Most RCMs project largest percentage losses of more than 80% across the Alpine forelands and  
550 especially in its topographic depressions such as the Po and Rhone valleys. Over the Alpine ridge,  
551 reductions are smaller but still mostly negative. Elevated regions between Southeastern Switzerland,  
552 Northern Italy and Austria seem to be least affected by the overall snowfall reduction. Some of the  
553 simulations (e.g., CNRM-RCA, MPI-ESM-RCA or MPI-ESM-REMO) project only minor changes in  
554 these regions. Experiments employing the same RCM but different driving GCMs (e.g. the four  
555 simulations of RCA), but also experiments employing the same GCM but different RCMs (e.g. the four  
556 simulations driven by EC-EARTH, though different realizations) can significantly disagree in regional-  
557 scale change patterns and especially in the general magnitude of change. This highlights a strong  
558 influence of both the driving GCMs and the RCMs themselves on snowfall changes, representing  
559 effects of large-scale circulation and meso-scale response, respectively.

560 A more detailed analysis is provided in Fig. 8 which addresses the vertical and seasonal distribution of  
561 snowfall changes. It reveals that relative (seasonal mean) changes of  $S_{\text{mean}}$  appear to be strongly  
562 dependent on elevation (Fig.8, top left panel). The multi-model mean change ranges from -80% at low  
563 elevations to -10% above 3000 m a.s.l.. Largest differences between neighbouring elevation intervals  
564 are obtained from 750 m a.s.l. to 1500 m a.s.l.. Over the entire Alps, the results show a reduction of  
565  $S_{\text{mean}}$  by -35% to -55% with a multi-model mean of -45%. The multi-model spread appears to be rather  
566 independent of elevation and is comparably small, confirming that, overall, the spatial distribution of

567 the change pattern is similar across all model chains (cf. Fig. 7). All simulations point to decreases  
568 over the entire nine-month period September to May for the two elevation intervals <1000 m a.s.l. and  
569 1000 to 2000 m a.s.l.. Above 2000 m a.s.l., individual simulations show an increase of  $S_{\text{mean}}$  by up to  
570 20% in mid-winter which leads to a slightly positive change in the multi-model mean in January and  
571 February.

572 Decreases of  $S_{\text{freq}}$  are very similar to changes in mean snowfall. Mean September-May changes are  
573 largest below 1000 m a.s.l., while differences among elevation intervals become smaller at higher  
574 elevations. In-between is a transition zone with rather strong changes with elevation, which  
575 approximately corresponds to the mean elevation of the September-May zero-degree line in today's  
576 climate (e.g., Ceppi et al., 2012; MeteoSchweiz, 2016). Individual simulations with large reductions in  
577  $S_{\text{mean}}$ , such as the RCA experiments, also project strongest declines in  $S_{\text{freq}}$ . In contrast, the mean  
578 snowfall intensity  $S_{\text{int}}$  is subject to smallest percentage variations in our set of snowfall indices. Strong  
579 percentage changes for some models in September are due to the small sample size (only few grid  
580 points considered) and the low snowfall amounts in this month. Apart from mid elevations with  
581 decreases of roughly -10%, mean intensities from September to May are projected to remain almost  
582 unchanged by the end of the century. For both seasonal and monthly changes, model agreement is  
583 best for high elevations while the multi-model spread is largest for the lowlands. Large model spread  
584 at low elevations might be caused by the small number of grid points used for averaging over the  
585 respective elevation interval, especially in autumn and spring.

586 Similar results are obtained for the heavy snowfall indices  $S_{\text{q99}}$  and  $S_{\text{1d}}$ . While percentage decreases  
587 at lowermost elevations are even larger than for  $S_{\text{mean}}$ , losses at high elevations are less pronounced,  
588 resulting in similar domain-mean change signals for heavy and mean snowfall. Substantial differences  
589 between monthly  $\delta S_{\text{q99}}$  and  $\delta S_{\text{1d}}$  appear at elevations below 1000 m a.s.l.. Here, percentage losses of  
590  $S_{\text{q99}}$  are typically slightly more pronounced. Above 2000 m a.s.l. both indices appear to remain almost  
591 constant between January and March with change signals close to zero. The multi-model mean  
592 changes even hint to slight increases of both indices. Concerning changes in the snowfall fraction, i.e.,  
593 in the relative contribution of snowfall to total precipitation, our results indicate that current seasonal  
594 and domain mean  $S_{\text{frac}}$  might drop by about -50% (Fig. 8, lowermost row). Below 1000 m a.s.l., the  
595 strength of the signal is almost independent of the month, and multi-model average changes of the  
596 snow fraction of about -80% are obtained. At higher elevations changes during mid-winter are less  
597 pronounced compared to autumn and spring but still negative.

## 598 **5 Discussion**

### 599 **5.1 Effect of temperature, snowfall frequency and intensity on snowfall changes**

600 The results in Section 4 indicate substantial changes of snowfall indices over the Alps in regional  
601 climate projections. With complementary analyses presented in Figures 9 and 10 we shed more light  
602 on the responsible mechanisms, especially concerning projected changes in mean and heavy  
603 snowfall. For this purpose Figures 9a-b,e-f show the relationship of both mean and heavy snowfall  
604 amounts in the CTRL period and their respective percentage changes with the climatological CTRL

605 temperature of the respective (climatological) month, elevation interval and GCM-RCM chain. For  
606 absolute amounts ( $S_{\text{mean}}$ ,  $S_{\text{q99}}$ ; Fig. 9a,e) a clear negative relation is found, i.e., the higher the CTRL  
607 temperature the lower the snowfall amounts. For  $S_{\text{mean}}$  the relation levels off at mean temperatures  
608 higher than about 6°C with mean snowfall amounts close to zero. For temperatures below about -6°C  
609 a considerable spread in snowfall amounts is obtained, i.e., mean temperature does not seem to be  
610 the controlling factor here. Relative changes of both quantities (Fig. 9b,f), however, are strongly  
611 controlled by the CTRL period's temperature level with losses close to 100% for warm climatic settings  
612 and partly increasing snowfall amounts for colder climates. This dependency of relative snowfall  
613 changes on CTRL temperature is in line with previous works addressing future snowfall changes on  
614 both hemispheric and regional scales (de Vries et al., 2014; Krasting et al., 2013; Räisänen, 2016).  
615 The spread of changes within a given CTRL temperature bin can presumably be explained by the  
616 respective warming magnitudes that differ between elevations, months and GCM-RCM chains. About  
617 half of this spread can be attributed to the month and the elevation alone (compare the spread of the  
618 black markers to the one of the red markers which indicate multi-model averages).

619 For most months and elevation intervals, percentage reductions in  $S_{\text{mean}}$  and  $S_{\text{q99}}$  reveal an almost  
620 linear relationship with  $\delta S_{\text{freq}}$  (Fig. 9c, g). The decrease of  $S_{\text{freq}}$  with future warming can be explained  
621 by a shift of the temperature probability distribution towards higher temperatures, leading to fewer  
622 days below the freezing level (Fig. 10, top row). Across the three elevation intervals <1000 m a.s.l.,  
623 1000-2000 m a.s.l. and > 2000 m a.s.l., relative changes in the number of days with temperatures  
624 below the freezing level ( $T \leq 0^\circ\text{C}$ ) are in the order of -65%, -40% and -20%, respectively (not shown).  
625 This approximately corresponds to the simulated decrease of  $S_{\text{freq}}$  (cf. Fig 8), which in turn, is of a  
626 similar magnitude as found in previous works addressing future snowfall changes in the Alps  
627 (Schmucki et al., 2015b; Zubler et al., 2014). Due to the general shift of the temperature distribution  
628 and the "loss" of very cold days (Fig. 10, top row) future snowfall furthermore occurs in a narrower  
629 temperature range (Fig. 10, second row).

630 Contrasting this general pattern of frequency-driven decreases of both mean and heavy snowfall, no  
631 changes or even slight increases of  $S_{\text{mean}}$ ,  $S_{\text{q99}}$  and  $S_{\text{1d}}$  at high elevations are expected in mid-winter  
632 (see Fig. 8). This can to some part be explained by the general increase of total winter precipitation  
633 (Rajczak et al., 2017; Smiatek et al., 2016) that obviously offsets the warming effect in high-elevation  
634 regions where a substantial fraction of the future temperature PDF is still located below the rain-snow  
635 transition (Fig. 10, top row). This process has also been identified in previous works to be, at last  
636 partly, responsible for future snowfall increases (de Vries et al., 2014; Krasting et al., 2013; Räisänen,  
637 2016). Furthermore, the magnitude of the increases of both mean and heavy snowfall is obviously  
638 driven by positive changes of  $S_{\text{int}}$ , while  $S_{\text{freq}}$  remains constant (Fig. 9c,g). An almost linear relationship  
639 between positive changes of  $S_{\text{int}}$  and positive changes of  $S_{\text{mean}}$  and  $S_{\text{q99}}$  is obtained (Fig. 9d,h; upper  
640 right quadrants). Nevertheless, the high-elevation mid-winter growth in  $S_{\text{mean}}$  is smaller than the  
641 identified increases of mean winter total precipitation. This can be explained by the persistent  
642 decrease of  $S_{\text{frac}}$  during the cold season (see Fig. 8, lowermost row).

