Abstract

26
27 Permafrost peatlands store large amounts of carbon potentially vulnerable to
28 decomposition. However, the fate of that carbon in a changing climate remains uncertain
29 in models due to complex interactions among hydrological, biogeochemical, microbial,
30 and plant processes. In this study, we estimated effects of climate forcing biases present
31 in global climate reanalysis products on carbon cycle predictions at a thawing permafrost
32 peatland in subarctic Sweden. The analysis was conducted with a comprehensive
33 biogeochemical model (*ecosys*) across a permafrost thaw gradient encompassing intact
34 permafrost palsa with an ice core and a shallow active layer, partly thawed bog with a
35 deeper active layer and a variable water table, and fen with a water table close to the
36 surface, each with distinct vegetation and microbiota. Using *in situ* observations to
37 correct local cold and wet biases found in the Global Soil Wetness Project Phase 3
38 (GSWP3) climate reanalysis forcing, we demonstrate good model performance by
39 comparing predicted and observed carbon dioxide (CO₂) and methane (CH₄) exchanges,
40 thaw depth, and water table depth. The simulations driven by the bias-corrected climate
41 suggest that the three peatland types currently accumulate carbon from the atmosphere,
42 although the bog and fen sites can have annual positive radiative forcing impacts due to
43 their higher CH₄ emissions. Our simulations indicate that projected precipitation increases
44 could accelerate CH₄ emissions from the palsa area, even without further degradation of
45 palsa permafrost. The GSWP3 cold and wet biases for this site significantly alter
46 simulation results and lead to erroneous active layer depth (ALD) and carbon budget
47 estimates. Biases in simulated CO₂ and CH₄ exchanges from biased climate forcing are as
48 large as those among the thaw stages themselves at a landscape-scale across the

49 examined permafrost thaw gradient. Future studies should thus not only focus on changes
50 in carbon budget associated with morphological changes in thawing permafrost, but also
51 recognize the effects of climate forcing uncertainty on carbon cycling.

52 **1. Introduction**

53 Confidence in future climate projections depends on the accuracy of terrestrial
54 carbon budget estimates, which are presently very uncertain (Friedlingstein et al., 2014;
55 Arneeth et al., 2017). In addition to the complexity in physical process representations, a
56 major source of this uncertainty comes from challenges in quantifying climate responses
57 induced by biogeochemical feedbacks. Increases in atmospheric carbon dioxide (CO₂)
58 concentrations can directly stimulate carbon sequestration from plant photosynthesis
59 (Cox et al., 2000; Friedlingstein et al., 2006) and indirectly stimulate carbon emissions
60 (e.g., from soil warming and resulting increased respiration), although the predicted
61 magnitudes of these exchanges strongly depend on model process representations (Zaehle
62 et al., 2010; Grant, 2013, 2014; Ghimire et al., 2016; Chang et al, 2018).

63 The undecomposed carbon stored in permafrost is of critical importance for
64 biogeochemical feedbacks to climate because it is about twice as much as currently is in
65 the atmosphere (Hugelius et al., 2014) and is vulnerable to release to the atmosphere as
66 permafrost thaws (Schuur et al., 2015). O'Donnell et al. (2012) suggested that permafrost
67 thaw would result in a net loss of soil organic carbon from the entire peat column because
68 accumulation rates at the surface were insufficient to balance deep soil organic carbon
69 losses upon thaw. Jones et al. (2017) indicated that the loss of sporadic and discontinuous
70 permafrost by 2100 could result in a release of up to 24 Pg of soil carbon from permafrost
71 peatlands to the atmosphere. Lundin et al. (2016) reported that it is plausible (71%
72 probability) for the high latitude terrestrial landscapes to serve as a net carbon source to
73 the atmosphere, although its peatland components would remain atmospheric carbon
74 sinks.

75 In addition to the overall carbon balance of the changing Arctic, the type of
76 carbon gaseous emission is important to climate feedbacks. High latitudes are predicted
77 to get wetter (IPCC, 2014), and saturated anaerobic conditions facilitate methane (CH₄)
78 production, which is a much more efficient greenhouse gas than CO₂ in terms of global
79 warming potential. Even habitats that can be net carbon sinks can produce positive
80 radiative forcing impacts on climate due to CH₄ release, as Bäckstrand et al. (2010)
81 showed for a subarctic peatland. Under projected warming and wetting trends in the
82 Arctic (Collins et al., 2013; Bintanja and Andry, 2017), carbon cycle feedbacks over the
83 permafrost region could become stronger as increased precipitation enhances surface
84 permafrost thaw and strengthens CH₄ emissions by expansion of anaerobic volume
85 (Christensen et al., 2004; Wickland et al., 2006).

86 The Stordalen Mire in northern Sweden (68.20°N, 19.05°E) is in the
87 discontinuous permafrost zone, encompassing a mosaic of thaw stages with associated
88 distinct hydrology and vegetation (Christensen et al. 2004; Malmer et al., 2005),
89 microbiota (Mondav and Woodcroft et al., 2014; Mondav et al., 2017; Woodcroft and
90 Singleton et al., 2018), and organic matter chemistry (Hodgkins et al., 2014). These
91 landscapes have been shifting over the last half-century to a more thawed state, likely due
92 to recent warming (Christensen et al. 2004). Drier hummock sites dominated by shrubs
93 have degraded to wetter sites dominated by graminoids (Malmer et al., 2005; Johansson
94 et al., 2006). The thaw-induced habitat shifts are associated with increases in landscape-
95 scale CH₄ emissions (Christensen et al. 2004; Johansson et al., 2006; Cooper et al., 2017)
96 reflective of the higher CH₄ emissions of the wetter thawed habitats (McCalley et al.,
97 2014). The higher CO₂ uptake in later thaw-stage habitats has not compensated for the

98 increase in positive radiative forcing from elevated CH₄ emissions (Bäckstrand et al.,
99 2010; Deng et al., 2014).

100 The impacts of climate sensitivity on the terrestrial carbon cycle have been
101 investigated at the global scale, and the results highlight the need to consider uncertainty
102 in climate datasets when evaluating permafrost region carbon cycle simulations
103 (Ahlström et al., 2017; Guo et al., 2017; Wu et al., 2017). Ahlström et al. (2017) showed
104 that climate forcing biases are responsible for a considerable fraction (~40%) of the
105 uncertainty range in ecosystem carbon predictions from 18 Earth System Models (ESMs)
106 reported by Anav et al. (2013). Guo et al. (2017) concluded that the differences in climate
107 forcing contribute to significant differences in simulated soil temperature, permafrost
108 area, and **Active Layer Depth (ALD)**. Wu et al. (2017) demonstrated that differences
109 among climate forcing datasets contributes more to predictive uncertainty than
110 differences in apparent model sensitivity to climate forcing. However, notably, none of
111 these studies accessed the effects on CH₄ emissions, and their spatial resolution could not
112 represent site-level spatial heterogeneity observed in arctic tundra (Grant et al. 2017a;
113 2017b).

