6 **Abstract.** Basic statistical metrics such as autocorrelations and across-region lag
7 correlations of sea ice variations provide benchmarks for the assessments of forecast skill
8 achieved by other methods such as more sophisticated statistical formulations, numerical
9 models, and heuristic approaches. However, the strong negative trend of sea ice coverage
10 in recent decades complicates the evaluation of statistical skill by inflating the correlation
11 of interannual variations of pan-Arctic and regional ice extent. In this study we provide a
12 quantitative evaluation of the contribution of the trend to the predictive skill of monthly
13 and seasonal ice extent on the pan-Arctic and regional scales. We focus on the Beaufort
14 Sea where the Barnett Severity Index provides a metric of historical variations in ice
15 conditions over the summer shipping season. The variance about the trend line differs little
16 among various methods of detrending (piecewise linear, quadratic, cubic, exponential).
17 Application of the piecewise linear trend calculation indicates an acceleration of the trend
18 during the 1990s in most of the Arctic subregions. The Barnett Severity Index as well as
19 September pan-Arctic ice extent show significant statistical predictability out to several
20 seasons when the data include the trend. However, this apparent skill largely vanishes
21 when the data are detrended. No region shows significant correlation with the detrended
22 September pan-Arctic ice extent at lead times greater than a month or two; the concurrent
23 correlations are strongest with the East Siberian Sea. The Beaufort Sea's ice extent as far
24 back as July explains about 20% of the variance of the Barnett Severity Index, which is
25 primarily a September metric. The Chukchi Sea is the only other region showing a
26 significant association with the Barnett Severity Index, although only at a lead time of a
27 month or two.

28

29 **1 Introduction**

30 One of the most widely monitored variables in the climate system is Arctic sea ice. By any
31 measure, Arctic sea ice has decreased over the past few decades (AMAP, 2017). September sea
32 ice extent during the past 5-10 years has been approximately 50% of the mean for the 1979-2000
33 period. (Consistent measurements by satellite passive microwave sensors began in 1979). The
34 recent decline is unprecedented in the satellite record, in the period of direct observations dating
35 back to 1850 (Walsh et al., 2016), and in paleo reconstructions spanning more than 1400 years
36 (Kinnard *et al.*, 2011). The recent reduction of sea ice has been less in winter and spring than in
37 summer and autumn, resulting in a sea ice cover that is largely seasonal (AMAP, 2017). The
38 increasingly seasonal ice cover contrasts with the Arctic Ocean's predominantly multiyear ice
39 pack of the pre-2000 decades. When compared to the reductions of the spatial extent of sea ice,
40 the percentage reductions of ice volume and thickness are even larger. Ice thickness decreased
41 by more than 50% from 1958-1976 to 2003-2008 (Kwok and Rothrock, 2009), and the
42 percentage of the March ice cover made up of thicker multiyear ice (ice that has survived a
43 summer melt season) decreased from 75% in the mid-1980s to 45% in 2011 (Maslanik *et al.*,
44 2011). Laxon et al. (2013) indicate a decrease of 64% in autumn sea ice volume from 2003-08 to
45 2012.

46 While the loss of sea ice is generally presented in terms of pan-Arctic metrics, regional
47 trends can be quite different from the pan-Arctic trends. The Bering Sea, for example, showed a
48 positive trend of coverage (fewer open water days) from 1979 through 2012 (Parkinson, 2014),
49 even though regions to its north (the Chukchi and Beaufort Seas) showed some of the largest
50 decreases of summer ice coverage in the entire Arctic (Onarheim et al., 2018). The other area of
51 strong decreases of ice coverage has been the Barents/Kara Sea region.

52 The Beaufort Sea serves as an illustrative example of the impacts of trends and variability
53 of sea ice. The number of open water days immediately offshore of the Beaufort coast has been
54 60-120 in recent years. Parkinson's (2014) Figure 2 shows that the number of open water days
55 increased by 20-30 days per decade over the period 1979-2013. However, as recently as the
56 1970s, there were summers with little or no open water in this region, as described by Crowley
57 Maritime, one of the major barge operators in the Alaska region:

58 “With pipeline construction well underway in 1975, the Crowley summer sealift
59 flotilla to the North Slope faced the worst Arctic ice conditions of the century. In fleet
60 size, it was the largest sealift in the project's history with 47 vessels amassed to carry
61 154,420 tons of cargo, including 179 modules reaching as tall as nine stories and
62 weighing up to 1,300 tons each. Vessels stood by for nearly two months waiting for the
63 ice to retreat. Finally in late September the ice floe moved back and Crowley's tugs and
64 barges lined up for the slow and arduous haul to Prudhoe Bay. When the ice closed again,
65 it took as many as four tugs to push the barges, one at a time, through the ice”.

