11 **Ice streams are corridors of fast-flowing ice that control mass transfers from continental**
12 **ice sheets to oceans. Their flow speeds are known to accelerate and decelerate, their**
13 **activity to switch on and off, and even their locations to shift entirely. Our analogue**
14 **physical experiments reveal that a lifecycle incorporating evolving subglacial meltwater**
15 **routing and bed erosion can govern this complex transitory behaviour. The model ice**
16 **streams switch on when subglacial water pockets drain as marginal outburst floods. Then**
17 **they decelerate as basal coupling increases as a consequence of the lubricating water**
18 **drainage system spontaneously organising itself into channels that erode tunnel valleys.**
19 **They surge or jump in location when these water drainage systems maintain low discharge**
20 **but they ultimately switch off when tunnel valleys have expanded to develop efficient**
21 **drainage systems. Beyond reconciling previously disconnected observations of modern**
22 **and ancient ice streams into a single lifecycle, the modelling suggests that tunnel valley**
23 **development may be crucial in stabilising portions of ice sheets during periods of climate**
24 **change.**

25 **Keywords:** ice streams, experimental modelling, subglacial meltwater drainage, tunnel
26 valleys, subglacial outburst floods

27 1. Introduction

28 Continental ice sheets currently store the equivalent of a 65 m thick global equivalent
29 water layer and have been major contributors to the nearly 85 mm global sea level rise measured
30 between 1993 and 2017 (*Vaughan et al., 2013; Beckley et al., 2015*). The mass transfer from
31 these ice sheets to the ocean is spatially heterogeneous: approximately 80% of the ice discharge
32 is focused in a finite number of ice streams, which act as preferential drainage pathways for
33 meltwater and sediment also (*Bamber et al., 2000; Bennett, 2003*).

34 Modern and palaeo ice streams are typically hundreds of kilometres long and a few
35 kilometres to tens of kilometres wide, with ice velocities of the order 10^2 to 10^4 m.yr⁻¹. They
36 occur in all known ice sheets, but why and where they initiate, and the controls on their
37 dynamics remain debated. Numerical modelling suggests that ice flow might self-organise into
38 regularly-spaced ice streams as a consequence of thermomechanical feedbacks within ice
39 (*Payne and Dongelmans, 1997; Hindmarsh, 2009*) or because of inherent instability of thin

40 subglacial meltwater films (*Kyrke-Smith et al., 2014*). Numerous observations however, have
41 highlighted preferential location of ice streams at sites of specific bed properties such as in
42 topographic troughs, over areas of soft sedimentary geology, zones of higher geothermal heat
43 flux or as a consequence of where subglacial meltwater is routed (*Winsborrow et al., 2010*;
44 *Kleiner et al., 2014*). These viewpoints might not be mutually exclusive if self-organisation
45 into regularly-spaced streams is the primary control but that it is strongly mediated by local bed
46 templates (e.g. troughs) or events (meltwater drainage) that initiate or anchor streams in certain
47 locations. Exploring this hypothesis by numerical modelling has not yet been achieved because
48 of uncertainties in how to formulate basal ice flow in relation to bed friction, and due to
49 challenges of including all potentially relevant processes, especially so for subglacial water
50 flow (*Flowers, 2015*).

51 Observations of spatial and temporal variations in the activity of ice streams against
52 fluctuations in their subglacial hydrology suggest that the style and flux of water drainage is a
53 major component driving change. Examples include: reorganisation of subglacial drainage
54 systems (*Elsworth and Suckale, 2016*), subglacial water piracy, and development and migration
55 of transient subglacial water pockets (*Gray et al., 2005; Peters et al., 2007; Siegfried et al.,*
56 *2016*). However, these relations have been observed or inferred independently, at different
57 places and on yearly timescales, thus limiting our understanding of them of them as primary
58 drivers or as more minor effects of change. In this paper, we circumvent the challenge of
59 numerically modelling ice stream initiation and dynamics, including subglacial water drainage,
60 by exploiting a physical laboratory approach that simultaneously combines ice flow, water
61 drainage and bed erosion.