643 For elevation intervals with simulated monthly temperatures between  $-6^{\circ}\text{C}$  and  $0^{\circ}\text{C}$  in the CTRL  
644 period,  $S_{\text{mean}}$  appears to decrease stronger than  $S_{\text{q99}}$  (cf. Fig. 9b,f). O’Gorman (2014) found a very  
645 similar behaviour when analysing mean and extreme snowfall projections over the Northern  
646 Hemisphere within a set of GCMs. This finding is related to the fact that future snowfall decreases are  
647 mainly governed by a decrease of snowfall frequency while snowfall increases in high-elevated  
648 regions in mid-winter seem to be caused by increases of snowfall intensity. It can obviously be  
649 explained by the insensitivity of the temperature interval at which extreme snowfall occurs to climate  
650 warming and by the shape of the temperature – snowfall intensity distribution itself (Fig. 10, third row).  
651 The likely reason behind positive changes of  $S_{\text{int}}$  at high-elevated and cold regions is the higher water  
652 holding capacity of the atmosphere in a warmer climate. According to the Clausius-Clapeyron relation,  
653 saturation vapour pressure increases by about 7% per degree warming (Held and Soden, 2006).  
654 Previous studies have shown that simulated changes of heavy and extreme precipitation on daily time  
655 scales are consistent with this theory (e.g., Allen and Ingram, 2002; Rajczak et al., 2017). In terms of  
656 snowfall, we find the Clausius-Clapeyron relation to be applicable for negative temperatures up to  
657 approximately  $-5^{\circ}\text{C}$  as well (Fig. 10, third row, dashed lines). Inconsistencies for temperatures  
658 between  $-5^{\circ}\text{C}$  and  $0^{\circ}\text{C}$  are due to a snow fraction  $sf < 100\%$  for corresponding precipitation events.

659 For further clarification, Figure 11 schematically illustrates the governing processes behind the  
660 changes of mean and heavy snowfall that differ between climatologically warm (decreasing snowfall)  
661 and climatologically cold climates (increasing snowfall). As shown in Figure 10 (third row), the mean  
662  $S_{\text{int}}$  distribution is rather independent on future warming and similar temperatures are associated with  
663 similar mean snowfall intensities. In particular, heaviest snowfall is expected to occur slightly below the  
664 freezing level in both the CTRL and the SCEN period (Fig. 11a). How often do such conditions prevail  
665 in the two periods? In a warm current climate, i.e., at low elevations or in the transition seasons, heavy  
666 snowfall only rarely occurs as the temperature interval for highest snowfall intensity is already situated  
667 in the left tail of the CTRL period’s temperature distribution (Fig. 11b). With future warming, i.e., with a  
668 shift of the temperature distribution to the right, the probability for days to occur in the heavy snowfall  
669 temperature interval (dark grey shading) decreases stronger than the probability of days to occur in  
670 the overall snowfall regime (light grey shading). This results in (1) a general decrease of snowfall  
671 frequency, (2) a general decrease of mean snowfall intensity and (3) a general and similar decrease of  
672 both mean and heavy snowfall amounts. In contrast, at cold and high-elevated sites CTRL period  
673 temperatures are often too low to trigger heavy snowfall since a substantial fraction of the temperature  
674 PDF is located to the left of the heavy snowfall temperature interval (Fig. 11 c). The shifted distribution  
675 in a warmer SCEN climate, however, peaks within the temperature interval that favours heavy  
676 snowfall. This leads to a probability increase for days to occur in the heavy snowfall temperature range  
677 despite the general reduction in  $S_{\text{freq}}$  (lower overall probability of days to occur in the entire snowfall  
678 regime, light grey). As a consequence, mean  $S_{\text{int}}$  tends to increase and the reduction of heavy snowfall  
679 amounts is less pronounced (or even of opposing sign) than the reduction in mean snowfall. For  
680 individual (climatologically cold) regions and seasons, the increase of mean  $S_{\text{int}}$  might even  
681 compensate the  $S_{\text{freq}}$  decrease, resulting in an increase of both mean and heavy snowfall amounts.  
682 Note that in a strict sense these explanations only hold in the case that the probability of snowfall to  
683 occur at a given temperature does not change considerably between the CTRL and the SCEN period.

684 This behaviour is approximately found (Fig. 10, bottom row), which presumably indicates only minor  
685 contributions of large scale circulation changes and associated humidity changes on both the  
686 temperature - snowfall frequency and the temperature - snowfall intensity relation.

## 687 **5.2 Emission scenario uncertainty**

688 The projections presented in the previous sections are based on the RCP8.5 emission scenario, but  
689 will depend on the specific scenario considered. To assess this uncertainty we here compare the  
690 RCM<sub>sep+ba</sub> simulations for the previously shown RCP8.5 emission scenario against those assuming the  
691 more moderate RCP4.5 scenario. As a general picture, the weaker RCP4.5 scenario is associated  
692 with less pronounced changes of snowfall indices (Fig. 12). Differences in mean seasonal  $\delta S_{\text{mean}}$   
693 between the two emission scenarios are most pronounced below 1000 m a.s.l. where percentage  
694 changes for RCP4.5 are about one third smaller than for RCP8.5. At higher elevations, multi-model  
695 mean changes better agree and the multi-model ranges for the two emission scenarios start  
696 overlapping, i.e., individual RCP4.5 experiments can be located in the RCP8.5 multi-model range and  
697 vice versa. Over the entire Alpine domain, about -25% of current snowfall is expected to be lost under  
698 the moderate RCP4.5 emission scenario while a reduction of approximately -45% is projected for  
699 RCP8.5. For seasonal cycles, the difference of  $\delta S_{\text{mean}}$  between RCP4.5 and RCP8.5 is similar for  
700 most months and slightly decreases with altitude. Above 2000 m a.s.l., the simulated increase of  $S_{\text{mean}}$   
701 appears to be independent of the chosen RCP in January and February, while negative changes  
702 before and after mid-winter are more pronounced for RCP8.5. Alpine domain mean  $\delta S_{\text{q99}}$  almost  
703 doubles under the assumption of stronger GHG emissions. This is mainly due to differences at low  
704 elevations whereas above 2000 m a.s.l.  $\delta S_{\text{q99}}$  does not seem to be strongly affected by the choice of  
705 the emission scenario. Differences in monthly mean changes are in close analogy to  $\delta S_{\text{mean}}$ . Higher  
706 emissions lead to a further negative shift in  $\delta S_{\text{q99}}$ . Up to mid-elevations differences are rather  
707 independent of the season. However, at highest elevations and from January to March, differences  
708 between RCP4.5 and RCP8.5 are very small.

709 Despite the close agreement of mid-winter snowfall increases at high elevations between the two  
710 emission scenarios, obvious differences in the spatial extent of the region of mean seasonal snowfall  
711 increases can be found (cf Figs. S7 and 7 for  $\delta S_{\text{mean}}$ , and Figs. S8 and S9 for  $\delta S_{\text{q99}}$ ). In most  
712 simulations, the number of grid cells along the main Alpine ridge that show either little change or even  
713 increases of seasonal mean  $S_{\text{mean}}$  or  $S_{\text{q99}}$  is larger for RCP4.5 than for RCP8.5 with its larger warming  
714 magnitude.

## 715 **5.3 Intercomparison of projections with separated and raw snowfall**

716 The snowfall projections presented above are based on the RCM<sub>sep+ba</sub> data set, i.e. on separated and  
717 bias-adjusted snowfall amounts. To assess the robustness of these estimates we here compare the  
718 obtained change signals against the respective signals based on RCM<sub>sep+nba</sub> (separated and not bias-  
719 adjusted) and simulated raw snowfall output (RCM<sub>raw</sub>). This comparison is restricted to the seven  
720 RCMs providing raw snowfall as output variable (see Tab. 1).

721 The three different change estimates agree well with each other in terms of relative snowfall change  
722 signals (Fig. 13, top row). Multi-model mean relative changes are very similar for all analysed snowfall  
723 indices and elevation intervals. In many cases, separated and not bias-adjusted snowfall ( $RCM_{sep+nba}$ )  
724 is subject to slightly smaller percentage decreases. Multi-model mean differences between  $RCM_{sep+ba}$ ,  
725  $RCM_{sep+nba}$  and  $RCM_{raw}$  simulations are smaller than the corresponding multi-model spread of  
726  $RCM_{sep+ba}$  simulations and emission scenario uncertainties (cf. Figs. 12, 13 and S10). This agreement  
727 in terms of relative change signals is in contrast to absolute change characteristics (Fig. 13, bottom  
728 row). Results based on the three data sets agree in the sign of change, but not in their magnitude,  
729 especially at high elevations >2000 m a.s.l.. As the relative changes are almost identical, the absolute  
730 changes strongly depend upon the treatment of biases in the control climate.