114 Here, we use the ecosystem model *ecosys*, which employs a comprehensive set of
115 coupled biogeochemical and hydrological processes, to estimate the effects of climate
116 forcing uncertainty and sensitivity on CO₂ and CH₄ exchanges and **ALD** simulations. For
117 the Stordalen Mire site, we estimated bias in the Global Soil Wetness Project Phase 3
118 (GSWP3) climate reanalysis dataset using site-level long-term meteorological
119 measurements and evaluated impacts on simulated soil and plant processes across the
120 permafrost thaw gradient. This approach enables us to assess model sensitivity to

121 individual climate forcing biases, instead of the aggregated uncertainty range embedded
122 in climate datasets (e.g., variations of climate conditions represented in different climate
123 datasets) presented in previous studies. We address the following questions for our study
124 site at the Stordalen Mire: (1) What are the biases embedded in the GSWP3 climate
125 reanalysis dataset? (2) How do those biases affect model predictions of **ALD**, CO₂
126 exchanges, and CH₄ exchanges? (3) How does climate sensitivity vary across the stages
127 of permafrost thaw? In addition to improving understanding of permafrost responses to
128 climate, we identify ecosystem carbon prediction uncertainty induced by climate forcing
129 uncertainty in general as the biases found in GSWP3 were consistent with other climate
130 reanalysis datasets during the last decade (section 3).

131

132 **2. Methods and Data**

133 **2.1 Study site description**

134 Our study sites are located at the Stordalen Mire (68.20 °N, 19.03 °E: 351 m
135 above sea level), which is about 10 km southeast of the Abisko Scientific Research
136 Station (ANS) in northern Sweden. Significant changes in climate over this region have
137 been recorded during the last few decades. The annual mean air temperature measured at
138 the ANS has risen by 2.5 °C from 1913 to 2006, where it exceeded the 0 °C threshold
139 (0.6 °C in 2006) for the first time over the past century (Callaghan et al., 2010). The
140 measured annual total precipitation has also increased from 306 mm y⁻¹ (years 1913 to
141 2009) to 336 mm y⁻¹ (years 1980 to 2009) (Olefeldt and Roulet, 2012), along with
142 increased variability in extreme precipitation (Callaghan et al., 2010). The measured
143 annual maximum snow depth has increased from 59 cm (years 1957 to 1971) to 70 cm

144 (years 1986 to 2000), and the snow cover period with snow depth greater than 20 cm has
145 decreased from 5.8 months (years 1957 to 1971) to 4.9 months (years 1986 to 2000)
146 (Malmer et al., 2005). Inception of peat deposition at the Stordalen Mire has been dated
147 at around 6,000 calendar years before present (cal. BP) (Sonesson 1972) in the southern
148 part of the mire and at around 4,700 cal. BP in the northern part (Kokfelt et al., 2010).
149 Kokfelt et al. (2010) suggested that permafrost aggregation initiated during the Little Ice
150 Age (around 120–400 cal. BP) in the Stordalen Mire.

151 The Stordalen Mire can be broadly classified into three peatland types: intact
152 permafrost palsa, partly thawed bog, and fen (Hodgkins et al., 2014), hereafter referred to
153 as palsa, bog, and fen (Figure 1). The spatial distribution of these peatland types in 2000
154 are described in Olefeldt and Roulet (2012). The palsa sites are ombrotrophic and raised
155 0.5 to 2.0 m above their surroundings, with a relatively thin peat layer (0.4 to 0.7 m,
156 Rydén et al., 1980), thinner active layer depth (less than 0.7 m in late summer), and no
157 measurable water table depth (Bäckstrand et al., 2008a; 2008b; Olefeldt and Roulet,
158 2012). The bog sites are ombrotrophic and are wetter than the palsa sites, with a thicker
159 peat layer (0.5 to ~1 m, Rydén et al., 1980), deeper ALD (greater than 0.9 m), and water
160 table depth fluctuating from 35 cm below the peat surface to the ground surface
161 (Bäckstrand et al., 2008a; 2008b; Olefeldt and Roulet, 2012). The fen sites are
162 minerotrophic, receiving a large amount of water from a lake to the east of the mire, with
163 water table depths near or above the ground surface (Bäckstrand et al., 2008a; 2008b;
164 Olefeldt and Roulet, 2012). All three of the investigated peatland types were there before
165 1930's, based on Swedish military photography.

166 Differences in hydrology and permafrost conditions create high spatial
167 heterogeneity with different soil moisture, pH, and nutrient conditions that support
168 different plant communities (Bäckstrand et al., 2008a; 2008b). The palsa is dominated by
169 dwarf shrubs with some sedges, feather mosses, and lichens (Malmer et al., 2005;
170 Bäckstrand et al., 2008a; 2008b; Olefeldt and Roulet, 2012). The bog is dominated by
171 *Sphagnum* spp. mosses with a moderate abundance of sedges (Malmer et al., 2005;
172 Bäckstrand et al., 2008a; 2008b; Olefeldt and Roulet, 2012). The fen sites we studied are
173 dominated by sedges (Bäckstrand et al., 2008a; 2008b).

174

175 **2.2 Field measurements**

176 Continuous daily meteorological measurements have been recorded at the ANS
177 since 1913, including air temperature, precipitation, wind speed, wind direction, relative
178 humidity, and snow depth. Measurements of solar radiation, longwave radiation, and soil
179 temperature are also available at the ANS since 1982. The soil thaw depth (measured to
180 90 cm) and water table depth measurements were taken in the three peatland types 3 to 5
181 times per week from early May to mid-October during 2003 to 2007 (Bäckstrand et al.,
182 2008b).

183 CO₂ and CH₄ exchanges at the three peatland types were measured with
184 automated chambers during the thawed seasons from 2002 to 2007 (Bäckstrand et al.,
185 2008b). Chamber lids were removed when snow accumulates in winter (around
186 November), and the sampling period for each year ranged from days 87–147 in 2002
187 (shortest) and days 148–341 in 2005 (longest) (Bäckstrand et al., 2008b; Bäckstrand et
188 al., 2010). Three chambers were in the palsa, three were in the bog, and two were in the

189 fen (we term each chamber a ‘subsite’ in the following). Each chamber covered an area
190 of 0.14 m² with a height of 25–45 cm depending on the vegetation and the depth of
191 insertion and was closed for 5 minutes every 3 hours to measure CO₂ and total
192 hydrocarbon (THC) exchanges. CH₄ exchanges were manually observed approximately 3
193 times per week, and these measurements were used to quantify the proportion of CH₄ in
194 the measured THC (Bäckstrand et al., 2008a). The CH₄ exchanges were near zero in the
195 palsa sites (Bäckstrand et al., 2008a; Bäckstrand et al., 2008b; Bäckstrand et al., 2010), so
196 they were not used in model evaluation. We used the CO₂ and CH₄ exchanges observed
197 at 3-hourly steps when the R² values recorded in the measurements were greater than 0.8
198 (Tokida et al., 2007), and then calculated the associated daily mean exchanges when there
199 were 8 measurements per day (Table 1). The quality-controlled daily measurements only
200 covered 12.4–33.7% of the daily data points because of the lack of continuous quality-
201 controlled 3-hourly measurements. The data screening was applied to exclude unreliable
202 measurements and avoid biases from inappropriate gap filling, which is necessary for
203 model evaluations. More detailed descriptions of the CO₂ and CH₄ exchanges
204 measurements can be found in Bäckstrand et al. (2008a).