62 Connections between ice stream activity and subglacial hydrology are supported by the
63 occurrence of geomorphic markers of meltwater drainage on palaeo-ice stream beds (*Margold*
64 *et al., 2015; Livingstone et al., 2016; Patterson, 1997*). Among these landforms, tunnel valleys
65 deserve specific attention because they have high discharge capacities and, as such, may be
66 major contributors to the release of meltwater and sediment to the ocean; they may also promote
67 ice sheet stability by reducing the lubricating effect of high basal water pressure. Tunnel valleys
68 are elongated and over-deepened hollows, up to hundreds of kilometres long, several kilometres
69 wide and hundreds of meters deep. Their formation is generally attributed to subglacial
70 meltwater erosion but there is still no consensus on their development processes and on their
71 relationship to ice streaming. A conundrum being that ice streams appear to require high water
72 pressure while tunnel valleys are believed to involve low water pressure (*Marczinek and*
73 *Piotrowski, 2006*).

74 Ice streaming and tunnel valley development are both suspected to be linked to the
75 release of catastrophic glacial outburst floods at ice sheet margins (*Bell et al., 2007; Hooke and*
76 *Jennings, 2006; Jørgensen and Piotrowski, 2003; Alley et al., 2006*). Such outburst floods can
77 profoundly and rapidly alter the oceanic environment by transferring considerable amounts of
78 ice, freshwater and sediment from continents to oceans (*Evatt et al., 2006*). The suspected
79 connection between ice streams, tunnel valleys and outburst floods has never been observed or
80 modelled however.

81 Here, we describe the results of a physical experiment performed with an innovative analogue
82 modelling device that provides simultaneous constraints on ice flow, subglacial meltwater
83 drainage, subglacial sediment transport and subglacial landform development (*Lelandais et al.*,
84 *2016*; Fig. 1). From these results, we infer that ice streaming, subglacial meltwater pocket
85 migration, subglacial drainage reorganisation, tunnel valley formation and glacial outburst
86 floods are linked in **influencing the location and dynamics of ice streams**. This **reconciles**
87 a single story several detached inferences, derived from observations at different timescales and
88 at different places on modern and ancient ice streams.