731 In summary, these findings indicate that (a) the snowfall separation method developed in the present  
732 work yields rather good proxies for relative changes of snowfall indices in raw RCM output (which is  
733 not available for all GCM-RCM chains), and that (b) the additional bias adjustment of separated  
734 snowfall amounts only has a weak influence on relative change signals of snowfall indices, but can  
735 have substantial effects on absolute changes.

## 736 **6 Conclusions and outlook**

737 The present work makes use of state-of-the-art EURO-CORDEX RCM simulations to assess changes  
738 of snowfall indices over the European Alps by the end of the 21st century. For this purpose, snowfall is  
739 separated from total precipitation using near-surface air temperature in both the RCMs and in the  
740 observation-based estimate on a daily basis. The analysis yields a number of robust signals,  
741 consistent across a range of climate model chains and across emission scenarios. Relating to the  
742 main objectives we find the following:

743 **Snowfall separation on the RCM grid.** Binary snow fractionation with a fixed temperature threshold  
744 on coarse-resolution grids (with 11 km resolution) leads to an underestimation of mean snowfall and  
745 an overestimation of heavy snowfall. To overcome these deficiencies, the Richards snow fractionation  
746 method is implemented. This approach expresses that the coarse-grid snow fraction depends not only  
747 on daily mean temperature, but also on topographical subgrid-scale variations. Accounting for the  
748 latter results in better estimates for mean and heavy snowfall. However, due to limited observational  
749 coverage the parameters of this method are fitted for Switzerland only and are then applied to the  
750 entire Alpine domain. Whether this spatial transfer is robust could further be investigated by using  
751 observational data sets covering the full domain of interest but is out of the scope of this study.

752 **Snowfall bias adjustment.** Simulations of the current EURO-CORDEX ensemble are subject to  
753 considerable biases in precipitation and temperature, which translate into biased snowfall amounts. In  
754 the EVAL period, simulated precipitation is largely overestimated, with increasing biases toward higher  
755 altitudes. On the other hand, simulated near surface temperatures are generally too low with largest  
756 deviations over mountainous regions. These findings were already reported in previous studies for  
757 both the current EURO-CORDEX data set but also for previous RCM ensembles (e.g. Frei et al., 2003;  
758 Kotlarski et al., 2012; Kotlarski et al., 2015; Rajczak et al., 2013; Smiatek et al., 2016). By

759 implementing a simple bias adjustment approach, we are able to partly reduce these biases and the  
760 associated model spread, which should enable more robust change estimates. The adjusted model  
761 results reproduce the seasonal cycles of mean snowfall fairly well. However, substantial biases remain  
762 in terms of heavy snowfall, snowfall intensities (which in general are overestimated), snowfall  
763 frequencies, and spatial snowfall distributions. Further improvements might be feasible by using more  
764 sophisticated bias adjustment methods, such as quantile mapping (e.g., Rajczak et al., 2016), local  
765 intensity scaling of precipitation (e.g., Schmidli et al., 2006), or weather generators (e.g. Keller et al.,  
766 2016). Advantages of the approach employed here are its simplicity, its direct linkage to the snowfall  
767 separation method and, as a consequence, its potential ability to account for non-stationary snowfall  
768 biases. Furthermore, a comparison to simulated raw snowfall for a subset of seven simulations  
769 revealed that relative change signals are almost independent of the chosen post-processing strategy.

770 **Snowfall projections for the late 21st century.** Snowfall climate change signals are assessed by  
771 deriving the changes in snowfall indices between the CTRL period 1981 - 2010 and the SCEN period  
772 2070 - 2099. Our results show that by the end of the 21st century, snowfall over the Alps will be  
773 considerably reduced. Between September and May mean snowfall is expected to decrease by  
774 approximately -45% (multi-model mean) under an RCP8.5 emission scenario. For the more moderate  
775 RCP4.5 scenario, multi-model mean projections show a decline of -25%. These results are in good  
776 agreement with previous works (e.g. de Vries et al., 2014; Piazza et al., 2014, Räisänen, 2016). Low-  
777 lying areas experience the largest percentage changes of more than -80%, while the highest Alpine  
778 regions are only weakly affected. Variations of heavy snowfall, defined by the 99% all-day snowfall  
779 percentile, show an even more pronounced signal at low-lying elevations. With increasing elevation,  
780 percentage changes of heavy snowfall are generally smaller than for mean snowfall. O'Gorman (2014)  
781 found a very similar behaviour by analysing projected changes in mean and extreme snowfall over the  
782 entire Northern Hemisphere. He pointed out that heavy and extreme snowfall occurs near an optimal  
783 temperature (near or below freezing, but not too cold), which seems to be independent of climate  
784 warming. We here confirm this finding. At mid and high elevations heavy snowfall in a warmer climate  
785 will still occur in the optimal temperature range, hence, heavy snowfall amounts will decrease less  
786 strongly compared to mean snowfall, and may even increase in some areas.

787 At first approximation, the magnitude of future warming strongly influences the reduction of mean and  
788 heavy snowfall by modifying the snowfall frequency. Snowfall increases may however occur at high  
789 (and thus cold) elevations, and these are not caused by frequency changes. Here, snowfall increases  
790 due to (a) a general increase of total winter precipitation combined with only minor changes in snowfall  
791 frequency, and (b) more intense snowfall. This effect has a pronounced altitudinal distribution and may  
792 be particularly strong under conditions (depending upon location and season) where the current  
793 climate is well below freezing. With the expected warming a shift towards a temperature range more  
794 favourable to snowfall (near or below freezing, but not too cold) can be expected with corresponding  
795 increases of mean snowfall, despite a general decrease of the snowfall fraction.

796 Note that individual EURO-CORDEX experiments were completely or partly omitted from our analysis  
797 (see Supplementary Material, Part B and Table 1). However, when comparing the ensemble results

798 based on the reduced and the full model set only slight differences are found and our main results and  
799 conclusions do not change (compare Figure 12 to Figure S15). This indicates a robust ensemble  
800 analysis that is only little affected by potentially critical shortcomings of individual simulations.

801 The identified future changes of snowfall over the Alps can lead to a variety of impacts in different  
802 sectors. With decreasing snowfall frequencies and the general increase of the snowline (e.g.,  
803 Beniston, 2003; Gobiet et al., 2014; Hantel et al., 2012), both associated with temperature changes,  
804 ski lift operators are looking into an uncertain future. A shorter snowfall season will likely put them  
805 under greater financial pressure. Climate change effects might be manageable only for ski areas  
806 reaching up to high elevations (e.g. Elsasser and Bürki, 2002). Even so these resorts might start later  
807 into the ski season, the snow conditions into early spring could change less dramatically due to  
808 projected high-elevation snowfall increases in mid-winter. A positive aspect of the projected decrease  
809 in snowfall frequency might be a reduced expenditures for airport and road safety (e.g., Zubler et al.,  
810 2015).

811 At lower altitudes, an intensification of winter precipitation, combined with smaller snowfall fractions  
812 (Serquet et al., 2013), increases the flood potential (Beniston, 2012). Snow can act as a buffer by  
813 releasing melt water constantly over a longer period of time. With climate warming, this storage  
814 capacity is lost, and heavy precipitation immediately drains into streams and rivers which might not be  
815 able to take up the vast amount of water fast enough. Less snowmelt will also have impacts on  
816 hydropower generation and water management (e.g., Weingartner et al., 2013). So far, many Alpine  
817 regions are able to bypass dry periods by tapping melt water from mountainous regions. With reduced  
818 snow-packs due to less snowfall, water shortage might become a serious problem in some areas.

819 Regarding specific socio-economic impacts caused by extreme snowfall events, conclusions based on  
820 the results presented in this study are difficult to draw. It might be possible that the 99% all-day  
821 snowfall percentile we used for defining heavy snowfalls, is not appropriate to speculate about future  
822 evolutions of (very) rare events (Schär et al., 2016). To do so, one might consider applying a  
823 generalized extreme value (GEV) analysis which is more suitable for answering questions related to  
824 rare extreme events.

## 825 **7 Data Availability**

826 The EURO-CORDEX RCM data analysed in the present work are publicly available - parts of  
827 them for non-commercial use only - via the Earth System Grid Federation archive (ESGF;  
828 e.g., <https://esgf-data.dkrz.de>). The observational datasets RHiresD and TabsD as well as  
829 the snow depth data for Switzerland are available for research and educational purposes  
830 from [kundendienst@meteoschweiz.ch](mailto:kundendienst@meteoschweiz.ch). The analysis code is available from the  
831 corresponding author on request.

