12 **Abstract**

13 Continuous measurements of reactive gases in the snowpack and above the snowpack surface were
14 conducted at Concordia Station (Dome C), Antarctica, from December 2012 - January 2014. Measured
15 species included ozone, nitrogen oxides, gaseous elemental mercury, and formaldehyde, for study of
16 photochemical reactions, surface exchange, and the seasonal cycles and atmospheric chemistry of these
17 gases. The experiment was installed ~1 km from the main station infrastructure inside the station clean
18 air sector and within the station electrical power grid boundary. Air was sampled continuously from three
19 inlets on a 10 m meteorological tower, as well as from two above and four below the surface sampling
20 inlets from within the snowpack. Despite being in the clean air sector, over the course of the 1.2-year
21 study, we observed on the order of 15 occasions when exhaust plumes from the camp, most notably from
22 the power generation system, were transported to the study site. Continuous monitoring of nitrogen
23 oxides (NO_x) provided a measurement of a chemical tracer for exhaust plumes. Highly elevated levels of
24 NO_x (up to 1000 x background) and lowered ozone (down to ~50%), most likely from titration with nitric
25 oxide, were measured in air from above and within the snowpack. Within 5-15 minutes from observing
26 elevated pollutant levels above the snow, rapidly increasing and long-lasting concentration enhancements
27 were measured in snowpack air. While pollution events typically lasted only a few minutes to an hour
28 above the snow surface, elevated NO_x levels were observed in the snowpack lasting from a few days to
29 one week. These observations add important new insight to the discussion of if and how snow-
30 photochemical experiments within reach of the power grid of polar research sites are possibly
31 compromised by the snowpack being chemically influenced (contaminated) by gaseous and particulate
32 emissions from the research camp activities. This question is critical for evaluating if snowpack trace
33 chemical measurements from within the camp boundaries are representative for the vast polar ice sheets.

34 **Introduction**

35 Research conducted during the past ~15 years has revealed an active and remarkable spatial diversity
36 of atmospheric oxidation chemistry in the polar lower atmosphere [Grannas *et al.*, 2007]. Ozone plays a

37 fundamental role in controlling the lifetime of many atmospheric trace gases directly and indirectly by
38 modulating atmospheric OH. Unlike the episodic ozone depletion events observed at coastal sites, the
39 opposite effect (i.e. ozone production) has been observed in the Antarctic interior [Crawford *et al.*, 2001;
40 Helmig *et al.*, 2007b; Helmig *et al.*, 2008a; Legrand *et al.*, 2009; Legrand *et al.*, 2016]. The discovery of
41 ozone production chemistry in the remote and pristine Antarctic environment was rather surprising
42 because hitherto photochemical production in the lower atmosphere had exclusively been associated
43 with polluted urban environments [Molina and Molina, 2004]. Photochemical production and snowpack
44 emissions of nitric oxides (NO_x) have been identified as underlying processes driving this chemistry. NO_x
45 has been shown to be formed from photochemical reactions in the snowpack [Honrath *et al.*, 1999; Jones
46 *et al.*, 2000], with deposited nitrate constituting the reservoir of this chemistry. NO_x play a crucial role in
47 snow photochemical reactivity [Murray *et al.*, 2015]. NO_x mixing ratios in interstitial air resulting from
48 photochemical reactions can exceed those in the air above the snowpack by a factor of ~50 [Van Dam *et al.*
49 *et al.*, 2015].