205

206 **2.3 GSWP3**

207 GSWP3 is an ongoing modeling activity that provides global gridded
208 meteorological forcing (0.5° x 0.5° resolution) and investigates changes in energy, water,
209 and carbon cycles throughout the 20th and 21st centuries. The GSWP3 dataset is based on
210 the 20th Century Reanalysis (Compo et al., 2011), using a spectral nudging dynamical
211 downscaling technique described in Yoshimura and Kanamitsu (2008). A more detailed

212 description of the GSWP can be found in Dirmeyer (2011) and van den Hurk et al.
213 (2016).

214 In this study, we extracted the meteorological conditions at the Stordalen Mire
215 from 1901 to 2010 from the GSWP3 climate reanalysis dataset. The 3-hourly products of
216 air temperature, precipitation, solar radiation, wind speed, and specific humidity were
217 interpolated to hourly intervals with cubic spline interpolation to serve as the
218 meteorological inputs used in our model.

219 The GSWP3 dataset was chosen over other existing climate reanalysis datasets for
220 its spatial and temporal resolutions. For example, the Climatic Research Unit (CRU;
221 Harris et al., 2014) dataset provided monthly meteorological forcing at $0.5^\circ \times 0.5^\circ$
222 resolution; the National Centers for Environmental Prediction (NCEP; Kalnay et al.,
223 1996; Kanamitsu et al., 2002) dataset provided 6-hourly meteorological forcing at T62
224 Gaussian grid ($\sim 1.915^\circ \times 1.895^\circ$ resolution); the CRUNCEP (Viovy, 2018) dataset
225 provided 6-hourly meteorological forcing at $0.5^\circ \times 0.5^\circ$ resolution; and the European
226 Centre for Medium-Range Weather Forecasts (ECMWF; Berrisford et al., 2011) dataset
227 provided 3-hourly meteorological forcing with 125 km ($\sim 1.125^\circ$) horizontal resolution.
228

229 **2.4 Model description**

230 *Ecosys* is a comprehensive biogeochemistry model that simulates ecosystem
231 responses to diverse environmental conditions with explicit representations of microbial
232 dynamics and soil carbon, nitrogen, and phosphorus biogeochemistry. The **aboveground**
233 processes are represented in multi-layer plant interacting canopies, and the **belowground**
234 processes are represented in multiple soil layers with multi-phase subsurface reactive

235 transport. *Ecosys* operates at variable time steps (down to seconds) determined by
236 convergence criteria, and it can be applied at patch-scale (spatially homogenous one-
237 dimensional) and landscape-scale (spatially variable two- or three-dimensional). Detailed
238 descriptions, including inputs, outputs, governing equations, parameters, and references
239 of the *ecosys* model can be found in Grant (2013). A qualitative summary of the *ecosys*
240 model structure is provided in the supplemental material to this article.

241 The *ecosys* model has been extensively tested against eddy covariance fluxes and
242 related ecophysiological measurements with a wide range of sites and weather conditions
243 in boreal, temperate, and tropical forests (Grant et al., 2007a; Grant et al., 2007c; Grant et
244 al., 2009a; Grant et al., 2009b; Grant et al., 2009c; Grant et al., 2010), wetlands (Dimitrov
245 et al., 2011; Grant et al., 2012b; Dimitrov et al., 2014; Mezbahuddin et al., 2014),
246 grasslands (Grant and Flanagan, 2007; Grant et al., 2012a), tundra (Grant et al., 2003;
247 Grant et al., 2011b; Grant 2015; Grant et al., 2015), croplands (Grant et al., 2007b; Grant
248 et al., 2011a), and other permafrost-associated habitats (Grant and Roulet, 2002; Grant,
249 2017a; Grant et al., 2017b). All *ecosys* model structures are unchanged from those
250 described in these earlier studies.

251 **2.5 Experimental design**

252 To evaluate the effects of climate on model predictions, we conducted four sets of
253 simulations at each of the three peatland types at the Stordalen Mire from 1901 to 2010.
254 The climate data from 1901 to 2001 were used for model initialization (i.e., spinup) and
255 those from 2002 to 2010 were used for analysis. The 110 year simulations were
256 performed to ensure the simulation was equilibrated with local climate (Grant et al.
257 2017a).

258 The meteorological conditions for all the simulations were based on the hourly
259 data extracted from the GSWP3 climate reanalysis dataset (section 2.3). The monthly
260 mean bias of the GSWP3 for this location was calculated by comparing it to the air
261 temperature and precipitation measured at the ANS, for years 1913 to 2010 (section 3.1).
262 The full series of air temperature and precipitation extracted from GSWP3 were then
263 bias-corrected using the monthly mean bias calculated from 1913 to 2010; we label this
264 model scenario CTRL. Our bias correction was conceptually similar to the one used in
265 Ahlström et al. (2017), where the bias-corrected climate forcing fields were the ESM
266 outputs adjusted by the corresponding bias calculated from observations in a reference
267 period.

268 The simulation results from CTRL should represent the reliability of applying
269 *ecosys* at the Stordalen Mire because CTRL is driven by the best local climate
270 description. We first evaluated predicted thaw depth, water table depth, and CO₂ and CH₄
271 exchanges using the CTRL simulation (section 3.2 to 3.4). In the second set of
272 simulations, BIASED-COLD, the biased GSWP3 air temperature data was used, and we
273 corrected only the GSWP3 precipitation. Deviations between CTRL and BIASED-COLD
274 reflect biased air temperature's effects on responses across the thaw gradient. In the third
275 set of simulations, BIASED-WET, we bias-corrected the air temperature extracted from
276 GSWP3, which allows us to quantify the effects of biased precipitation. Finally, we used
277 the meteorological conditions directly extracted from GSWP3 to drive our fourth set of
278 simulations, BIASED-COLD&BIASED-WET, which reveals the uncertainty range of
279 subarctic peatland simulation associated with the local biases in GSWP3 climate forcing.

280 While the three peatland types share the same climate conditions, they differ in
281 soil hydrologic conditions and vegetation characteristics (section 2.1; Figure 1). The bulk
282 density and porosity profiles were set to the values reported in Rydén et al. (1980), who
283 suggested a decreasing trend of bulk density and an increasing trend of porosity from
284 palsa (0.12 Mgm⁻³ at surface; 92–93% within the upper 10 cm) to bog and fen (0.06
285 Mgm⁻³ at surface; 96–97% within the upper 10 cm). The peatland soil carbon-to-nitrogen
286 (CN) ratios and pH values were assigned according to Hodgkins et al. (2014), who
287 documented an increasing trend of pH from palsa (4.0), to bog (4.2), to fen (5.7), and a
288 decreasing trend of soil organic matter CN ratio from bog (46±18), to palsa (39±24), to
289 fen (19±0.4). Common values of field capacity (0.4) and wilting point (0.15) were used
290 for the three peatland types (Deng et al., 2014). The soil property parameters used in our
291 simulation for the three peatland types are summarized in Supplemental Material Table1.