## 832 **8 Competing Interests**

833 The authors declare that they have no conflict of interest.

## 834 **9 Acknowledgements**

835 We gratefully acknowledge the support of Jan Rajczak, Urs Beyerle and Curdin Spirig (ETH Zurich) as  
836 well as Elias Zubler (MeteoSwiss) in data acquisition and pre-processing. Christoph Frei (MeteoSwiss)  
837 and Christoph Marty (WSL-SLF) provided important input on specific aspects of the analysis. The  
838 GTOPO30 digital elevation model is available from the U.S. Geological Survey. Finally, we thank the  
839 climate modelling groups of the EURO-CORDEX initiative for producing and making available their  
840 model output.

1010 **Figures**

1011

1012

1013

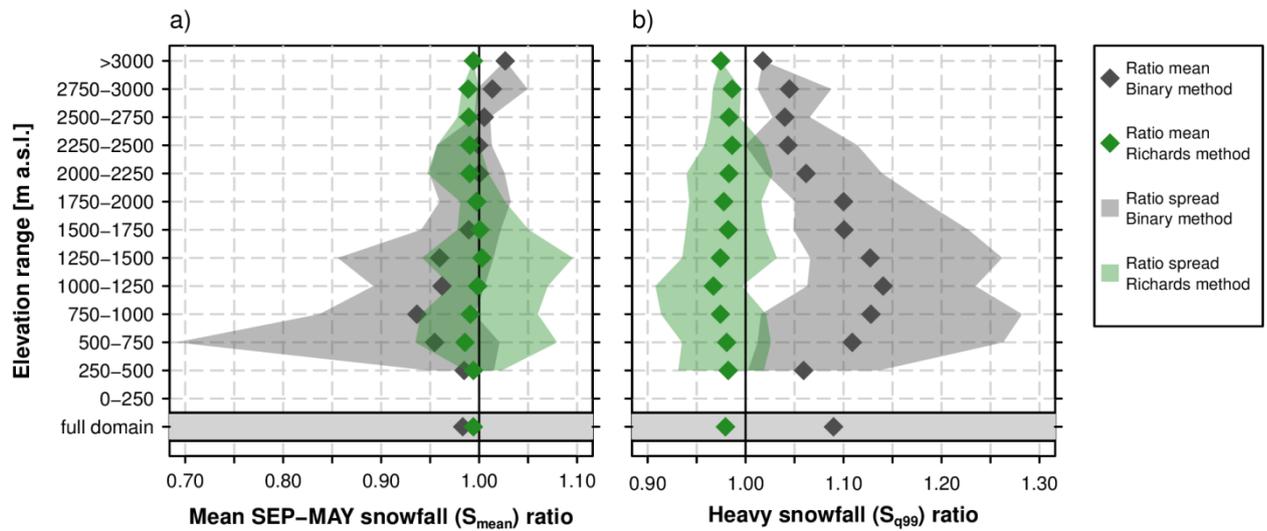

1014

1015 **Figure 1** GTOPO30 topography (<https://ta.cr.usgs.gov/GTOPO30>) aggregated to the EUR-11 (0.11°) RCM grid.

1016 The coloured area shows the Alpine domain used for the assessment of snowfall projections. The bold black

1017 outline marks the Swiss sub-domain used for the assessment of the bias adjustment approach.

1018

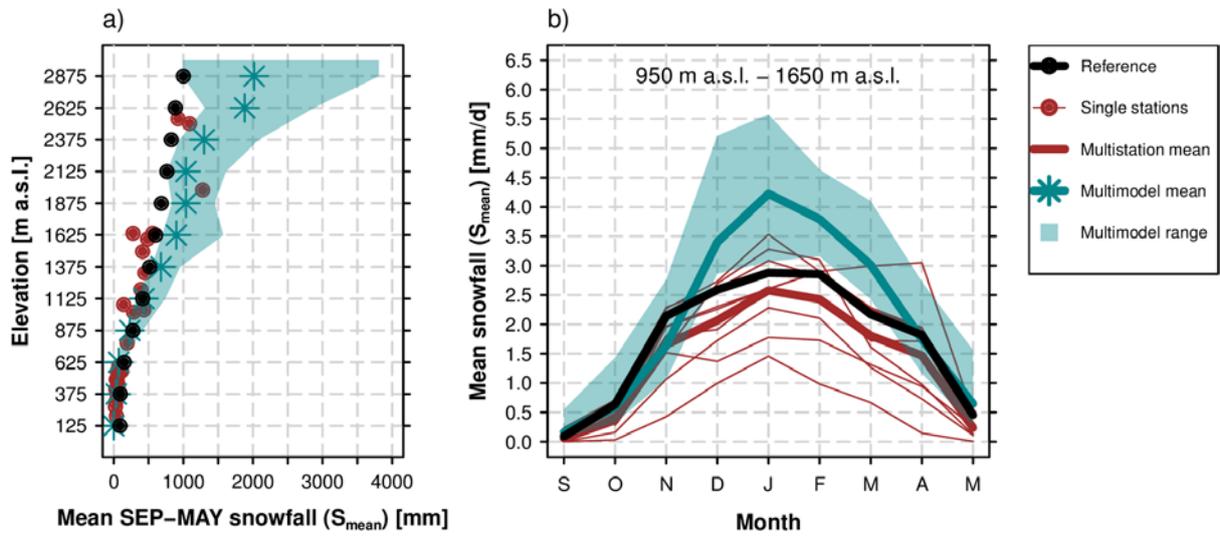

1019

1020

1021 **Figure 2** Snowfall ratios for the Binary and Richards snow fractionation method. Ratios represent the quotient of  
 1022 the snowfall as estimated by the respective method and the snowfall as estimated by the *Subgrid* method. Ratios  
 1023 are valid at the coarse-resolution grid (12 km). a) Ratios for mean snowfall,  $S_{mean}$ . b) Ratios for heavy snowfall,  
 1024  $S_{q99}$ . Ratio means were derived after averaging the corresponding snowfall index for 250 m elevation intervals in  
 1025 Switzerland while the ratio spread represents the minimum and maximum grid point-based ratios in the  
 1026 corresponding elevation interval. This analysis is entirely based on the observational data sets TabsD and  
 1027 RhiresD.

1028

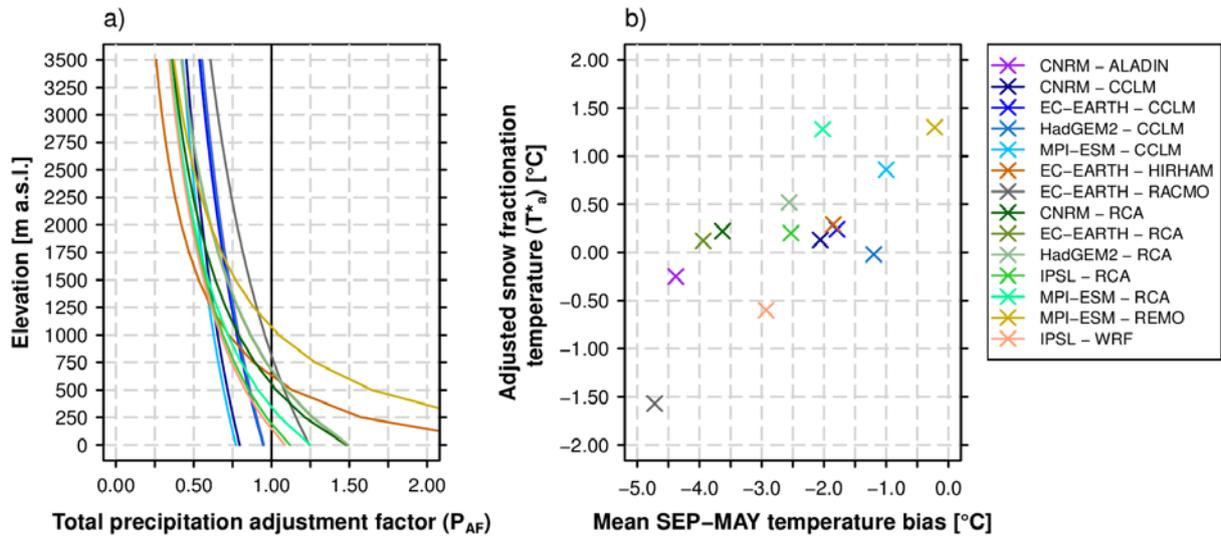

1029

1030

1031 **Figure 3** Comparison of measured fresh snow sums of 29 MeteoSwiss stations (red) against simulated RCM raw  
1032 snowfall in Switzerland (green) and against the 2 km reference snowfall grid obtained by employing the *Subgrid*  
1033 *method* (black) in the EVAL period 1971-2005. a) Mean September – May snowfall vs. elevation. Both the  
1034 simulation data (green) and the reference data (black) are based on the spatio-temporal mean of 250 m elevation  
1035 ranges and plotted at the mean elevation of the corresponding interval. b) Seasonal September-May snowfall  
1036 cycle for the elevation interval 950 m a.s.l. to 1650 m a.s.l.. Simulated multi-model means and spreads are based  
1037 on a subset of seven EURO-CORDEX simulations of the reduced model set providing raw snowfall as output  
1038 variable (see Tab. 1).