50 This concentration gradient is driving NO_x emission fluxes out of the snowpack into the overlying
51 atmosphere [Jones *et al.*, 2001; Honrath *et al.*, 2002], which, under stable atmospheric conditions, can
52 cause large NO_x enhancements in the atmospheric surface layer [Helmig *et al.*, 2008b; Neff *et al.*, 2008;
53 Frey *et al.*, 2011; Frey *et al.*, 2013], and in the presence of solar irradiance trigger photochemical ozone
54 production, with resulting peak ozone levels that can be double those in the boundary layer [Crawford *et al.*
55 *et al.*, 2001; Helmig *et al.*, 2008a; Legrand *et al.*, 2016]. Experiments on reactive nitrogen chemistry
56 investigating this rather unexpected ozone production chemistry have built on a variety of atmospheric
57 research strategies, including snowpack air sampling [Dibb *et al.*, 2002; Jacobi *et al.*, 2004; Helmig *et al.*,
58 2007a; Van Dam *et al.*, 2015], snow chambers [Dibb *et al.*, 2002], snow chemical analyses [Dassau *et al.*,
59 2002; Dibb *et al.*, 2007b; France *et al.*, 2011; Erbland *et al.*, 2013], atmospheric monitoring [Frey *et al.*,
60 2011; Kramer *et al.*, 2015; Legrand *et al.*, 2016], surface fluxes [Jones *et al.*, 2001; Honrath *et al.*, 2002;
61 Frey *et al.*, 2011; Frey *et al.*, 2015], and boundary layer vertical profiling [Helmig *et al.*, 2008a; Frey *et al.*,
62 2015].

63 Most of these studies rely on observations from dedicated campaigns at research stations, including
64 photochemistry campaigns at Summit, Greenland [Dibb *et al.*, 2007a], the Antarctic Tropospheric
65 Chemistry Investigation [ANTCI; Eisele and Davis, 2008] at the South Pole, the Chemistry of the Antarctic
66 Boundary Layer and the Interface with Snow (CHABLIS) experiment at Halley [Jones *et al.*, 2008], and the
67 Oxidant Production over Antarctic Land and its Export (OPALE) campaign at Concordia Station [Preunkert
68 *et al.*, 2012]. A common limitation of these studies is that experiments were conducted in proximity to
69 large research stations, where use of fuel-powered engines in generators and vehicles cause exhaust
70 emissions with highly elevated concentrations of particulates and gases, particularly of volatile organic
71 compounds (VOC) and NO_x. A critical question is if and how this pollution, and possibly secondary
72 products formed during the atmospheric transport and deposition, impact the snow chemical position
73 and reactivity, and potentially the findings from this aforementioned literature. This is of particular
74 importance for oxidized nitrogen species. This experiment yielded for the first time a year-long record of
75 NO_x and O₃ in an Antarctic snowpack at Concordia and the atmosphere above it. This experiment also
76 gave us the opportunity to study and evaluate occurrences of pollution episodes, using the NO_x monitoring
77 as a sensitive chemical tracer for identification of exhaust plumes.

78 **Methods**

79 **Location:** This experiment was conducted at the French/Italian Antarctic research station Concordia,
80 located at the Dome Circe or Dome Charlie (Dome C, 75.1°S/123.35°E 3233 m asl, mean temperature
81 -55°C). An experimental site was established at the border of the clean air sector, approximately ~1 km
82 west of the station common buildings (Figure 1). The clean air sector is located in the opposite direction
83 of the prevailing wind direction. The site consisted of a 8 m x 2 m x 2.5 m underground laboratory posit-
84

Figure 1: Satellite image of research station Concordia with location of the snow photochemistry experiment indicated by the red cross and text. Its location was ~1 km west of the station main buildings and power generation plant.

85

86 ioned at the border of the clean air area, a 10 m tall meteorological tower, and two snow air sampling
87 manifolds placed 15 m into clean snow ('snow tower') for sampling the atmosphere and the snow
88 interstitial air (Figure 2). The installation was in late November 2012 with continuous monitoring
89 conducted to January 2014 (14 months).

90 **Meteorological Tower:** A 10 m meteorological tower (Figure 2a) was equipped with two sonic
91 anemometers for atmospheric turbulence measurements, and three gas sampling inlets (0.5 m, 2 m, 10
92 m) with sampling lines inside a heated conduit running to the laboratory. The upper inlet was attached

Figure 2: (a) Meteorological tower with the station infrastructure in the background. The wooden box to the left is the entry hatch to the underground laboratory. Air sampling inlets were located at 0.5 m, 2 m and 10 m above the surface on the tower. Two snowpack air sampling towers were located approximately 7 m to the left and 10 m to the right of the base of the meteorological tower. (b) One of the two snow pack air sampling manifold (snow tower), with one pair of inlets right on the snow surface, and one inlet pair at ~ 30 cm height. Four more equivalent sampling inlet pairs are below the snow surface at 30 cm depth intervals extending to a maximum depth of 1.2 m.