292

293 3 Results and Discussion

294 3.1 GSWP3 climate comparison to observations

295 As described in section 2.3, we extracted meteorological conditions at the
296 Stordalen Mire from the GSWP3 climate reanalysis dataset. The closest GSWP3 grid cell
297 was centered at 68.0 °N and 19.0 °E, which covers the Stordalen Mire and the ANS. The
298 annual mean air temperature and precipitation calculated at this GSWP3 grid cell were -
299 3.65 °C and 683.88 mm y⁻¹, respectively, for years 1913 to 2010. A cold bias (-3.09 °C)
300 was identified in the GSWP3 annual mean air temperature during the 1913 to 2010
301 period, although a very high correlation coefficient (r = 0.99) was found when compared
302 with the ANS measurements (Figure 2a). Both time series exhibit an overall warming

303 trend from the early 20th century to the present ($0.01^{\circ}\text{C y}^{-1}$), with an even larger warming
304 trend from 1980 to 2010 ($0.05^{\circ}\text{C y}^{-1}$ [ANS] and $0.04^{\circ}\text{C y}^{-1}$ [GSWP3]).

305 Similarly, the GSWP3 annual total precipitation data correlates well with ANS
306 measurements ($r = 0.80$) but has a wet bias of 380 mm y^{-1} between 1913 and 2010
307 (Figure 2b). An increasing trend in annual total precipitation was recorded in both time
308 series from the early 20th century to present (0.47 mm y^{-2} [ANS] and 1.07 mm y^{-2}
309 [GSWP3]), although a decreasing trend was found from 1980 to 2010 (-0.56 mm y^{-2}
310 [ANS] and -2.39 mm y^{-2} [GSWP3]).

311 The seasonal cycle of the GSWP3 monthly mean air temperature also matches
312 that measured at the ANS, with a very high correlation coefficient ($r = 0.99$; Figure 3a).
313 The underestimation bias and inter-annual variability of GSWP3 air temperature are
314 greater in winter (maximum underestimate in December, at -4.52°C with inter-annual
315 variability of 3.53°C) and smaller in summer (minimum underestimate in July, at -1.52
316 $^{\circ}\text{C}$ with inter-annual variability of 1.65°C), respectively.

317 The magnitude and inter-annual variability of the GSWP3 monthly mean
318 precipitation are comparable between winter and summer, while the ANS measurements
319 exhibit stronger seasonality with lower magnitudes during winter. Despite the differences
320 found in seasonal patterns, a high correlation coefficient ($r = 0.64$) was found between the
321 monthly mean precipitation extracted from GSWP3 and the ANS measurements. The
322 overestimation of monthly mean precipitation was greatest in December (43.25 mm
323 month^{-1}) and smallest in August ($18.75\text{ mm month}^{-1}$).

324 These comparisons suggest that GSPW3 air temperature and precipitation data
325 reasonably capture measured seasonal and long-term trends over past decades, but are

326 biased cold and wet compared to observations, especially during winter. Similar cold and
327 wet biases exist in CRUNCEP and ECMWF climate reanalysis datasets during our 2003
328 to 2007 study period (Supplemental Material Figure 1). The annual mean air temperature
329 and precipitation at the Stordalen Mire for years 2003 to 2007 were $-2.49\text{ }^{\circ}\text{C}$ and 795.09
330 mm y^{-1} ; $-2.46\text{ }^{\circ}\text{C}$ and 708.60 mm y^{-1} ; and $-2.28\text{ }^{\circ}\text{C}$ and 765.67 mm y^{-1} in the GSWP3,
331 CRUNCEP, and ECMWF climate reanalysis datasets, respectively.

332

333 **3.2 Model testing**

334 **3.2.1 Thaw depth**

335 We first evaluated *ecosys* against observations using bias-corrected climate
336 forcing (i.e., the CTRL simulation). Predicted thaw depth agrees well with measurements
337 collected from 2003 to 2007 for all examined peatland types (Figure 4), with a correlation
338 coefficient of 0.95, 0.87, and 0.41 at the palsa, bog, and fen, respectively. Both
339 simulations and observations show that the rate of thaw depth deepening in the summer
340 varies with peatland type (i.e., relatively slow, moderate, and rapid in the palsa, bog, and
341 fen, respectively).

342 Predicted and observed maximum thaw depth (i.e., ALD) in the intact permafrost
343 palsa was between 45 and 60 cm in September. In the partly thawed bog, the simulated
344 thaw depth is slightly shallower than that observed before August. The simulated bog
345 thaw depth becomes greater than 90 cm by the end of August, which matches the time
346 when measured thaw depth reaches its maximum. The thaw depth becomes greater than
347 90 cm by the end of July in the fen. The patterns of thawing permafrost presented here

348 are consistent with Deng et al. (2014), who simulated the same site using the DNDC
349 model.

350

351 **3.2.2 CO₂ exchanges**

352 The daily Net Ecosystem Exchange (NEE) simulated in the CTRL simulation
353 reasonably captures observed seasonal dynamics from 2003 to 2007 for all the examined
354 peatland types (Figure 5). The simulations and observations generally showed net CO₂
355 uptake (with some episodic CO₂ emissions) during summer and release during winter.
356 The observations and simulations also showed large CO₂ emissions in the palsa site
357 during fall of 2004. Simulated fall CO₂ bursts in the three sites in other years could not be
358 confirmed because of a lack of observations during these periods. Similar to the patterns
359 reported in Raz-Yaseef et al. (2016), some episodic CO₂ emission pulses were simulated
360 as surface ice thaws in spring, but there were no measurements to confirm those events.
361 The correlation coefficients of the simulated and observed daily NEE ranged from 0.58 to
362 0.60, and most of the discrepancies between the simulations and observations were within
363 the ranges of NEE variability measured at different subsites (automated chambers) within
364 the same peatland type.

365 As described in section 2.2, simulated CO₂ exchanges were evaluated for 3-hourly
366 and daily time steps when quality-controlled measurements were available (R² values and
367 relative root mean squared errors (RRMSEs) shown in Table 2). Simulated NEE is in
368 reasonable agreement with the 3-hourly NEE measurements with RRMSEs ranging
369 from 8.4 to 19.1%. Model comparisons with observations were generally poorer at daily
370 time steps, although the calculated RRMSEs were comparable to those reported in Deng

371 et al. (2014). We suspect these differences resulted from uncertainty in determining an
372 accurate observed daily NEE representative of the entire peatland type due to (1) limited
373 daily data points (less than 14% across the study period, Table 1) due to lack of
374 continuous quality-controlled 3-hourly measurements and (2) the large variability of daily
375 NEE ranges measured at different subsites within the same peatland type (Figure 5). Our
376 results thus indicate that NEE is affected by thaw stage (Bäckstrand et al., 2010; Deng et
377 al., 2014) and fine scale spatial heterogeneity of the system. More detailed measurements
378 with higher spatial and temporal resolutions within the same peatland type would be
379 necessary to characterize the effects of this type of heterogeneity.

380

381 3.2.3 Water table depth and CH₄ exchanges

382 Simulated water table depth generally captures observed seasonal patterns
383 measured in the bog and fen sites from 2003 to 2007 (Figure 6a, c). During summer, the
384 predicted bog water table depth fluctuates around the ground surface (-7 to -1 cm), and
385 the predicted water table depth is at or above the ground surface in the fen. Water table
386 depths simulated by *ecosys* are generally higher than measured in the bog, where
387 measured water table depths are often below the ground surface with greater seasonal
388 variability. Simulated fen water table depths have better overall fit to observations, being
389 higher (~5 cm) than measurements in 2003 and 2004, close to measurements in 2005 and
390 2006, and slightly deeper (~2 cm) than measurements in 2007. These differences in
391 modeled and observed water table depth could be driven by the limitations of our one-
392 dimensional column simulation which inhibits lateral water transport and hinders the
393 variations of water table depth, which is a particular issue in simulating the dynamic

394 water table of the bog. A multi-dimensional simulation that includes realistic topographic
395 effects could help improve the representation of water table dynamics, and estimates of
396 the measurement uncertainty would help facilitate the assessment of simulation bias.