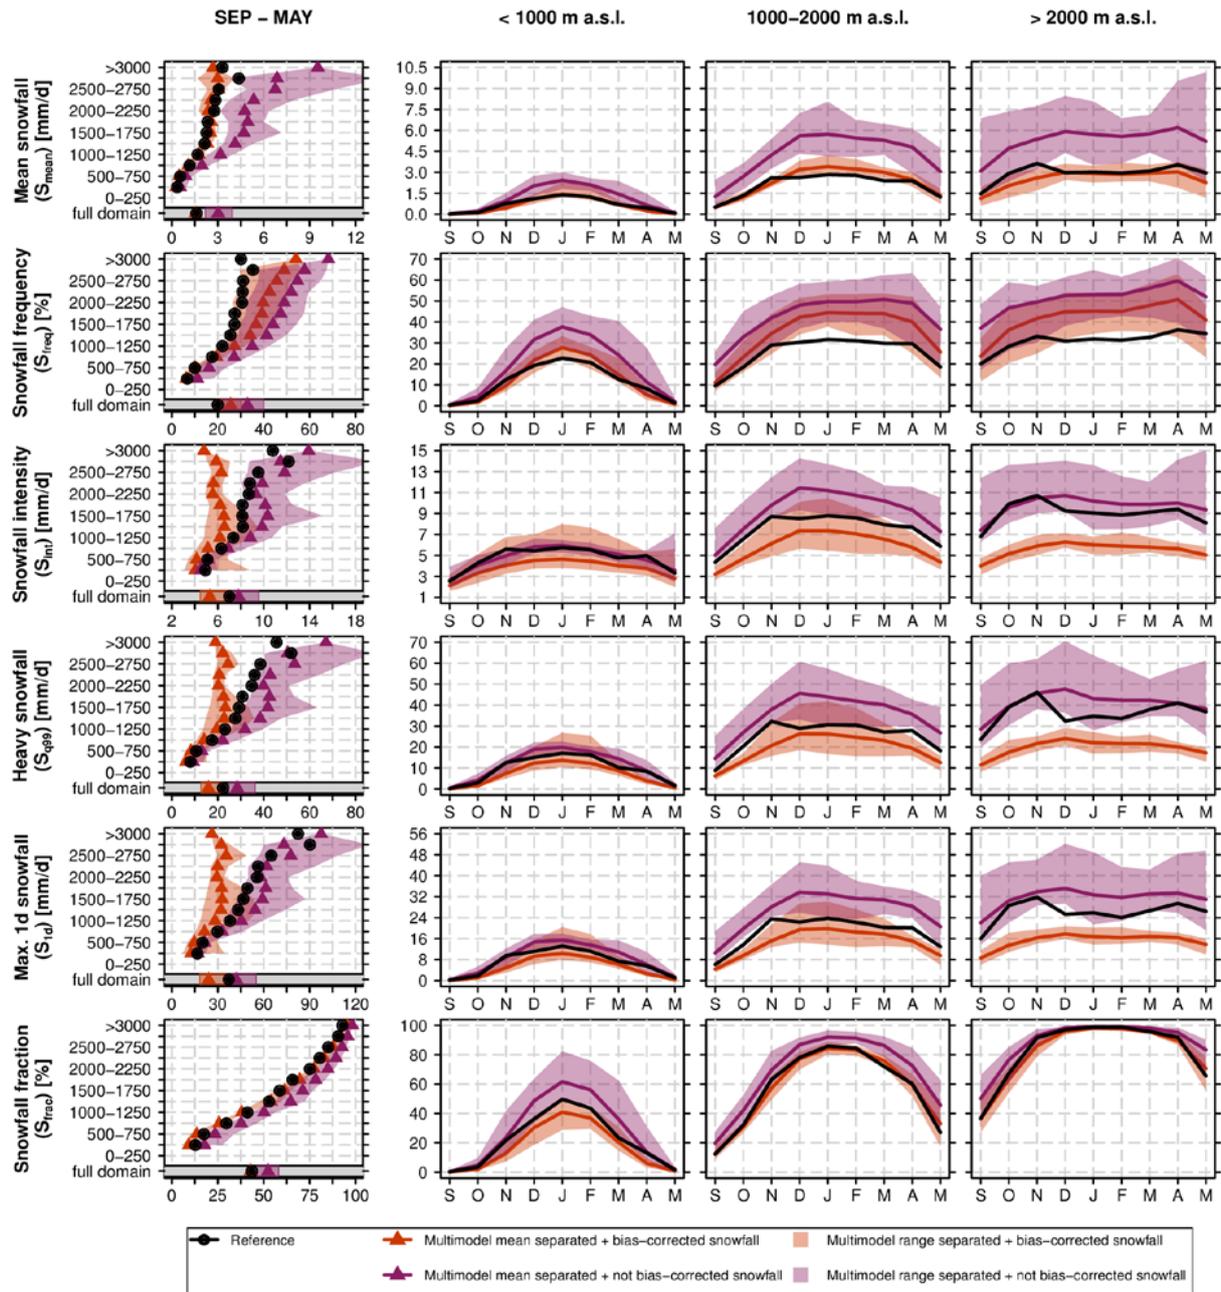

1039

1040

1041  
1042  
1043

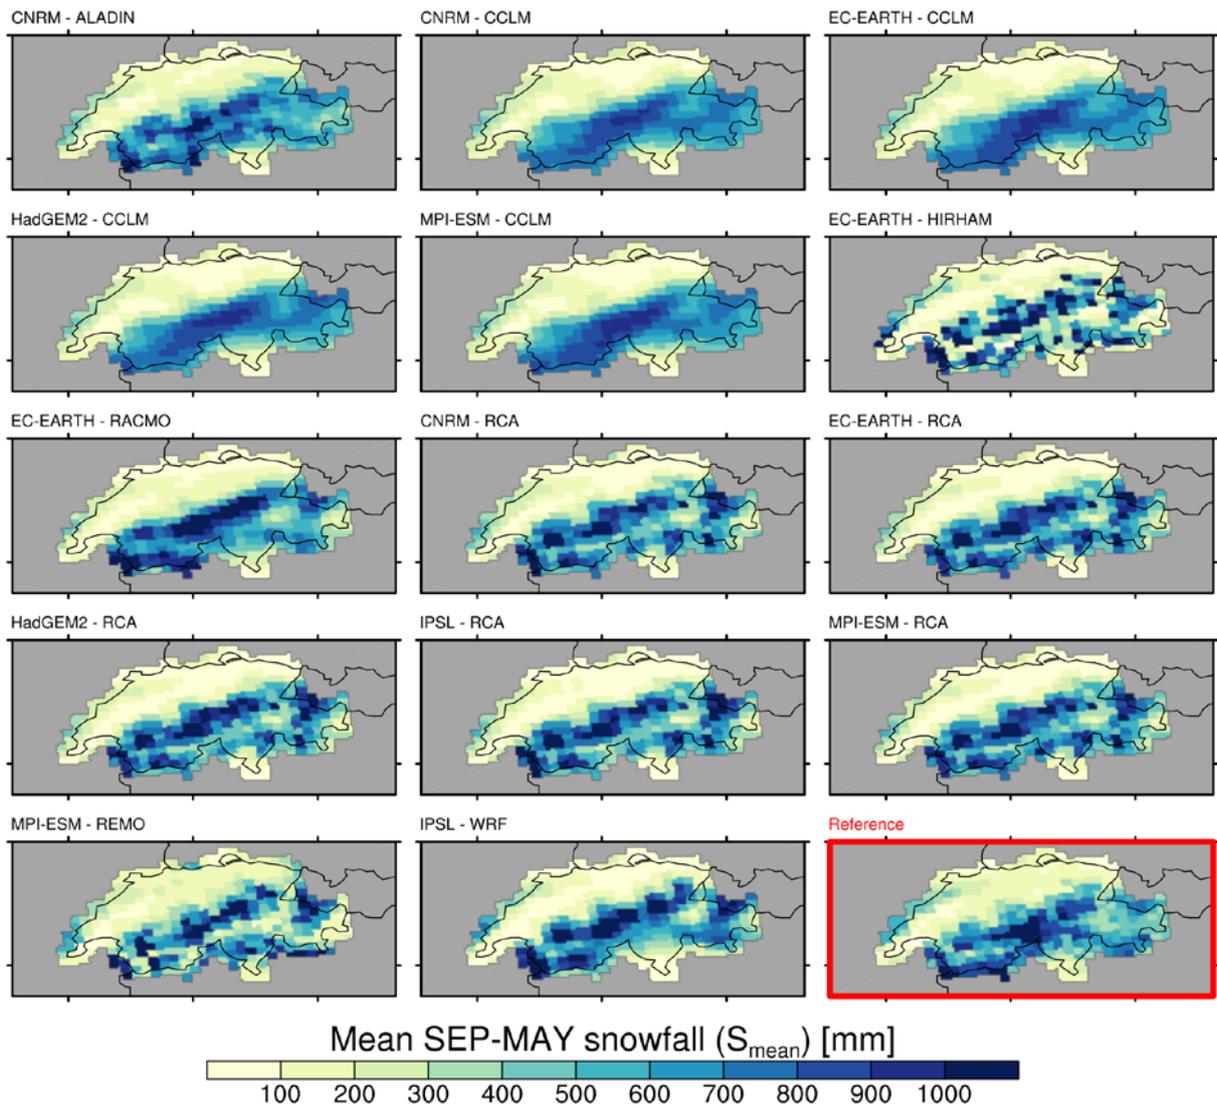

**Figure 4** Overview of bias adjustment. a) Elevation-dependent total precipitation adjustment factors,  $P_{AF}$ , for the full model set (14 GCM-RCM chains; see Eq. 10). b) Scatterplot of mean September to May temperature biases (RCM simulation minus observational analysis) vs. adjusted snow fractionation temperatures,  $T^*_a$ .