93

94 to a manual pulley allowing that inlet to be lowered for side by side sampling of both inlets for tracking
95 and correcting sampling inlet/lines biases.

96 Snowpack Air Sampling: Two identical multi-inlet snow sampling manifolds ('snow tower') for collection
97 of interstitial and ambient air at six ~ 20 cm vertical intervals were constructed, with a similar design to
98 that described by [Seok *et al.*, 2009] (Figure 2b). The snow tower consisted of a vertical post of square
99 aluminum alloy (3.8 x 3.8 cm) with eight 60 cm long cross arms spaced vertically every 30 cm. Each of the
100 cross bars supported a pair of sampling inlets. The inlets were fitted with 25 mm Acrodisc hydrophobic
101 polytetrafluoroethylene (PTFE) syringe filters (Pall Life Sciences, Ann Arbor, Michigan, USA) to prevent
102 snow and ice crystals from being pulled into the sampling line. For the installation, a snow pit was dug
103 and the lines inserted into the clean untouched walls of the pit. The hole was then refilled with the
104 excavated snow, respecting the stratigraphy as much as possible. Insulated and heated sampling lines
105 connected the sampling inlets to the chemical analyzers in the underground laboratory. All sampling lines
106 were of 0.64 cm o.d. x 30 m long pre-conditioned PFA tubing, except the lines to the gradient inlets on
107 the meteorological tower, which were of 0.78 cm o.d. because they were continuously pumped to
108 maintain a flow of 2 l min^{-1} . Air was pulled through the snow tower sampling lines by the combined flow
109 of the gas analyzers (ozone monitor 1 l min^{-1} , a gaseous elemental mercury (GEM) analyzer 1 l min^{-1} , NO_x
110 monitor 1 l min^{-1}). A maximum of two monitors sampled from the snow tower inlets together at a given
111 time to limit the maximum snow air sampling. Since each line connected to a pair of inlets at equal height,
112 the effective flow through each inlet was a maximum of $\sim 1 \text{ l min}^{-1}$. Each height was sampled for 10 min
113 every 2 hours, resulting in an approximate volume of a sphere with a radius of 25 cm around each inlet
114 every 2 hours. Each sampling inlet had a thermocouple wire attached for monitoring the snowpack
115 temperature gradient.

116 Ozone Measurements: Ozone was measured with a Thermo Environmental (TEI) 49i UV absorption
117 monitor that was calibrated against a NOAA Global Monitoring Division reference standard before field
118 shipment.

119 NO_x Measurements: Nitrogen oxides were monitored with a TEI chemiluminescence analyzer (TEI 42C-
120 TL). The TEI 42C-TL has two channels. The first channel measures NO via NO + O₃ chemiluminescence.
121 The second channel measures total nitrogen oxides (NO_x = NO + NO₂) by redirecting air through a heated
122 (325°C) molybdenum converter, which causes NO₂—including other oxidized nitrogen compounds—to be
123 converted to NO. NO₂ is then determined by subtracting NO, obtained from the first channel, from the
124 resulting NO_x signal. There are a number of other oxidized nitrogen species that can contribute to the
125 NO₂ measurement [Steinbacher *et al.*, 2007]. The error in the NO₂ measurement increases with rising
126 levels of interfering gases such as nitrous acid (HONO), peroxyacetyl nitrate (PAN), and alkyl nitrates that
127 contribute to the NO₂-mode signal. Consequently, NO₂ concentrations obtained with the TEI 42C-TL
128 represent an estimate for the sum of these oxidized nitrogen species. Field calibrations were conducted
129 with a NIST-traceable 1 ppm NO in N₂ gas standard (Scott-Marine, Inc., Riverside, CA, USA) that was
130 dynamically diluted to low ppb mixing ratios with NO_x-scrubbed ambient air.