66 — *From Crowley Maritime, 50 Years of Service in Alaska (2002)*

67 As will be shown, the contrast between present-day ice conditions and the Crowley
68 experience of the 1970s is largely a manifestation of the trend of Beaufort Sea ice cover.
69 However, sea ice also exhibits large year-to-year variability, which has been superimposed on
70 the recent trend towards less sea ice in the Arctic. This variability challenges users of coastal
71 waters in various sectors and lies at the heart of the sea ice prediction problem. While the
72 climatological seasonal cycle and even observed trends provide an initial expectation for the sea
73 ice conditions that will be present in a particular region at a particular time of year, the
74 departures from the climatological mean, whether or not the mean is adjusted for a trend, is
75 affected by the atmospheric forcing (winds, air temperatures, radiative fluxes) and oceanic
76 forcing (currents, water temperatures) of the particular year. These departures have a large
77 component of internal variability and hence are difficult to predict over monthly and seasonal
78 timescales (Serreze et al., 2017), raising questions about the extent to which sea ice variations
79 may be predictable. Even ice-ocean models, which are initialized to current sea ice and ocean
80 conditions, require atmospheric and oceanic forcing in order to predict future ocean states. The
81 predictability of sea ice variations beyond the mean seasonal cycle and ongoing trends is the
82 main focus of this paper.

83 The present paper also extends Drobot's (2003) study of the predictability of Beaufort-
84 Chukchi sea ice. Drobot used data from 1979-2000 to assess predictability of a measure of
85 Beaufort Sea summer ice severity (Section 2 below) based on antecedent sea ice conditions as
86 well as several atmospheric indices. While some skill was found in predictions based on
87 indicators from the previous seasons, the limited sample of years used in developing the

88 statistical models raises questions about broader applicability. In this regard, Drobot (2003, p.
89 1161) states “...if the Arctic climate changes, the methods described here will need to be
90 altered”. In fact, the Arctic climate and, in particular, its sea ice regime, have changed with the
91 unprecedented retreat of sea ice in the post-2000 period. The impact of the trend on statistical
92 predictability is a focus of the present paper. Another relevant study is that of Blanchard-
93 Wrigglesworth et al. (2011), who found evidence that persistence of ocean temperature
94 anomalies across seasons has a detectable impact on sea ice variations, implying some
95 predictability over seasonal timescales. However, as with Drobot (2003), the extent to which
96 such relationships are affected by detrending remains to be established.

97 The present paper has three main objectives: (1) to quantify predictability inherent in
98 antecedent spatial distributions of sea ice, (2) to distinguish predictability of pan-Arctic sea ice
99 from that of regional predictability, and (3) to distinguish quantitatively the trend-derived
100 predictability and predictability of departures from trend.

101 More generally, the results presented here can serve to provide a baseline for distinguishing
102 contributions to sea ice forecast skill arising from seasonal climatologies, persistence, and trend.
103 This baseline can, in turn, serve as benchmarks for measuring improvements achieved by more
104 sophisticated prediction approaches such as ice-ocean models, analog systems, neural networks
105 and other more comprehensive statistical methods. The Sea Ice Prediction Network, previously
106 known as the Sea Ice Outlook (Stroeve et al., 2014), provides an annual compilation of seasonal
107 sea ice forecasts, which are grouped into three categories: physical/dynamical models, statistical
108 methods, and heuristic approaches. While the methodology used in this paper falls into the
109 statistical category, the distinctions between (a) pan-Arctic and regional skill and (b) trend-
110 derived and interannual forecast skill are relevant to all three approaches to sea ice prediction.