1044  
1045

1046 **Figure 5** Evaluation of snowfall indices in the EVAL period 1971-2005 for the 12 snowfall separated + bias-  
 1047 adjusted ( $RCM_{sep+ba}$ ) and 12 snowfall separated + not bias-adjusted ( $RCM_{sep+nba}$ ) RCM simulations of the  
 1048 reduced model set vs. observation-based reference. The first column shows the mean September-May snowfall  
 1049 index statistics vs. elevation while the monthly snowfall indices (spatially averaged over the elevation intervals  
 1050 <1000 m a.s.l., 1000 m a.s.l.-2000 m a.s.l. and >2000 m a.s.l.) are displayed in columns 2-4.

1051

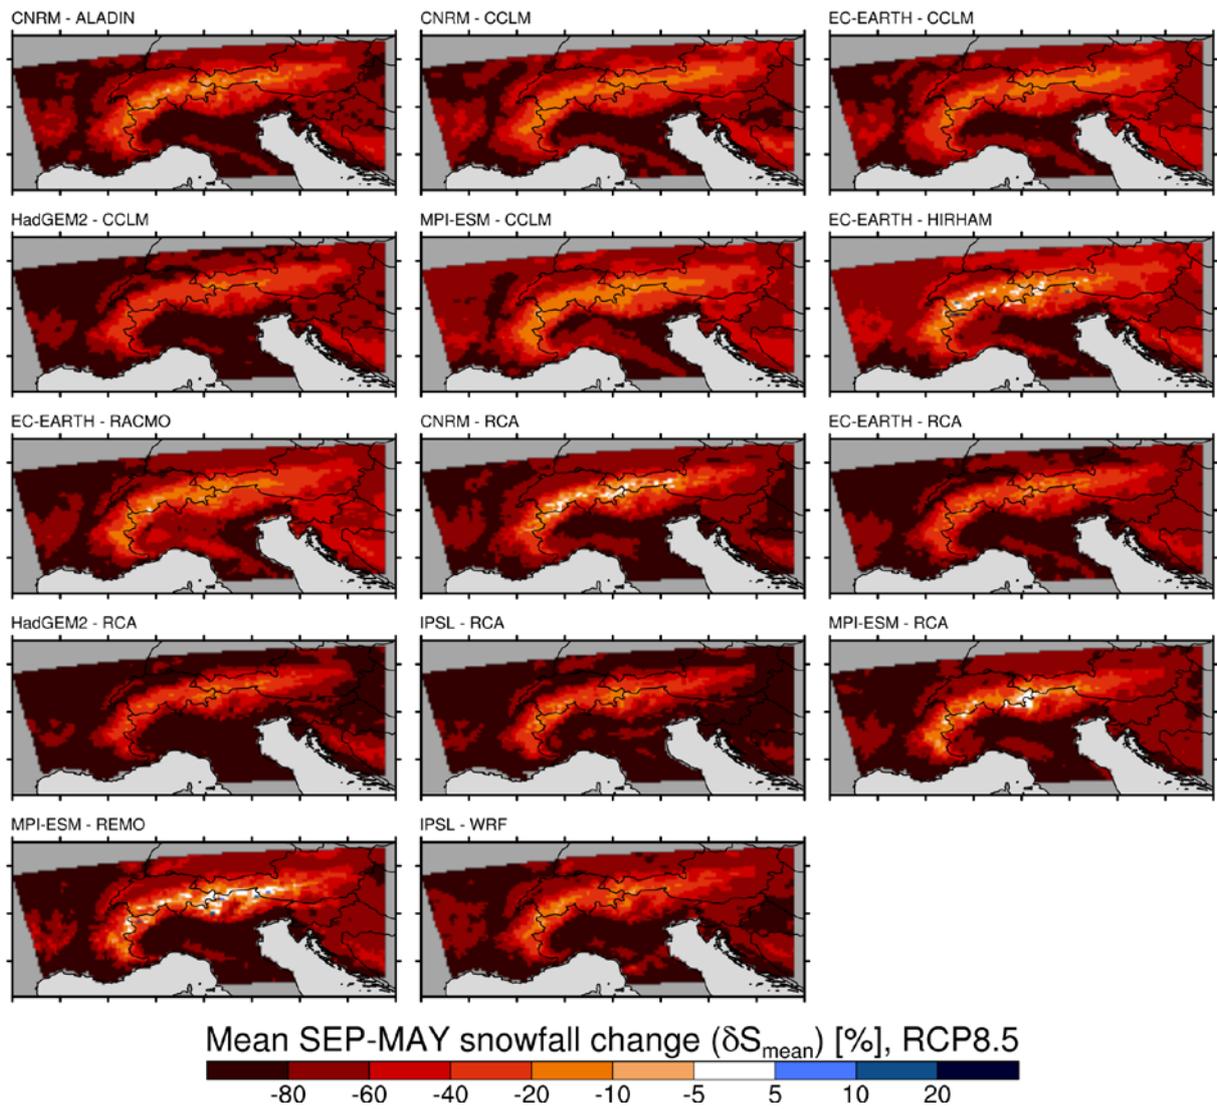

1052

1053

1054 **Figure 6** Spatial distribution of mean September-May snowfall,  $S_{\text{mean}}$ , in the EVAL period 1971-2005 and for the  
 1055 14 snowfall separated + bias-adjusted RCM simulations ( $\text{RCM}_{\text{sep+ba}}$ ) of the full model set. Lower right panel:  
 1056 observation-based reference.