397 Simulated and measured daily CH₄ exchanges correlate reasonably well in the
398 bog ($r = 0.49$) and well in the fen ($r = 0.65$) across the study period (Figure 6b, d). Both
399 the simulations and observations have stronger CH₄ emissions during summer with peak
400 emissions in late summer. Some episodic CH₄ emission pulses (Mastepanov et al., 2008)
401 were simulated during shoulder seasons, and the simulated amount of post-growing
402 season CH₄ emissions agrees well with those measured in 2007.

403 Most of the discrepancies between simulated and observed CH₄ emissions were
404 within the variability of measurements across subsites within the same peatland type. The
405 3-hourly and daily RRMSEs ranged from 11.1 to 22.3% (Table 2) and the daily RRMSEs
406 were comparable to results presented in Deng et al. (2014). Our results show that model
407 evaluation of CH₄ emissions with finer temporal resolution observations is not necessarily
408 superior to evaluation with coarser temporal resolution, as compared to the NEE
409 counterpart, which could be related to weaker CH₄ emission variability measured across
410 subsites within the same peatland type (Figure 6b, d).

411

412 3.3 Variability across the permafrost thaw gradient

413 Thaw rate and ALD increase along the thaw gradient (i.e., palsa to bog to fen),
414 and landscape variations are generally greater than simulated inter-annual variability
415 (Figure 7a). Maximum carbon uptake also increases along the thaw gradient, and
416 variations across the landscape are comparable with simulated intra-seasonal and inter-

417 annual variabilities (Figure 7b). The simulated mean seasonal cumulative NEE were
418 calculated based on the seasonality identified in Bäckstrand et al. (2010), and the results
419 show that the magnitude of mean growing season CO₂ uptake is highest in the fen and
420 lowest in the palsa (Table 3). The same rank applies to the magnitude of mean CO₂
421 emissions over the non-growing season, although differences across the thaw gradient are
422 smaller.

423 CH₄ emission rates increase significantly along the thaw gradient, and the palsa
424 site emissions are negligible (Figure 7c). Mean cumulative CH₄ emissions simulated in
425 the fen are much higher than those in the bog, and most CH₄ emissions occur during the
426 growing season (Table 3). The higher CH₄ emissions in the fen can be attributed to its
427 faster seasonal thaw rate (Figure 7a) and a water table depth close to the surface (Figure
428 6c). Seasonal cumulative NEE and CH₄ emissions from observations could not be
429 accessed due to the lack of continuous quality controlled carbon flux measurements
430 during our study period (Table 1).

431

432 **4. Climate sensitivity of permafrost thaw**

433 **4.1 Thaw responses to climate**

434 For each of the four sets of simulations with different climate forcing (section
435 2.5), simulated mean ALD from 2003 to 2007 is always greatest in the fen and lowest in
436 the palsa (Figure 8). This consistent trend along the thaw gradient indicates that ALDs
437 are largely regulated by their distinct ecological and hydrological conditions, because all
438 three sites had the same climate forcing in each set of simulations (i.e., CTRL, BIASED-
439 COLD, BIASED-WET, and BIASED-COLD&BIASED-WET). Therefore, the palsa,

440 bog, and fen have different resilience against the changes in climate forcing, and this type
441 of ecosystem resilience plays an important role in determining ALD under changes in
442 climate conditions.

443 Effects of climate on simulated ALD are similar across peatland types (Figure 8).
444 With increased precipitation (BIASED-WET vs. CTRL), simulated ALD generally
445 becomes deeper with greater inter-annual variability because the increased snowpack
446 depth keeps the soil warmer with lower soil ice content during winter. This effect is less
447 prominent in the comparison between experiments BIASED-COLD and BIASED-
448 COLD&BIASED-WET, because the cold biases in these two experiments (section 3.1)
449 constrain ALD development. For example, summertime soil heating in some of the
450 simulation years was not strong enough to thaw the soil ice between 20-40 cm completely
451 in the BIASED-COLD&BIASED-WET run, resulting in shallower ALDs simulated in
452 the palsa and fen even with the snowpack warming effect. The simulated ALD also
453 becomes deeper with higher air temperature (CTRL vs. BIASED-COLD; BIASED-WET
454 vs. BIASED-COLD&BIASED-WET) at all the examined peatland types. This response
455 is more evident in the comparison between experiments BIASED-WET and BIASED-
456 COLD&BIASED-WET, probably driven by their wet biases (section 3.1) that facilitate
457 ALD deepening (via increased thermal conductivity and advective heat transport; Grant
458 et al. 2017a). Similar dependencies between ALD and climate were shown in Åkerman
459 and Johansson (2008) and Johansson et al. (2013), based on multi-year measurements and
460 snow manipulation experiments.

461 Therefore, the combined cold and wet biases in the GSWP3 climate reanalysis
462 dataset could counteract their individual effects on simulated ALD development at the

463 Stordalen Mire. Our results indicate a 28.6%, 0.7%, and 11.7% underestimation of ALD
464 simulated in the palsa, bog, and fen, respectively, when applying the GSWP3 climate
465 reanalysis data over this region without proper bias correction (BIASED-
466 COLD&BIASED-WET vs. CTRL). Our sensitivity analysis suggests that projected
467 warming and wetting trends (Collins et al., 2013) could significantly increase ALD in the
468 Arctic, since increases in precipitation and air temperature can both contribute to ALD
469 deepening.

470

471 **4.2 Carbon budget responses to climate**

472 **Simulations** with the four climate forcing datasets (section 2.5) **indicate annual**
473 **mean (from 2003 to 2007) CO₂ sinks** and **CH₄ sources**, except the weak CO₂ emissions
474 simulated **in** the fen in experiment BIASED-COLD&BIASED-WET **due to reduced**
475 **sedge productivity driven by increased temperature and oxygen stresses** (Figure 9a,b).
476 Our results also indicate that differences in annual CO₂ and CH₄ exchanges across the
477 four climate forcing datasets for a single peatland type are as large as those across
478 peatland types for a single climate forcing dataset (Figure 9a,b). These large CO₂ and
479 CH₄ exchanges climate sensitivities demonstrate that the peatland's dynamical responses
480 to climate have stronger effects on the carbon cycle than on ALDs (Figure 8).

481 With bias-corrected precipitation, increased air temperature (CTRL vs. BIASED-
482 COLD) leads to stronger CO₂ uptake and greater CH₄ emissions at all the examined
483 peatland types (Figure 9a,b), mainly because enhanced sedge growth facilitates carbon
484 cycling under a warmer environment (results not shown). This air temperature sensitivity
485 affects CO₂ and CH₄ exchanges within the same peatland type without significantly

486 changing ALD (Figure 8). For both experiments, CO₂ uptake and CH₄ emissions are
487 greatest in the fen and lowest in the palsa, consistent with the measurements reported in
488 Bäckstrand et al. (2010) for the same period. Based on the Coupled Model
489 Intercomparison Project, phase 5 (CMIP5) ESM simulations, arctic annual mean surface
490 air temperature is projected to increase by 8.5±2.1 °C over the 21st century (Bintanja and
491 Andry, 2017). This projected air temperature increase is more than double the air
492 temperature difference between site-observed and GSWP3 temperatures, which could
493 significantly enhance CH₄ emissions regardless of palsa degradation into bog and fen.