111 **2 Metrics of sea ice coverage**

112 Historical variations of sea ice are documented using various metrics, including sea ice extent,
113 ice-covered area, and thickness. Sea ice extent is the total area within the ice edge, which is
114 typically taken to be the 15% contour of sea ice concentration. Ice extent is readily obtainable
115 from satellite measurements, as is the actual ice-covered area if the open water within the ice edge
116 is accurately depicted. Surface-based observations from ships or coastal locations typically
117 capture only the ice edge and are therefore useful primarily in the mapping of ice extent. While

118 maps of ice extent exist back to the 1800s, there are no such historical products for ice thickness.
119 *In situ* measurements of ice thickness are sparse in space and time, as are submarine sonar
120 measurements, which are not only sparse but often remain classified. Satellite-derived estimates
121 of ice thickness are subject to considerable uncertainty and have only recently come into use (e.g.,
122 CryoSat), while dynamic-thermodynamic model-based reconstructions of historical sea ice
123 thickness variations have only recently been attempted (Schweiger et al., 2018).

124 To explore predictability that may be inherent in the spatial distribution of sea ice, we compute
125 ice extent using a gridded Arctic-wide sea ice concentration product developed for research
126 applications such as serving as a surface boundary layer in atmospheric studies, or for
127 incorporation in reanalyses. *Gridded Monthly Sea Ice Extent and Concentration, 1850 Onward*
128 (Walsh et al., 2015), referred to in the National Snow and Ice Data Center (NSIDC) catalog as
129 G10010, is based on observations from approximately 15 historical sources between 1850 and
130 1978: the earliest are whaling records, and the most complete, in terms of coverage, are the Arctic-
131 wide analyses that the U.S. Navy compiled beginning in the 1950s. Beginning in 1979, sea ice
132 concentrations from passive microwave data are used exclusively in G10010. Ice concentration
133 fields on the 15th of each month are taken from the *NOAA/NSIDC Climate Data Record of Passive*
134 *Microwave Sea Ice Concentration, Version 2 (Meier et al., 2013)*.

135 Prior to the 1950s, most observations were from near or just within the ice edge. If only the
136 ice edge position was known, a gradient of ice concentration within the edge was imposed in order
137 to integrate the observations into G10010. The gradient was based on a climatology constructed
138 from the passive microwave data. Spatial and temporal gaps in observations were filled using an
139 analog technique that is described in the data product documentation. Each month's sea ice
140 concentration field in G10010 is an estimate of conditions at one time in the month, nominally the
141 15th day of the month (or as close to the 15th as data were available). The fields are at quarter-
142 degree resolution. From these fields one can derive monthly sea ice extent values. Sea ice extent
143 is computed as the area, in sq km, covered by all cells that contain ice in any concentration greater
144 than 15%. Sea ice extent is always greater than or equal to the actual ice-covered area, which
145 excludes the area of open water within the main ice pack.

146 Various studies (e.g. Partington et al., 2003; Agnew and Howell 2002) have shown that
147 passive microwave-derived sea ice data tend to underestimate ice concentration when compared
148 with operational analyses. *The Climate Data Record of Passive Microwave Sea Ice Concentration*

149 is a blend of output from two algorithms that results in higher ice concentrations overall for a better
150 match with the operational analyses that predate the satellite record. Even so, one might expect
151 to see a discontinuity in the G10010 time series of ice extent when the passive microwave record
152 starts in 1979, but this is not evident (see Fig. 10 in Walsh et al., 2016). While G10010 gives a
153 record of ice extent that has realistic variability back to 1850, it is difficult to assign an uncertainty
154 to the concentration fields and ice extent values derived from them. Ice extent will be more
155 accurate than actual ice-covered area because there are many more observations of the ice edge
156 than of the concentrations within interior pack. For this reason, we base our analysis on ice extent.

157 G10010 was used to compute the time series of monthly sea ice extent for the pan-Arctic
158 domain and various Arctic subregions in which sea ice is at least a seasonal feature. The
159 regionalization adopted here follows that of the MASIE (Multisensor Analyzed Sea Ice Extent)
160 product available from the National Snow and Ice Data Center
161 (http://nsidc.org/data/masie/browse_regions). MASIE is produced in cooperation with the U.S.
162 National Ice Center (NIC), and its regions are defined on the basis of NIC operational analyses
163 areas. We use the following MASIE regions: (1) Beaufort Sea, (2) Chukchi Sea, (3) East Siberian
164 Sea, (4) Laptev Sea, (5) Kara Sea, (6) Barents Sea, (7) East Greenland Sea, (8) Baffin Bay/Davis
165 Strait, (9) Canadian Archipelago, (10) Hudson Bay, (11) central Arctic Ocean and (12) Bering Sea.
166 There are several other MASIE regions (Baltic Sea, Yellow Sea, Cook Inlet) that are not used here
167 because they are not geographically connected with the main Arctic sea ice cover. Figure 1 shows
168 the regions.