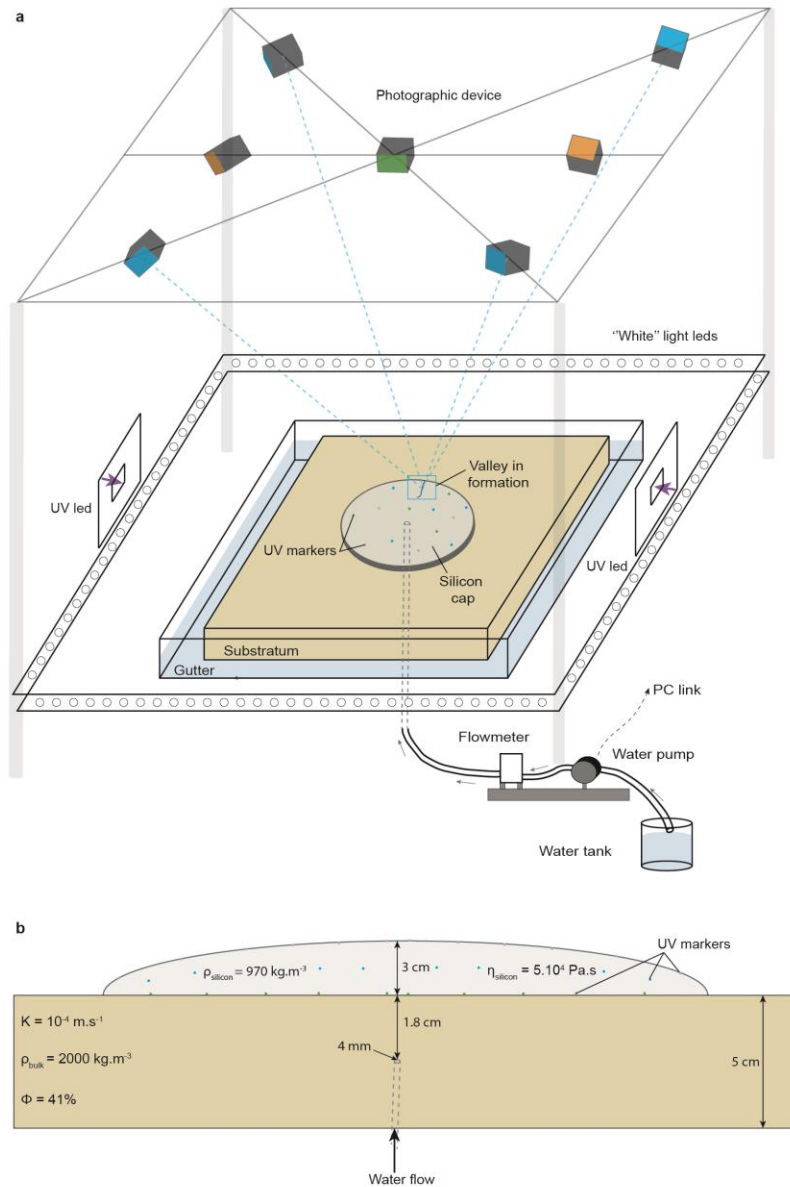

89 2. Experimental ice stream model

90 Ice stream dynamics are controlled by various processes that act at different space and time
91 scales; they also involve several components with complex thermo-mechanical behaviours (ice,
92 water, till, bedrock) (*Hindmarsh, 2009*). Considering all these processes and components
93 simultaneously is thus a challenge for modelling, especially with numerical computational
94 means (*Fowler and Johnson, 1995; Marshall, 2005; Bingham et al., 2010*). To **overcome partly**
95 this issue, we use an alternative experimental approach that allows simultaneous modelling of
96 ice flow, subglacial hydrology and sedimentary/geomorphic processes in a portion of an ice
97 sheet (*Paola et al., 2009*). Potentiometric surfaces that control subglacial water flow are
98 generally parallel to ice sheet surfaces (*Fountain and Walder, 1998*). Subglacial water drainage
99 is **thus controlled** by fluctuations in locations of ice sheet margins. The scaling of the experiment
100 **is based on this rule and is designed to ensure that the value of the ratio between margin velocity**
101 **and incision rate of tunnel valleys in the experiment equals its value in natural systems** (cf.
102 *Lelandais et al., 2016* for scaling details).

103 **The model is set in a glass box (70 cm long, 70 cm wide and 5 cm deep) (Fig. 1). A 5 cm thick,**
104 **flat, horizontal, permeable and erodible substratum, made of sand ($d_{50}=100\ \mu\text{m}$) saturated with**
105 **pure water and compacted to ensure homogeneous values for its density ($\rho_{\text{bulk}} = 2000\ \text{kg}\cdot\text{m}^{-3}$),**
106 **porosity ($\Phi = 41\ \%$) and permeability ($K = 10^{-4}\ \text{m}\cdot\text{s}^{-1}$), rests on the box floor. The**
107 **portion is modelled with a 3 cm thick layer of viscous ($\eta = 5\cdot 10^4\ \text{Pa}\cdot\text{s}$) and transparent but**
108 **refractive ($n = 1.47$) silicon putty placed on the substratum. The model is not designed to**
109 **simulate an entire ice sheet; it is circular in plan view (radius = 15 cm) however, to avoid lateral**
110 **boundary effects on silicon flow. Subglacial meltwater production is simulated by injection of**
111 **water with a punctual injector, 4 mm in radius, placed at a depth of 1.8 cm in the substratum,**
112 **and connected to a pump (Fig. 1). The injector is located below the centre of the silicon layer**
113 **to be consistent with the circular geometry of the experiment.** The water discharge is constant
114 ($1.5\ \text{dm}^3/\text{h}$) over the duration of the experiment and generates water flow at the silicon-
115 substratum interface and within the substratum. In contrast with ice, the commercial silicon
116 putty we use (Dow Corning, SGM36) is impermeable, Newtonian, isotropic, and its viscosity
117 is nearly independent of temperature between 10 and 30°C. Therefore, rheological softening of
118 ice with strain rate, temperature, anisotropy and meltwater content (*Bingham et al., 2010*)
119 cannot be reproduced. We did not try to include the equivalent of a till layer in the experiment,
120 although till deformation is **known** to promote ice stream **drift** (*Alley et al., 1987*). The velocity
121 contrasts observed in the experiment are thus likely to be amplified, in natural ice sheets, by the
122 complex rheological behaviour of ice and till. This may lead to the development of narrower

123 ice streams with higher relative velocities and sharper lateral shear margins in natural ice sheets
 124 than in the experiment (*Raymond, 1987; Perol et al., 2015*).