131 Snow Sampling and NO₃⁻ Determination:

132 The snow pit NO₃⁻ data stem from sampling that was done at and near Concordia between January 2009
133 and December 2010, and at ~3 m distance from snow tower 2 in January 2014. Snow was collected in pre
134 cleaned 50 ml centrifuge tubes inserted directly on a newly scraped wall of the snow pit. Nitrate
135 concentration in snow samples were measured directly in the field, at the wet chemistry laboratory of
136 Concordia station. Each sample was melted at room temperature and NO₃⁻ concentrations were
137 determined using a colorimetric method employed routinely at Concordia [Frey *et al.*, 2009].

138 **Results and Discussion**

139 Results of the year-round snowpack and ambient monitoring, including interpretations of photochemistry
140 will be presented elsewhere [Helmig *et al.*, 2018]. Here, we primarily focus on occurrences of pollution
141 transport to the site and its penetration into the snowpack.

142 Figure 3 shows a photograph of the station main buildings. The power plant is adjacent to the two column
143 structure. Approximately 300 m³ of Special Antarctic Blend (SAB) diesel fuel are burned in the plant for
144 electricity and heat generation per year. The exhaust plume from the 5-m high stack of the power plant
145 can be seen in the picture, blowing towards the west. Due to the typical strong stratification and stability
146 of the atmosphere near the surface, the plume does not rise far above the stack height, but instead gets
147 transported horizontally at a height of ~5 m above the snow surface. This is a typical exhaust plume
148 dispersion behavior for a cold regions environment, seen at many other polar research stations. The
149 plume typically does not hit the surface within the immediate distance of the stack location. Depending
150 on the actual turbulent mixing conditions it may take several hundreds of meters before the stack
151 emissions are encountered right at the surface.

152 Of the gases monitored in this experiment, NO_x were the most sensitive tracer for pollution impact. NO_x
153 in ambient air at Concordia remained well below 1 ppb during background conditions year-round [Helmig
154 *et al.*, 2018], in agreement with observations from prior shorter campaign NO_x measurement at Concordia

Figure 3: Photograph of Dome C station illustrating the dispersion of the exhaust plume from the electrical power generating plant during conditions with a strong surface temperature inversion. The plume is blown towards the west in the direction of the experimental site. This is a typical situation for a contamination event.

155

156 [Frey *et al.*, 2011; Frey *et al.*, 2013; Frey *et al.*, 2015]. We did not observe highly elevated NO levels in the
157 surface layer outside of pollution events, as what has been observed at South Pole [Helmig *et al.*, 2008b;
158 Neff *et al.*, 2008]. During pollution events, this threshold was exceeded very quickly in measurements
159 taken from the meteorological tower and from above-surface snow tower inlets, with resulting NO_x mixing
160 ratios rising to as high as close to 200 ppb, representing an up to 1000-fold enhancement over background
161 conditions (Figure 4).

162 During the course of the ~14 month study, a total of ~50 pollution events were observed, although some
163 events overlapped (Figure 4). Most of these occurrences were relatively short, with elevated mixing ratios
164 above the snowpack lasting from minutes to a few hours. Within the snowpack, NO_x mixing ratios
165 remained elevated for 1-5 days after the event. Integrated over the entire campaign, pollution episodes
166 constituted < 2.0 % of the measurements above the snowpack, and <10% of the measurements within
167 the snowpack. The correlation analyses of pollution occurrences with wind direction clearly defines the
168 direction of the transport. The predominant wind direction sector at Concordia is southeast to northwest
169 (Figure 5a), with southeasterly winds having the largest share. NO_x levels were consistently well below 1
170 ppb when winds were from east to northeast. The sector with pollution transport is well defined, with
171 wind directions covering approximately 45-120° (Figure 5b). These sectors perfectly line up with the
172 upwind direction of the station power plant (Figure 1), clearly identifying the plant as the source of these
173 pollution occurrences.

Figure 4: NO_x measured from the above surface inlets on the two snow towers, and from all inlets on the meteorological tower. Circles represent 10-min averaged data. Plotted are data that were extracted from occurrences when NO_x was above 1 ppb, well above the background mixing ratio, and any time when the wind direction was from the polluted wind sector.