169 We also make use of the long ice extent record provided by G10010 to investigate the
170 predictability of the Barnett Severity Index, or BSI. The BSI is directly relevant to offshore
171 navigation applications in the Beaufort Sea. It is a metric of the severity of ice conditions, such as
172 conditions encountered by barges resupplying the North Slope. The BSI is determined once per
173 year, at the end of the summer shipping season, by analysts at the U.S. National Ice Center. It is a
174 unit-less linear combination of five parameters: 1) the distance in nautical miles from Point Barrow
175 northward to the ice edge on 15 September, 2) the distance from Point Barrow northward to the
176 4/8th ice concentration line on 15 September, 3) the number of days the entire sea route from the
177 Bering Strait to Prudhoe Bay is ice-free in a calendar year, 4) the number of days the entire sea
178 route to Prudhoe Bay is less than or equal to 4/8th ice concentration in a calendar year, and 5) the
179 temporal length of the navigable season, defined as the time period from the initial date the sea

180 route is less than 4/8th ice concentration to 1 October (Barnett, 1980). Figure 2 is a time series of
181 the BSI reconstructed from gridded sea ice concentration data (see Appendix). Higher values
182 indicate less severe ice conditions.

183 **3 Methods**

184 As shown in Figure 3, Arctic sea ice extents have generally been decreasing. The Beaufort
185 Sea is a prime example of a region in which summer and autumn sea ice coverage has been
186 decreasing, although winter (March) sea ice extent in the Beaufort Sea shows no trend or variability
187 because the ice edge extends to the coastline in March of every year, essentially eliminating year-
188 to-year variations. Consistent with the September decrease of Beaufort ice extent, the BSI has been
189 increasing over the past few decades. Two time series containing trends over time can show a
190 correlation simply because the trends are present in the time series. A trend can be used as a
191 predictive tool by assuming its continuation into the future. However, continuation of a trend and
192 anticipation of it can inflate forecast skill in predictions of interannual variations. Indeed,
193 depictions of time-variations of a quantity such as sea ice extent are often shown as departures
194 from a trend line in order to highlight the interannual variations. Because one of our main interests
195 in this study is whether or not interannual variations of preceding regional extent values correlate
196 with later BSI values, so want to exclude the effect of the overall trends in the correlation of these
197 time series. To do this, we must de-trend the data in the time series.

198 The choice of a function with which to de-trend the time series should be determined by
199 features of the series itself. The detrended time series should exclude the general tendency to
200 change over time, but preserve a measure of the year-to-year variability of the series. Because the
201 change in sea ice extent is more pronounced in the most recent decades (Figure 3), it is not
202 sufficient to simply detrend using a multi-decadal linear fit to the time series.

203 We explored several functional forms which fit the time series, including linear, quadratic,
204 cubic, and exponential functions. We found that a simple two-piece linear function – wherein the
205 data are modeled by two line segments that intersect at a ‘break-point’ year – had the lowest
206 average RMS difference between the time series and the fitted function, although fits using other
207 functions had only slightly larger RMS differences. This choice of the detrending fit has the
208 additional feature of giving a sense of when the ice extent trend began to change more strongly.

209 The two-piece linear fits were obtained by using standard statistical algorithms. A function
210 defined by two intersecting half-lines can be specified by the coordinates of one point on each
211 half-line and the intersection point. With the x-axis as time, and the y-axis as the value of the sea
212 ice extent, the x-values of the non-intersecting points can be chosen to be 1953 and 2013, the first
213 and last years of the BSI dataset. This leaves four values for the function to fit: the series value in
214 1953, the series value in 2013, and the year and value at the intersection point, also referred to here
215 as the break-point. We note that the break-point is not specified by the user but is determined by
216 the algorithm so that the fit to the time series is optimized.