1057

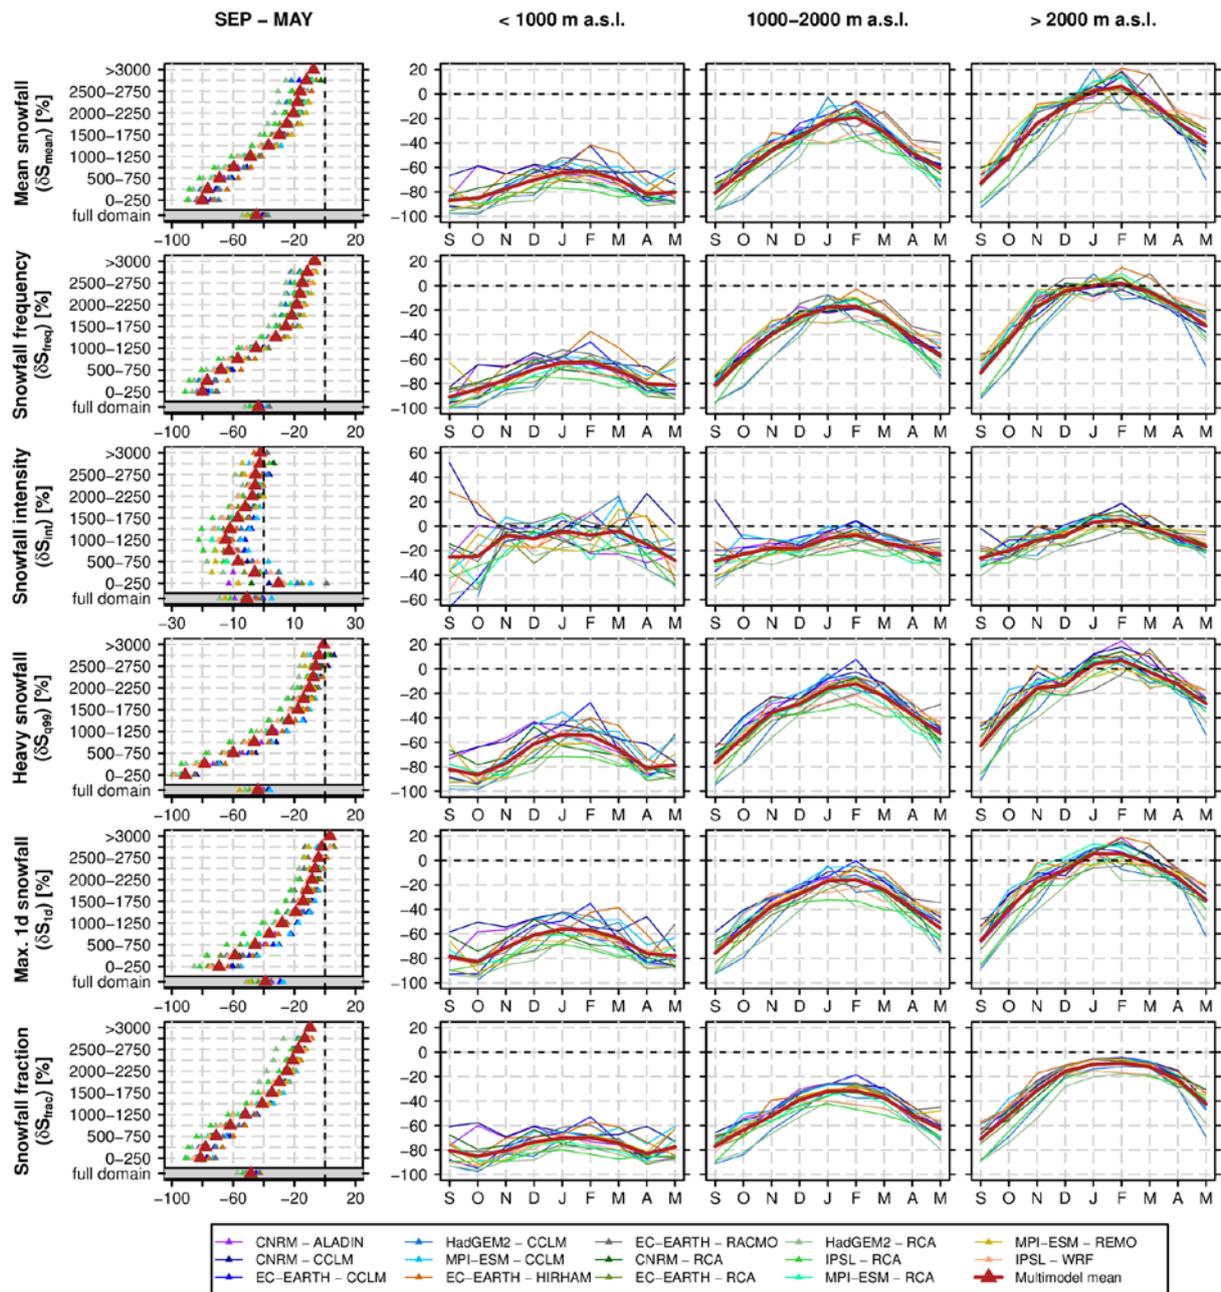

1058

1059

1060 **Figure 7** Spatial distribution of relative changes (SCEN period 2070-2099 with respect to CTRL period 1981-  
 1061 2010) in mean September-May snowfall,  $\delta S_{\text{mean}}$ , for RCP8.5 and for the 14 snowfall separated + bias-adjusted  
 1062 RCM simulations (RCM<sub>sep+ba</sub>) of the full model set. For RCP4.5, see Fig. S7.

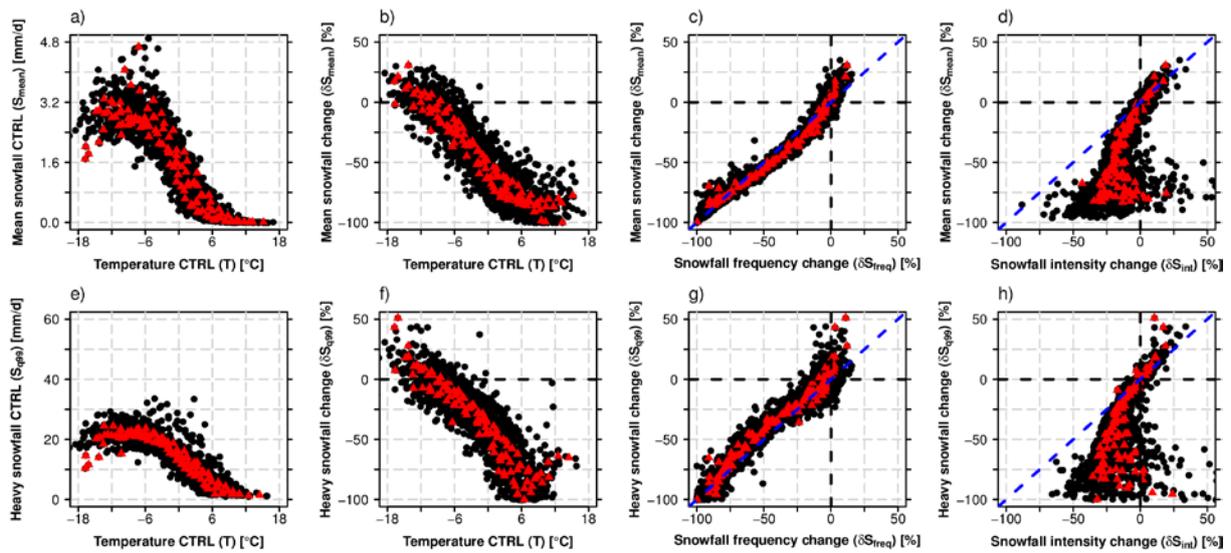

1063

1064  
1065

1066 **Figure 8** Relative changes (SCEN period 2070-2099 with respect to CTRL period 1981-2010) of snowfall indices  
1067 based on the 14 snowfall separated + bias-adjusted RCM simulations ( $RCM_{sep+ba}$ ) of the full model set for  
1068 RCP8.5. The first column shows the mean September-May snowfall index statistics vs. elevation. Monthly  
1069 snowfall index changes (spatially averaged over the elevation intervals <math>< 1000</math> m a.s.l., <math>1000</math> m a.s.l.-<math>2000</math>  
1070 m a.s.l.) are displayed in columns 2-4.