494 On the other hand, wet biases (BIASED-WET and BIASED-COLD&BIASED-
495 WET) increase CH₄ emissions in the palsa; wetter and colder conditions result in as much
496 CH₄ release as the current fen, while wetter conditions alone drive palsa emissions
497 comparable to the current bog (Figure 9b). The large precipitation sensitivity found in
498 palsa CH₄ emissions could have strong effects on palsa carbon cycling because arctic
499 precipitation is projected to increase by 50 – 60% towards the end of the 21st century
500 (based on CMIP5 estimates; Bintanja and Andry, 2017). The comparison between
501 experiments BIASED-WET and BIASED-COLD&BIASED-WET shows that in the
502 palsa, increased air temperature strengthens CO₂ uptake and weakens CH₄ emissions.
503 This shift is primarily driven in the model by increased shrub and moss productivity
504 under the warmer environment, which facilitate CO₂ uptake while drying out the soil and
505 reducing CH₄ emissions (results not shown). In the bog and fen sites, increased air
506 temperature under wet bias strengthens both the simulated CO₂ uptake and CH₄
507 emissions (BIASED-WET vs. BIASED-COLD&BIASED-WET), due to enhanced sedge
508 growth under the warmer environment that facilitates carbon cycling in the experiment

509 BIASED-WET. The low CH₄ emissions in bog and fen simulated in experiment
510 BIASED-COLD&BIASED-WET are driven by increased temperature and oxygen
511 stresses that greatly reduce heterotrophic respiration (CH₄ production) and sedge cover
512 (aerenchyma transport).

513 We assessed the integrated effects of the changes in CO₂ and CH₄ exchanges
514 identified in the full suite of simulations in terms of the Net Carbon Balance (NCB) and
515 net emissions of greenhouse gases expressed as CO₂ equivalents (Net Greenhouse Gas
516 Balance; NGGB). NCB was defined as the sum of the annual total CO₂ and CH₄
517 exchanges. NGGB was defined in a similar fashion as the NCB, but considers the greater
518 radiative forcing potential of CH₄ than CO₂ (28 times over a 100-year horizon, Myhre et
519 al., 2013) when calculating the annual total. The calculated NCB values are mostly
520 negative because the stronger CO₂ uptake dominates the weaker CH₄ emissions (Figure
521 9c). The results suggest that all the examined peatland types serve as net carbon sinks
522 under current climate (CTRL), consistent with the estimates reported in Deng et al.
523 (2014) and Lundin et al. (2016). We find a 24, 36, and 38 g C m⁻² y⁻¹ underestimation of
524 NCB simulated in the palsa, bog, and fen sites, respectively, due to the cold and wet
525 biases in the GSWP3 climate reanalysis dataset (BIASED-COLD&BIASED-WET vs.
526 CTRL). NGGB is affected more strongly by CH₄ emissions (Figure 9d) due to its larger
527 radiative forcing potential. NGGB values are positive over the bog and fen, suggesting
528 that these sites have positive radiative forcing impacts despite being net carbon sinks.
529 NGGB simulated in the palsa is generally negative (i.e., a net sink from the atmosphere)
530 due to lower CH₄ emissions, except for the simulation conducted without any climate bias
531 correction (correcting only air temperature increased CH₄ emissions but not enough to

532 compensate for the significantly higher CO₂ sink). Our results indicate that the simulated
533 NGGB would be biased by 298, -66, and -252 g CO₂-eq m⁻² y⁻¹ in the palsa, bog, and fen,
534 respectively, without proper bias correction for the GSWP3 climate reanalysis dataset
535 (BIASED-COLD&BIASED-WET vs. CTRL). Using the GSWP3 products directly thus
536 effectively eliminates the positive radiative forcing from the expanding bog and fen,
537 while creating a potentially dramatically inaccurate positive radiative forcing from the
538 shrinking palsa.

539

540 **4.3 Climate sensitivity versus landscape heterogeneity**

541 Climate sensitivity and landscape heterogeneity are defined here as variability
542 across the four climate forcing datasets for a single peatland type, and variability across
543 three peatland types with bias-corrected climate (CTRL), respectively. We estimated
544 carbon cycle variability associated with climate sensitivity and landscape heterogeneity to
545 quantify the corresponding uncertainty in our annual carbon cycle assessments from 2003
546 to 2007. Our results indicate that differences in simulated annual mean CO₂ exchanges
547 and NCB from climate sensitivity are greater than those from landscape heterogeneity
548 (Figure 9a,c); i.e., annual CO₂ uptake strength is more sensitive to climate forcing
549 uncertainty than to peatland type representation. In terms of the simulated annual mean
550 CH₄ emissions and NGGB, our results indicate that variability from climate sensitivity is
551 comparable to those from landscape heterogeneity (Figure 9b,d). Therefore, bias-
552 corrected climate and realistic peatland characterization are both necessary to reduce the
553 uncertainty in representing carbon cycling dynamics and their radiative forcing effects.

554 In addition to their effects on carbon cycle predictions, changes in climate
555 conditions also affect permafrost degradation and thus induce changes in areal cover of
556 peatland types. Malmer et al. (2005) showed that there were -0.95, 0.24, and 0.62 ha areal
557 cover changes (-10.3%, 4.0%, and 46.3% percentage changes) from 1970 to 2000 in
558 palsa, bog, and fen, respectively, at the Stordalen Mire. By applying the annual mean
559 CO₂ and CH₄ exchanges simulated with bias-corrected climate from 2003 to 2007, the
560 areal cover changes from 1970 to 2000 alone would lead to -44 kg C y⁻¹, 76 kg C y⁻¹, and
561 2076 kg CO₂-eq y⁻¹ changes in annual mean CO₂ exchanges, CH₄ exchanges, and NGGB,
562 respectively, at the Stordalen Mire. The changes in landscape-scale carbon cycle
563 dynamics indicate that the radiative warming impact of increased CH₄ emissions is large
564 enough to offset the radiative cooling impact of increased CO₂ uptake at the Stordalen
565 Mire, consistent with the estimates reported in Deng et al. (2014). The areal cover
566 changes across peatland types could persist or accelerate under the projected warming
567 and wetting trends in the Arctic (Collins et al., 2013; Bintanja and Andry, 2017), which
568 could stimulate CH₄ emissions and produce a stronger radiative warming impact.

569

570 **5. Conclusions**

571 We evaluated the climate bias in a widely used atmospheric reanalysis product
572 (GSWP3) at our northern Sweden Stordalen Mire site. We then applied a comprehensive
573 biogeochemistry model, *ecosys*, to estimate the effects of these biases on active layer
574 development and carbon cycling across a thaw gradient at the site. Our results show that
575 *ecosys* reasonably represented measured hydrological, thermal, and biogeochemical cycle
576 processes in the intact permafrost palsa, partly thawed bog, and fen. We found that the

577 cold and wet biases in the GSWP3 climate reanalysis dataset significantly alter model
578 simulations, leading to biases in simulated Active Layer Depths, Net Carbon Balance,
579 and Net Greenhouse Gas Balance by up to 28.6%, 38 g C m⁻² y⁻¹, and 298 g CO₂-eq m⁻²
580 y⁻¹, respectively. The Net Carbon Balance simulated with bias-corrected climate suggests
581 that all the examined peatland types are currently net carbon sinks from the atmosphere,
582 although the bog and fen sites can have positive radiative forcing impacts due to their
583 higher CH₄ emissions.