217 The two-piece linear fit was generated by allowing the SciPy ‘curve_fit’ routine (Jones et al.,
218 2001) to iterate to a solution. The ‘curve-fit’ method in the SciPy programming library permits
219 users to define an arbitrary function and to find a minimal least squares fit of that function’s
220 coefficients to a given dataset. The two-piece linear fit was used to detrend the BSI values as well
221 as the time series of the regional and pan-Arctic ice extents. In Figure 4, we show these various
222 fits to the time series of the BSI and the September Beaufort Sea ice extent. In the case of the two-
223 piece linear fit, the break-point (chosen to minimize the departures from trend) is in the early
224 1990s. It is visually apparent from Figure 4 that all four fits are comparable in terms of the overall
225 magnitudes of the departures from the trend lines. The root-mean-square departures from the
226 various trend lines indeed differed by less than 10%. Given the small differences between the fits,
227 we choose the two-piece linear for for the remainder of this study. An additional reason for
228 selecting the two-piece linear fit is that it allows comparisons of the timing of the break-points
229 across the various subregions.

230 After using the ‘linregress’ method from the SciPy (Jones et al., 2001) software library to fit
231 a line to regional monthly extent values and the BSI, we computed correlations between the
232 departures of the two time series from their respective two-piece trend lines. For comparison, we
233 also computed correlations between the “raw” (with trends) time series. The square of the Pearson
234 correlation coefficient (R^2) was computed using the ‘stats’ method from the SciPy package and
235 was used to determine whether and how strongly the two time-series are correlated with each other.

236

237 **4 Results**

238

239 Because changes of trend have not been addressed systematically in previous evaluations of
240 Arctic sea ice trends, we synthesized the break-point information across all regions and calendar
241 months (January-September) included in our study. Figure 5 groups the break-points into five year
242 periods ending in 1955, 1960, ..., 2015. Nearly all the break-points occur in the second half of the
243 study period, with a maximum in 1991-1995. The 1991-1995 period has more than twice as many
244 break-points as any other 5-year period. The break-points for our focal metrics, the BSI and
245 September pan-Arctic ice extent, are 1991 and 1996, respectively, consistent with the distribution
246 in Figure 5. These two metrics are included in the results summarized in Figure 5. One may
247 conclude that the 1990s, and to a lesser extent the first decade of the 2000s, represent the shift to
248 a more rapid rate of sea ice loss. If one is to argue for a “regime shift” in Arctic sea ice loss
249 (Lenton, 2012), this period would be the leading candidate.

250 In order to illustrate the effect of the detrending, Figure 6 shows the squares of the correlations
251 (R^2) between September pan-Arctic ice extent and the concurrent ice extent in each of the
252 subregions. The R^2 metric is used rather than R because R^2 corresponds to the explained variance.
253 The figure shows values of R^2 before detrending (upper numbers, regular font) and after detrending
254 (lower numbers, bold font). With the trend included, the R^2 values are relatively high in most
255 regions (except for the Bering Sea), ranging from 0.32 to 0.71, corresponding to accrual
256 correlations (R) ranging from 0.57 to 0.84. These correlations all exceed the 95% significance
257 thresholds, which range from 0.26 ($R^2 = 0.07$) for a 60-year samples with no autocorrelation to
258 0.38 ($R^2 = 0.14$) for a 60-year samples with an autocorrelation of 0.4. Because these correlations
259 are dominated by the trend, the larger values appear in the regions with trends that are most similar
260 to the pan-Arctic trend. When the data are detrended, the correlations are much smaller (R^2 values
261 in bold font in Fig. 6) although still larger than the 95% significance thresholds for 60-year samples
262 ($R = 0.26$, $R^2 = 0.07$). These smaller values indicate the relative contributions of regional variations
263 to the interannual variations of pan-Arctic ice extent. According to Figure 6, the regions
264 contributing most strongly to September pan-Arctic variations are the Beaufort and East Siberian
265 Seas.

266 Figure 7 shows the squares of the correlations between the annual BSI and regional
267 September ice extent before detrending both ice extent and the BSI (top number) and after
268 detrending (bottom number). While the actual correlations between the BSI and regional extent
269 are generally negative, the R^2 values plotted in Figure 7 are positive. Large values of R^2 appear in

270 most regions when the trend is included (upper numbers) because the BSI has a strong positive
271 trend over time while September ice extent in most regions has a negative trend. The R^2 values
272 are much weaker in regions away from the Beaufort Sea when the trends are removed (lower
273 numbers in Fig. 7). The detrended R^2 values show the spatial representativeness of the BSI as a
274 measure of interannual variations; this representativeness is limited primarily to the Beaufort and
275 Chukchi Seas, with a weak extension into the East Siberian Sea.