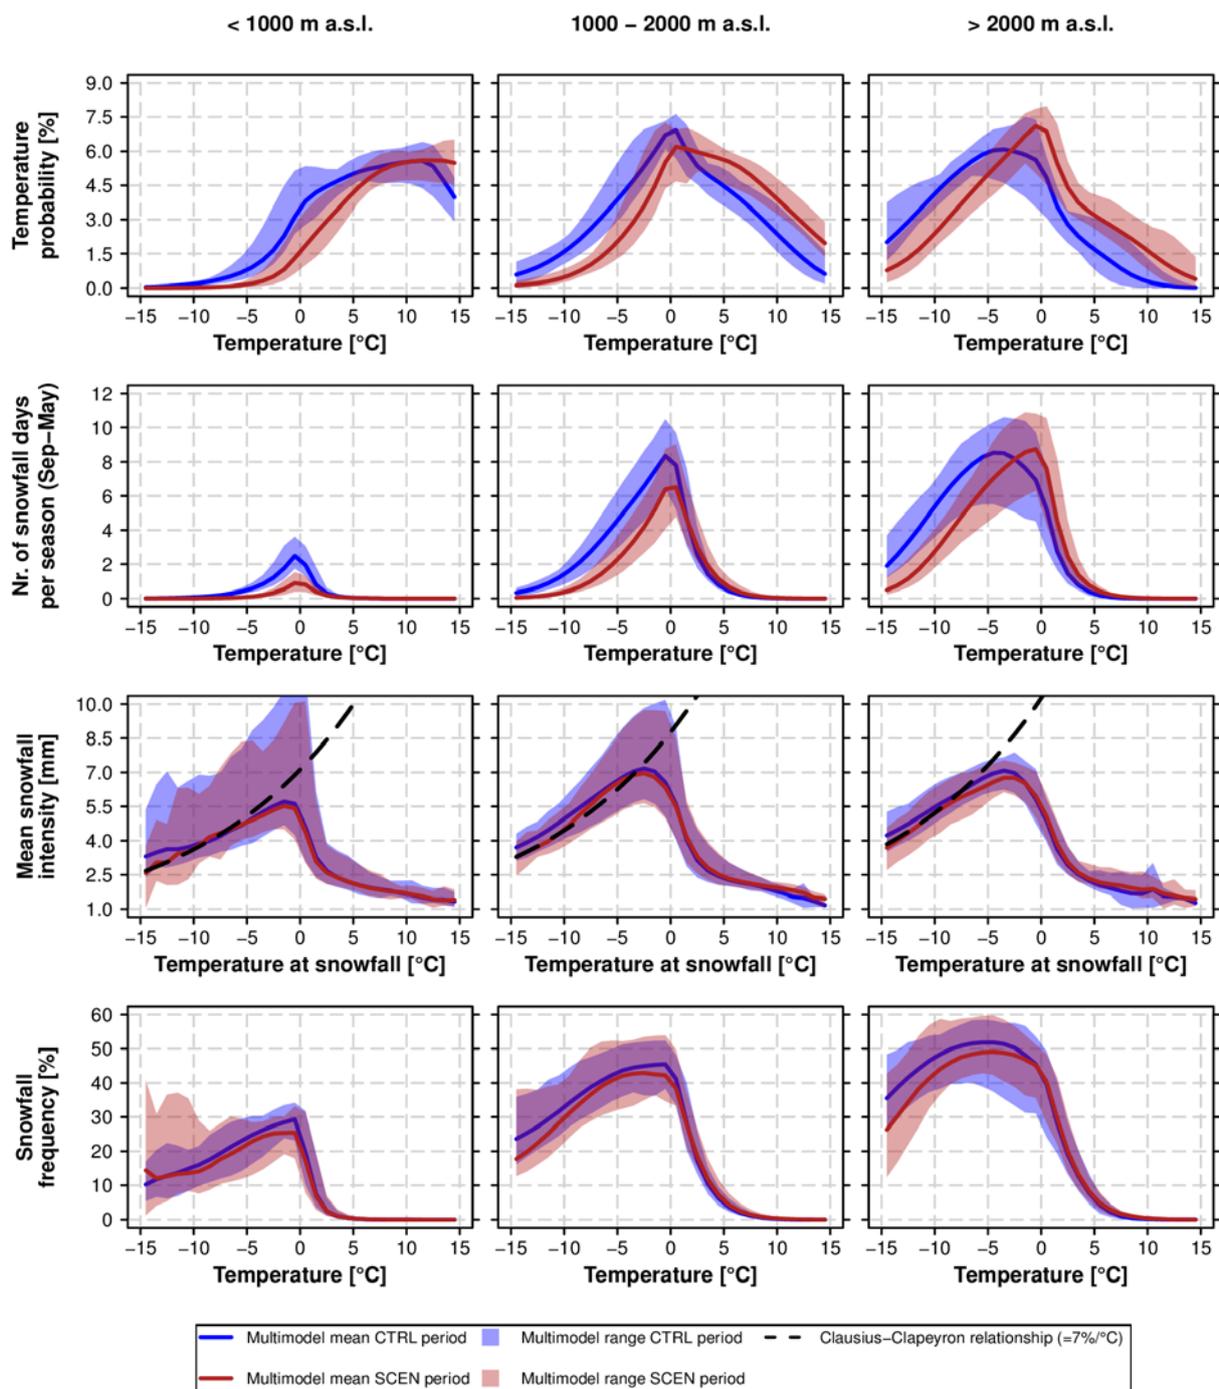

1071

1072  
1073

1074 **Figure 9** Intercomparison of various snowfall indices and relationship with monthly mean temperature in CTRL.  
 1075 For each panel, the monthly mean statistics for each 250 m elevation interval and for each of the 12 snowfall  
 1076 separated + bias-adjusted (RCMsep+ba) RCM simulations of the reduced model set (RCM<sub>sep+ba</sub>) were derived  
 1077 (black circles). Red triangles denote the multi-model mean for a specific month and elevation interval. The  
 1078 monthly statistics were calculated by considering all grid points of the specific elevation intervals which are  
 1079 available for both variables in the corresponding scatterplot only (area consistency). Relative changes are based  
 1080 on the RCP8.5 driven simulations (SCEN 2070-2099 wrt. CTRL 1981-2010).

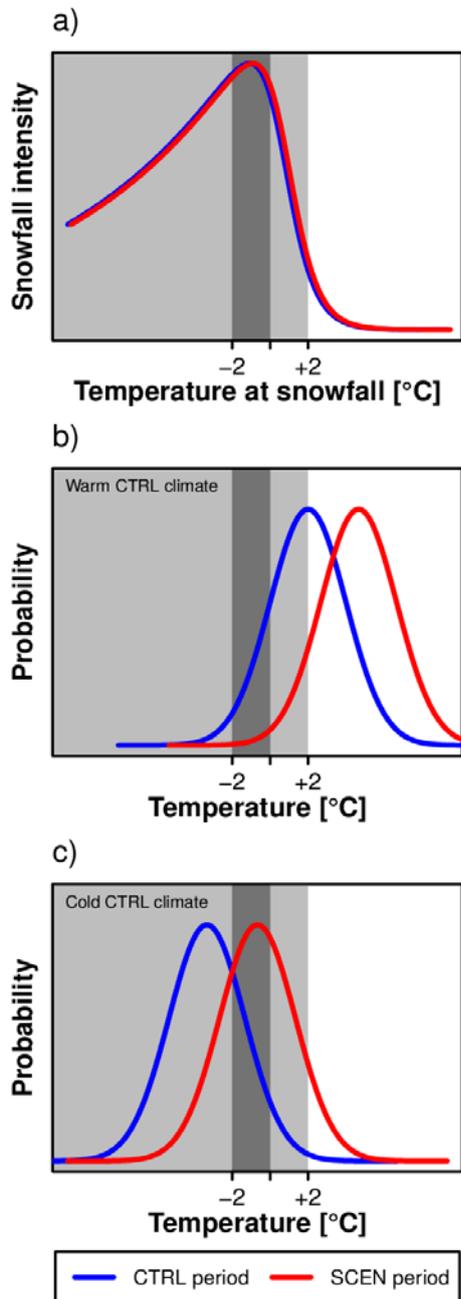

1081

1082

1083

1084 **Figure 10** Comparison of temperature probability, snowfall probability and mean snowfall intensity for the CTRL  
1085 period 1981-2010 and SCEN period 2070-2099 for RCP8.5. The analysis is based on data from the 12 snowfall  
1086 separated + bias-adjusted RCM simulations (RCM<sub>sep+ba</sub>) of the reduced model set. The top row depicts the PDF  
1087 of the daily temperature distribution, while the second row shows the mean number of snowfall days between  
1088 September and May, i.e., days with  $S > 1$  mm (see Tab. 2), in a particular temperature interval. The third row  
1089 represents the mean snowfall intensity,  $S_{int}$ , for a given snowfall temperature interval. In addition the Clausius-  
1090 Clapeyron relationship, centred at the  $-10^{\circ}\text{C}$  mean  $S_{int}$  for SCEN, is displayed by the black dashed line. PDFs and  
1091 mean  $S_{int}$  were calculated by creating daily mean temperature bins of width  $1^{\circ}\text{C}$ .

**Figure 11** Schematic illustration of the control of changes in snowfall intensity on changes in mean and extreme snowfall. a) Relation between temperature and mean snowfall intensity. b) Daily temperature PDF for a warm control climate (low elevations or transition seasons, i.e., beginning or end of winter). c) Daily temperature PDF for a cold control climate (high elevations or mid-winter). The blue line denotes the historical CTRL period, the red line the future SCEN period. The light grey shaded area represents the overall temperature interval at which snowfall occurs, the dark grey shading shows the preferred temperature interval for heavy snowfall to occur.

1115 **Tables**

1116

1117 **Table 1** Overview on the full and the reduced EURO-CORDEX simulations employed in this study. All  
 1118 experiments were realized on a grid covering the European domain with a horizontal resolution of approximately  
 1119 12 km (EUR-11) and were run for the emission scenarios RCP4.5 and RCP8.5. A subset of nine simulations  
 1120 provides raw snowfall, i.e., snowfall flux in kg/m<sup>2</sup>s, as output variable. The reduced model set excludes  
 1121 experiments that are subject to serious shortcomings (see Supplementary Material, Part B). For full institutional  
 1122 names the reader is referred to the official EURO-CORDEX website [www.euro-cordex.net](http://www.euro-cordex.net). Note that the EC-  
 1123 EARTH-driven experiments partly employ different realisations of the GCM run, i.e., explicitly sample the  
 1124 influence of internal climate variability in addition to model uncertainty.

1126

1127 **Table 2** Analysed snowfall indices. The last column indicates the threshold value in the CTRL period for  
 1128 considering a grid cell in the climate changes analysis (grid cells with smaller values are skipped for the  
 1129 respective analysis); first number: threshold for monthly analyses, second number: threshold for seasonal  
 1130 analysis.

<b>Index name</b>	<b>Acronym</b>	<b>Unit</b>	<b>Definition</b>	<b>Threshold for monthly / seasonal analysis</b>
Mean snowfall	$S_{mean}$	mm	(Spatio-)temporal mean snowfall in mm snow water equivalent (only "mm" thereafter).	1 mm / 10 mm
Heavy snowfall	$S_{q99}$	mm/d	Grid point-based 99% all day snowfall percentile.	1 mm / 1 mm
Max. 1 day snowfall	$S_{1d}$	mm/d	Mean of each season's or month's maximum 1 day snowfall.	1 mm / 1 mm
Snowfall frequency	$S_{freq}$	%	Percentage of days with snowfall $S > 1$ mm/d within a specific time period.	1 % / 1 %
Snowfall intensity	$S_{int}$	mm/d	Mean snowfall intensity at days with snowfall $S > 1$ mm/d within a specific time period.	$S_{freq}$ threshold passed
Snowfall fraction	$S_{frac}$	%	Percentage of total snowfall, $S_{tot}$ , on total precipitation, $P_{tot}$ , within a specific time period.	1 % / 1 %