584 Our results indicate that the annual means of ALD, CO₂ uptake, and CH₄
585 emissions generally increase along the permafrost thaw gradient at the Stordalen Mire
586 under current climate, consistent with previous studies in this region. Our analysis
587 suggests that palsa, bog, and fen differ strongly in their carbon cycling dynamics and
588 have different responses to climate forcing biases. Differences in simulated CO₂ and CH₄
589 exchanges driven by uncertainty from climate forcing are as large as those from
590 landscape heterogeneity across the examined permafrost thaw gradient. Model
591 simulations demonstrate that the palsa site exhibits the strongest sensitivity to biases in
592 air temperature and precipitation. The wet bias in GSWP3 could erroneously increase
593 predicted CH₄ emissions from the palsa site to a magnitude comparable to emissions
594 currently measured in **the** bog and fen sites. These results also show that increased
595 precipitation projected for high latitude regions could strongly accelerate CH₄ emissions
596 from the palsa area, even without degradation of palsa into bog and fen. Future studies
597 should thus recognize the effects of climate forcing uncertainty on carbon cycling, in
598 addition to tracking changes in carbon budgets associated with areal changes in
599 permafrost degradation.

934

935 Table 1. Temporal coverage of quality-controlled CO₂ and CH₄ exchanges measured by
 936 automated chambers at the three peatland types in the Stordalen Mire during the years
 937 2002 to 2007.

Sites	Number of data points	CO ₂		Number of data points	CH ₄	
		3 Hourly coverage (%)	Daily coverage (%)		3 Hourly coverage (%)	Daily coverage (%)
Palsa	12752	65.8	12.4	N/A	N/A	N/A
Bog	12821	68.5	12.7	6660	96.2	25.0
Fen	8989	63.8	13.7	4923	90.5	33.7

938

939 Table 2. Evaluation of the 3 hourly and daily CO₂ and CH₄ exchanges simulated at the
 940 palsa, bog, and fen sites. RRMSEs are relative root mean squared errors.

Sites	C component	3-Hourly		Daily	
		R ²	RRMSEs (%)	R ²	RRMSEs (%)
Palsa	CO ₂	0.48	13.4	0.36	18.3
Bog	CO ₂	0.63	19.1	0.44	35.8
	CH ₄	0.31	16.3	0.47	22.3
Fen	CO ₂	0.64	8.4	0.43	25.5
	CH ₄	0.44	11.1	0.54	16.9

941

942

943 Table 3. Means and standard deviations of cumulative CO₂ and CH₄ exchanges simulated
 944 in the palsa, bog, and fen during the period 2003 to 2007. All exchanges are in units of g
 945 C m⁻².

Sites	C flux component	Growing season; Days 119–288		Non-growing season; Days 1–118/289–365	
		Mean	Standard deviation	Mean	Standard deviation
Palsa	CO ₂	-72.70	19.10	38.89	4.09
	CH ₄	0.04	0.02	0.01	0.002
Bog	CO ₂	-79.59	21.46	42.89	2.16
	CH ₄	3.52	0.45	0.42	0.11
Fen	CO ₂	-88.65	7.26	44.41	6.13
	CH ₄	10.86	3.95	0.78	0.18

949 Figure 1. Schematic diagram of the sampling sites at Stordalen Mire.

950

951

952 Figure 2. Time series of air temperature (a) and precipitation (b) measured at ANS (red;
 953 years 1913–2016) and extracted from GSWP3 (blue; years 1901–2010). Dots are the
 954 annual means and solid lines are the decadal moving averages of the corresponding
 955 annual means. Thin and thick dashed lines are the trends for years 1913–2010, and years
 956 1980–2010, respectively. The inset r values are the correlation coefficients calculated
 957 between the two time series.

958

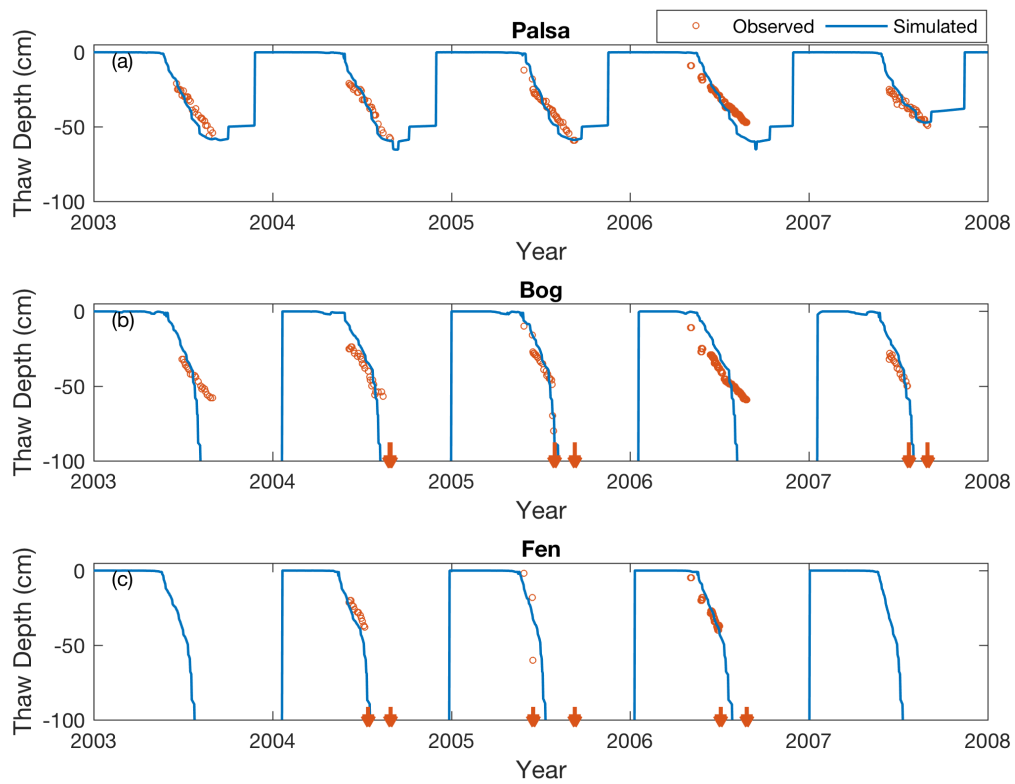

959

960 Figure 3. Monthly mean air temperature (a) and precipitation (b) measured at ANS (red)
 961 and extracted from GSWP3 (blue). The shaded area is the inter-annual variability for the
 962 corresponding dataset, represented by the standard deviations calculated at each month.