276 Because the potential for seasonal predictions is a key motivation for this study, we
277 examine cross-correlations in which the predictands (pan-Arctic ice extent and the BSI) lag
278 potential predictors (regional ice extents) by intervals ranging from zero (no lag) to several
279 seasons. Cross-correlations between non-detrended and detrended September pan-Arctic and
280 regional ice extent are summarized in Tables 1 and 2 respectively. Cross-correlations between
281 non-detrended and detrended BSI and regional ice extent are given in Tables 3 and 4
282 respectively. In all cases, the numerical values are the R^2 values. In order to illustrate the
283 contribution of the trend to the apparent predictability, we present these correlations graphically
284 for the regions which show the strongest associations with the September predictands. Figure 8
285 shows the R^2 values for cases in which September pan-Arctic ice extent lags by 0, 1, 2, ..., 8
286 months the ice extent in four subregions: the Beaufort, Chukchi, East Siberian and Barents Seas.
287 The red bars correspond to correlations computed from the data with the trends included. Not
288 surprisingly, the R^2 values are largest at zero lag. The rates at which the correlations decrease
289 with increasing lag vary regionally, reaching zero by 3-4 months for the Chukchi and East
290 Siberian Seas but remaining weakly positive for the Beaufort and Bering Seas back to the
291 preceding winter. The zero-month lag values are quite large for the Beaufort, Chukchi and East
292 Siberian regions, where they exceed $R^2 = 0.7$ ($R = 0.84$).

293 However, after detrending (using the two-piece linear best fits), most of the apparent
294 predictability is lost. As shown by the blue bars in Figure 8, nearly all the predictability from the
295 Barents and Chukchi Seas vanishes with the detrending, while only small fractions of explained
296 variance remain at non-zero lags when the Beaufort and East Siberian Seas are the predictors. For
297 example, when the regional extent leads by two months (July), the fractions of explained variance
298 are approximately 0.16 and 0.10 ($R \sim 0.40$ and 0.32) for the East Siberian and Beaufort Seas,
299 respectively. The implication is that the persistence of interannual variations about the trend line

300 makes only small contributions to interannual variations of pan-Arctic sea ice extent, and that these
301 small contributions result mainly from the Pacific sector of the Arctic.

302 The lagged R^2 values relevant to predictions of the Barnett Severity Index are shown in Figure
303 9. Because the BSI is based primarily on ice conditions in the Beaufort Sea in August and
304 September, it is not surprising that the correlation is largest for the Beaufort's ice extent in
305 September, when the R^2 value is approximately 0.8 for data that are not detrended. The August
306 and September values for the Chukchi are essentially as large as the corresponding Beaufort
307 values, indicating a spatial coherence of the variations (with trends included) in the two regions.
308 The antecedent extents in the East Siberian and Barents regions also explain significant fractions
309 of the variance when the trends are included.

310 The blue bars in Figure 9 are the lagged R^2 values based on the detrended data. Because the
311 trend's contribution to the predictability has been removed, these correlations provide the most
312 meaningful assessment of the seasonal predictability if the BSI based on antecedent ice conditions.
313 The largest correlations are for the Beaufort Sea, where the explained variances decrease from
314 about 0.55 ($R \sim 0.74$) in September to about 0.10 ($R \sim 0.32$) in June. The correlations for the
315 Chukchi are only slightly smaller, but the values for the East Siberian and Barents Seas are much
316 smaller, generally below 0.10. Because the other regions showed no significant correlations based
317 on the detrended data, we conclude that antecedent ice conditions in only the nearby seas enable
318 predictions of detrended interannual variations of the BSI and only from about June onward.
319 Moreover, that the skill at this seasonal lead time (a prediction made in June for September)
320 accounts for only about 10% of the variance of the BSI.