174

175

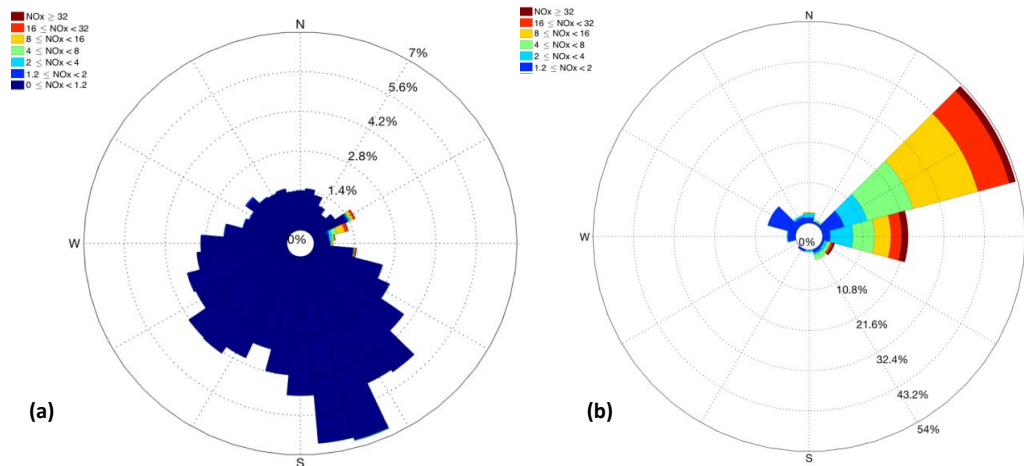

Figure 5: (a) Concentration wind rose with the relative frequency of NO_x mixing ratio data from the above surface inlets of the two snow towers segregated by 10° sectors for the full year of observation data. This panel shows all data. (b) The same analysis, with wind direction data binned in 20° sectors for events when NO_x in ambient air exceeded 1.2 ppb.

176

177 One of these elevated NO_x events is further investigated in Figure 6. Here, we show the measurements
178 from six inlets on the snow tower over a one-week period. The sampling of a polluted plume is first
179 observed in the two above surface inlets (orange/red colored data; +10 and +45 cm), by the sudden
180 increase of NO_x from well below 1 ppb to a mixing ratio of ~ 13 ppb. This spike in NO_x lasted for ~ 3 hours.
181 After that time, NO_x in air sampled above the surface dropped very quickly and equilibrated to prior mixing
182 ratios within less than 0.5 hours.

Figure 6. Measurements from the snow tower capturing a pollution event at Concordia during the middle of the winter (Day of Year 191 = July 11). Plotted time series traces correspond to the sampling heights indicated in the legend, with positive numbers giving the height above the snow surface, and negative numbers the depth below the snow surface. The right graph (b) is an enlargement of the data shown in the left (a). The sampling switched between the two snow towers every 24 hours leading to some abrupt shifts in NO_x measurements from within the snowpack.

183
184 A much different behavior was found in the air sampled from within the snowpack, indicated by the
185 data in the blueish colors. The onset of the pollution signal is delayed, by 1-3 hours, with progressively
186 later times towards deeper in the snowpack. Maximum mixing ratios that are reached in the snowpack
187 are lower, i.e. 10-50% those that were measured above the surface, with mixing ratio maxima becoming
188 progressively smaller with increasing depth. The most remarkable difference between the above and
189 below surface measurements is the longer residence time of the pollution signal in the snowpack. NO_x
190 mixing ratios in air withdrawn from all sampling inlets in the snowpack dropped steadily, but remained
191 elevated in comparison to levels seen before the pollution event for a week. The behavior seen in the
192 measurements from snow tower 1 were in full qualitative, and within $\sim 30\%$ quantitative agreement with
193 the concurrent observations from the second snow tower. After the pollution event, NO_x in the snowpack
194 air gradually declined over several days (Figure 6). Fitting of the data to an exponential decay function
195 yields similar results for all snowpack depths (Figure 7), with exponential regression fit R^2 results ≥ 0.95 .
196

Figure 7. Exponential decay function fits to the NO_x snowpack measurements versus time at four depths for the event starting on Day of Year 191 shown in Figure 6. The start of the event was defined as the time when high NO_x was detected above the snowpack. Solutions for the best fit exponential decay functions are given in the legend.