963 The inset r values are the correlation coefficients calculated between the two time series.

964

965

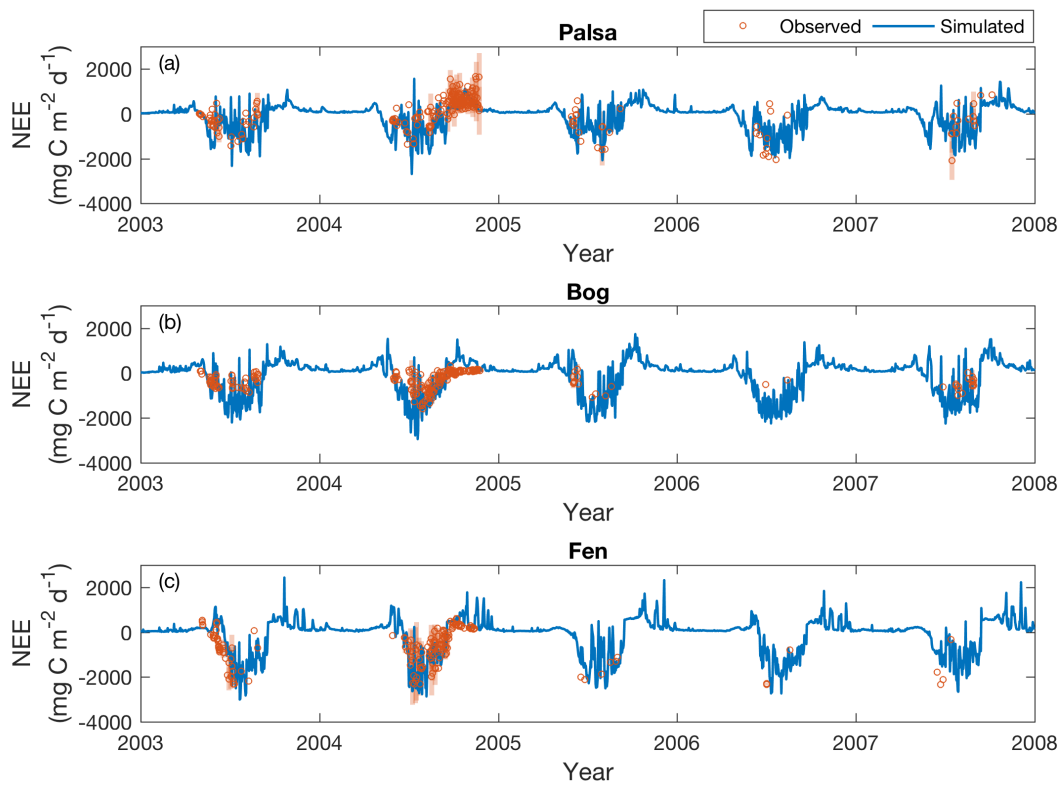

966 Figure 4. Simulated (solid lines) and measured (open circles) seasonal dynamics of thaw

967 depth at the palsa (a), bog (b), and fen (c) sites from 2003 to 2007. Downward arrows

968 indicate the time when measured thaw depth deepens below 90 cm for a measurement

969 year.

970

971

972 Figure 5. Simulated (solid lines) and measured (open circles) daily CO₂ exchanges (NEE)

973 at the palsa (a), bog (b), and fen (c) sites, from 2003 to 2007. Shaded bars are the

974 standard deviations of daily NEE measured across subsites under each peatland type.

975 Positive and negative values indicate effluxes from and influxes to the site, respectively.

976

977

978 Figure 6. Simulated (solid lines) and measured (open circles) water table depth and daily

979 CH₄ emissions at the bog and fen from 2003 to 2007. Shaded bars are the standard

980 deviations of the daily CH₄ emissions measured across the subsites under each peatland

981 type.

982

983

984 Figure 7. Daily thaw depth (a), daily NEE (b), and daily CH₄ (c) exchanges for the three

985 sites from 2003 to 2007. Solid lines and open circles are the simulated and measured

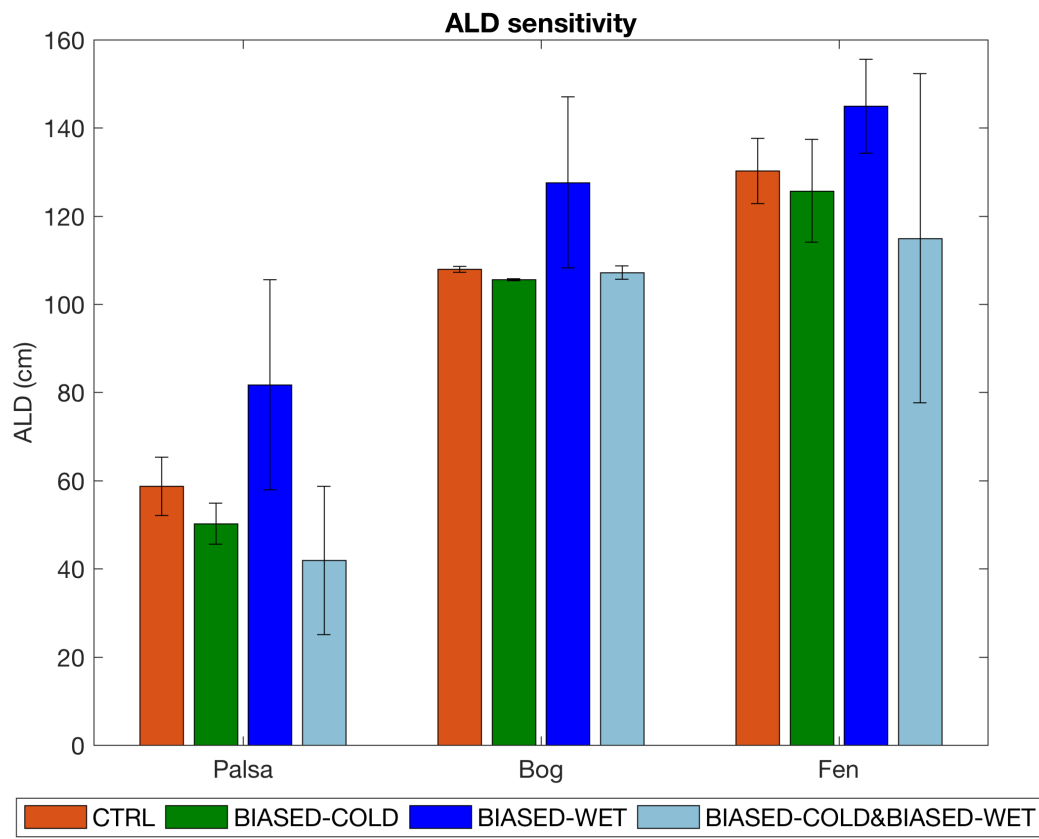

986 inter-annual means for each day of year, respectively. The shaded area is the simulated

987 inter-annual variability for the corresponding dataset, represented by the standard

988 deviations calculated at each day of year. Positive and negative carbon flux values

989 indicate effluxes from and influxes to the site, respectively.

990

991

992

Figure 8. Simulated ALD at the palsa, bog, and fen for four sets of climate forcing

993

(Section 2.5). Bars and error bars are means and standard deviations calculated from

994

2003 to 2007, respectively.

995

996

997

998 Figure 9. Annual CO₂ exchanges (a), CH₄ exchanges (b), Net Carbon Balance (c), and

999 Net Greenhouse Gas Balance (d) simulated at the palsa, bog, and fen, under each set of

1000 simulations. Bars and error bars are the means and standard deviations calculated from

1001 2003 to 2007, respectively. Positive and negative values indicate effluxes from and

1002 influxes to the site, respectively.