321

322 **5 Conclusion**

323 The substantial decrease of Arctic sea ice over the past several decades is well documented
324 (Cavalieri and Parkinson, 2012; Parkinson, 2014; Onarheim et al., 2018). Of all the regions
325 considered here, only the Bering Sea does not show a negative trend (Onarheim et al., 2018, their
326 Table 1). However, the extreme minima of Bering Sea ice during the past two winters (2016-17
327 and 2017-18) are starting to bring the Bering's trend into alignment with the other regions of the
328 Arctic.

329 The prominence of the trends in the time series of regional as well as pan-Arctic ice extent
330 makes it important to distinguish the contribution of the trend from other sources of predictability.

331 In this study we explored the use of several methods of detrending in order to evaluate the use of
332 ice anomaly persistence (autocorrelation) and regional cross-correlations as predictors of ice
333 variations. The two-piece linear trend evaluations generally have break-points (increases of
334 trends) in the 1990s, indicating that the rate of ice loss has been greater in the past two decades
335 than in the earlier portion of the satellite era that began in 1979.

336 Based on the raw (not detrended) time series, the antecedent ice extents provide significant
337 predictive skill for September pan-Arctic ice extent as well as for the Barnett Severity Index, which
338 is more specific to the Beaufort Sea. Significant portions of variance of both September metrics
339 are explained by the regional ice extents of prior seasons (and even years, given the multidecadal
340 scales of the trends). However, this predictive “skill” is attributable primarily to the trends in the
341 data. Removal of the trend leaves little forecast skill beyond a month or two when the forecast
342 method is limited to the relatively simple statistical correlations utilized here. The low skill for
343 the detrended September pan-Arctic ice extent is consistent with the findings of Stroeve et al.
344 (2014) based on the Sea Ice Outlook as part of the Study of Environmental Arctic Change
345 (SEARCH).

346 While there is statistical significance in the trend-derived skill at lead times of several seasons
347 and also in the remaining (detrended) skill at lead times of a month or two, statistical significance
348 does not equate to usefulness. Potential users of sea ice forecasts include local communities
349 engaging in offshore subsistence and travel activities, marine transport companies, offshore
350 resource extraction, and the tourism industry. The relatively small fractions of variance predictable
351 several months in advance using detrended data (Figures 6-9) will likely leave uncertainties that
352 are too great for many users. However the trend-derived skill, which can represent 50% or more
353 of the variance, may enable decisions if the interannual variations superimposed on the trend
354 represent acceptable risks for users of sea ice forecasts.

355 Challenges that follow from this study are (1) the placement of skill from other methods
356 (numerical models, heuristic approaches) into a framework of skill evaluation presented here, i.e.,
357 taking into account the skill attributable to trends, and (2) an assessment of the levels of skill
358 (reliability) necessary to enable decisions and planning by various user sectors. An avenue for
359 progress in both (1) and (2) is the Sea Ice Prediction Network, which is now entering its Phase 2
360 (<https://www.arcus.org/sipn>).

428 **Appendix.** Reconstruction of the Barnett Severity Index, 1953-2013

429

430 As described in Section 2, the Barnett Severity Index (BSI) is a combination of five metrics of ice
431 coverage in the Beaufort Sea. Drobot et al. (2003) used the BSI through 2000 in their evaluation
432 of predictability based on multilinear regression against various measures of sea ice cover. In
433 order to update the BSI for use in this study, we base a reconstruction on the digital grids of sea
434 ice concentration in the Historical Sea Ice Atlas (HSIA) for Alaska
435 (<http://seaiceatlas.snap.uaf.edu/>). As with the regional ice extent calculations using G10010
436 (Section 2), we use the HSIA because it extends the record 26 years back in time before the start
437 of the satellite passive microwave record. While the sources of the ice concentration data in the
438 HSIA are the same as in G10010, a notable advantage of the HSIA is its weekly temporal resolution
439 (vs. the monthly resolution of G10010). The HSIA also has a spatial resolution of $\frac{1}{4}^{\circ}$ latitude by
440 $\frac{1}{4}^{\circ}$ degree longitude. Because of the weekly time resolution, the distance metrics (3)-(5) of the
441 BSI are truncated to the nearest week. Similarly, the distance metrics (1) and (2) are truncated to
442 the nearest 27.8 km (15 n mi). One of the within-month dates of the HSIA grids is the 15th of each
443 month, so no temporal interpolation is necessary for metrics (1) and (2). The reconstructed values
444 of the BSI are listed in Table A1.