197

198

199 Effects of the exhaust transport were also observed in the ozone signal. Here, the signal was negative
200 from destruction of ozone by titration of NO in the exhaust plume. Up to 50% of the ambient ozone was
201 destroyed in air sampled from the above surface inlets. Similar to NO_x , this signal, albeit weaker and
202 attenuated in time, was also seen in the air sampled from within the snowpack (Supplement Figure S-1).

203 Nitrogen oxides undergo reaction with atmospheric oxidants, primarily the OH radical (summer only)
204 and ozone, yielding higher oxidized nitrogen species (including NO_3 , N_2O_5 , HNO_3 , HNO_4) that can further
205 react and partition into the snowpack aqueous and solid phases. The frequency, large enhancement, and
206 long duration (in the snowpack) of NO_x pollution events constitute an apparent unnatural source of NO_x
207 to the snowpack. One can hypothesize that further reaction of NO and NO_2 with oxidants, such as with
208 OH, may be a source of HNO_2 and HNO_3 in the snowpack, which would add acidity to the snow. This then
209 also poses the question if and to what degree photochemical processes, building for instance on NO_2^- or
210 NO_3^- as a substrate, may be altered from natural conditions. Further, the transformations of NO_x into
211 these higher oxidized species may potentially leave a long-lasting signature in the snowpack (such as of
212 NO_3^-).

213 We investigated this question by comparing NO_3^- results from snow pit sampling at different locations
214 within the camp and at up to 25 km distance of the Dome C. Nitrate in the snowpack shows a steep
215 vertical gradient, with highest levels observed right at the surface, and progressively lower concentrations
216 with increasing depth (Figure 8). The results from the seven snow pits are consistent in the depth profile;

217

Figure 8. Nitrate concentration in snow pits in proximity (~ 20 m) to the snow towers (warm colors) at the border of the clean air sector, and sampling locations up and downwind of Concordia (cold colors). Sampling dates are indicated in the figure legend. Horizontal error bars depict the estimated uncertainty of the chemical analysis, i.e. 10% at > 10 ng g⁻¹, 50% between 5-10 ng g⁻¹, and 100% at < 5 ng g⁻¹.

218

219 however, there appears to be a tendency that the four snow pits within the camp have somewhat higher,
220 as well as more variable snow NO₃⁻ at intermediate depths (around 50 cm). Deeper into the snowpack
221 the difference between the two groups of data becomes weaker. At 1 m depth, the snow age is
222 approximately ten years, and therefore approximately corresponds to the start of permanent and year-
223 round activities in 2005 (note that summer activities at Dome C were established in 1996). This behavior
224 in the NO₃⁻ vertical gradient in the Antarctic snowpack has been previously investigated and documented
225 [France *et al.*, 2011]. Further, relatively higher NO₃⁻ in the upper layers of the snowpack is observed during
226 the Antarctic summer (Supplement Figure S-2), with average NO₃⁻ levels approximately 5 times higher
227 than during the winter. This NO₃⁻ enhancement in surface snow and the seasonal cycle have been linked
228 to the production of HNO₃ in the photoactive summer months from reaction of OH with NO₂, with the
229 NO₃⁻ enhancement being the result of HNO₃ deposition to the snow surface [Erbland *et al.*, 2013].
230 Elevated NO₃⁻ concentrations observed at the surface of the snowpack are a common feature at low
231 accumulation regions, with the concentration values depending strongly on the strategy for collection of
232 the first few cm of the snow pack [Erbland *et al.*, 2013; Shi *et al.*, 2018]. With the sensitivity of surface
233 snow NO₃⁻ to the seasonal cycle and sampling strategy, the high variability of NO₃⁻ observed at the surface
234 precludes conclusive interpretation to what degree the snowpack at Concordia is impaired by ventilation
235 of the snowpack with pollution-NO_x enriched air. Contamination of the snow pack around the Concordia
236 station has been noted in previous investigation of black carbon, with a > 3-fold increase in concentration

237 between pre- and post-2003 [Warren *et al.*, 2006]. This increase in black carbon was shown to result in a
238 significant decrease in light penetration into the snowpack [Warren *et al.*, 2006; France *et al.*, 2011; Libois
239 *et al.*, 2013]. In addition to the experiments described thus far, during the 2014 campaign a number of
240 dynamic flow through snow chamber photochemistry experiments were conducted comparing snow from
241 near the snow tower site to snow sampled 25 km away from camp. These experiments showed on the
242 order of 15% differences in ozone loss in the chambers (*unpublished results*). We did not conduct a high
243 enough number of repeats for evaluating the repeatability of these experiments to gauge if and how much
244 of this signal was due to the experimental setup or the due to differences in the snowpack chemical
245 composition. Nonetheless, these preliminary findings point towards possible chemical behavior that is
246 potentially linked to differences in the snow sampling locations and camp influences.

247

248 **Summary and Conclusions**

249 With our snowpack sampling manifold we were able to sample snowpack air to a maximum depth of 70
250 cm below the surface. Up to ~2 ppb enhancement was observed at that depth from exhaust infiltration.
251 While our experiment wasn't able to access air deeper (than 70 cm), the concentration gradients observed
252 apply that this transport and contamination extends well beyond the depth that was probed in these
253 measurements.

254 Our experiment was a one spot measurement, at ~1 km distance from the camp main facilities. We have
255 no data that would allow us to assess to what distance from the camp the snowpack pollution from
256 exhaust infiltration would be of noticeable and of importance, but it likely extends well beyond the
257 distance of our site.

258 Our measurements from Concordia Station emphasize the pronounced and long-lasting influence that
259 station exhaust can have on NO_x levels in snowpack air. A tendency of potentially enhanced snowpack
260 NO₃⁻ levels in two snow pits collected at the camp, compared to data from three sites at further distance
261 supports the suspicion that the snowpack composition at the station may be compromised (i.e.
262 contaminated) from the re-occurring ventilation of the snowpack with polluted (NO_x-enriched) air.
263 Chemical signatures of other trace species that have enhanced concentration levels in engine exhaust,
264 such as black carbon, organic gases are left behind in the snowpack is already demonstrated, resulting in
265 a decrease of the e-folding depth of the light penetration. The associations shown in our study argue for
266 further investigation, for instance by a high resolution spatial survey of surface snow composition within
267 and beyond camp boundaries. Given the strong seasonality of NO₃⁻, this survey should be done with as
268 close as possible concurrently conducted snow sampling at selected locations to minimize the influence
269 of temporal changes on the NO₃⁻ signature.

270 These observations emphasize concerns about the representativeness of experimental snow chemistry
271 data collected within a Polar research camp periphery. This raises the question of how interpretations
272 from such experiments reflect conditions in the remote Polar environment. Furthermore, our findings
273 should motivate comparison studies with sampling along transects to further distances from the main
274 camp facilities. Comparison of these observations will likely yield new insights for evaluating prior polar
275 research site observations and interpretation of snow photochemistry in the glacial snowpack.

276

277 **Author contribution:**

278 DH oversaw the study, participated in field work, conducted data analyses and quality control, and
279 prepared the manuscript.

280 DL conducted data analyses, quality control, prepared figures, and contributed to the manuscript
281 preparation.

282 JH fabricated the instrumental equipment and data acquisition system, and participated in the field work.

283 JS contributed to the study design, participated in field work, conducted data analyses and interpretation,
284 and contributed to the manuscript preparation.

285

286

287 **Acknowledgements:**

288 We thank all staff and scientists who helped with the setup and maintenance of the experiment at
289 Concordia Station. A. Mass, W. Vicars, and A. Barbero helped with some of the field experimental work
290 and data processing. A. Barbero provided the photograph in Figure 3. The French partners acknowledge
291 technical support from the C2FN (French National Center for Coring and Drilling, handled by INSU), a grant
292 from Labex OSUG@2020 (Investissements d'avenir – ANR10 LABX56), and the program 1011 SUNITEDC
293 of the Institut Polaire Paul Emile Victor (IPEV). The U.S. scientists were supported through a grant from
294 the National Science Foundation (NSF), PLR#1142145.