125

126

127 **Figure 1.** Description of the analog device used in this study. a, Overview of the analog device. The
 128 analog device consists in a 70 cm long, 70 cm wide and 5 cm deep glass box filled with saturated and
 129 compacted sand simulating the substratum. The ice sheet portion is simulated by a circular layer of
 130 silicon putty containing 3 levels of UV markers. Meltwater production is simulated by a central and
 131 punctual injection of pure water within the substratum. Five synchronized cameras placed above the
 132 silicon putty (in blue) focus on the tunnel valley system and are used to produce digital elevation models
 133 by photogrammetry. Another camera (in orange) takes overview photographs of the analog device to
 134 follow the progress of the whole experiment. A last camera (in green) is positioned at the vertical of the
 135 silicon layer centre and is configured to take high-resolution photographs in black light of the UV
 136 markers (illuminated with two lateral UV led lights). b, Cross-sectional profile of the analog device
 137 displaying the position of the UV markers and the physical characteristics of both the substratum and
 138 the silicon layer.

139 To monitor the vertical displacements of the silicon surface and the development of landforms
140 on its substratum, we use six synchronised cameras equidistant from the experiment centre: two
141 cameras (orange on Fig. 1) cover the whole extent of the experiment and four cameras (blue on
142 Fig. 1) focus on specific regions to obtain higher resolution images. These cameras take
143 simultaneous pictures with differing positions and orientations. Digital elevation models of the
144 silicon surface and of the substratum are derived from these images by photogrammetry.
145 Numerical post-treatments are performed on the digital elevation models to remove distortions
146 of the substratum topography due to light refraction in the silicon putty (cf detailed post-
147 treatment methods in *Lelandais et al., 2016*). Tests performed on previously known
148 topographies show that the vertical precision of the retrieved digital elevation models is better
149 than 10^{-1} mm.

150 The flow velocity of the silicon layer is monitored near its base (V_{base}), at mid-depth (V_{mid}) and
151 at its surface (V_{surface}), with an additional camera placed over the centre of the experiment (green
152 on Fig. 1). For that purpose, the camera records the horizontal position, on pictures taken at
153 regular time intervals in ultraviolet, of 180 paint drops (1 mm in radius) placed at 1 mm above
154 the base, at mid-depth and at the surface of the silicon layer (Fig. S1). These passive markers
155 are transparent at visible wavelengths and do not alter pictures of the substratum taken through
156 the silicon cap. They represent less than 0.5% of the silicon layer in volume and tests have
157 shown that they do not affect its overall rheological behaviour. Uncertainties in the measured
158 position of markers on images are less than one pixel in size (10^{-1} mm), thus uncertainties in
159 the derived velocities are comprised between $5 \cdot 10^{-4}$ and $2 \cdot 10^{-3}$ mm/s, depending on the time
160 interval between photographs.

 175 velocity at silicon cap surface, (iii) cross-sectional velocity profiles (absolute velocity on right axis,
 176 velocity normalised by background velocity on left axis, profile locations indicated by white lines A-B
 177 on maps), (iv) vertical velocity profiles for silicon stream (red profiles, locations labelled 1 on maps)
 178 and for region opposed to silicon stream (black profiles, locations labelled 2 on maps).

179 3. Experimental results

180 As long as no water is injected in the substratum, the silicon layer spreads under its own weight
 181 and displays the typical parabolic surface profile of an ice sheet. It increases in diameter and
 182 decreases in thickness with time, thus producing a radial pattern of horizontal velocities, which
 183 increase in magnitude from the centre ($V_{\text{surface}} < 3 \cdot 10^{-3} \text{ mm s}^{-1}$) to the margin ($V_{\text{surface}} = 8 \cdot 10^{-3}$
 184 mm s^{-1}) (Fig. S2). V_{base} is close to 0 over the full extent of the silicon layer ($\frac{V_{\text{base}}}{V_{\text{surface}}} \sim 0\%$),
 185 indicating coupling with the substratum. The silicon flow pattern changes when meltwater
 186 production is simulated by injecting water at a constant discharge ($1.5 \text{ dm}^3/\text{h}$), beneath the
 187 silicon layer.

188 This experiment was repeated 12 times with identical input parameters. A six-stage ice stream
 189 lifecycle linking outburst flooding, transitory ice streaming and tunnel valley development has
 190 been observed for all these simulations (Fig. 2a-f, Fig. 4).

191 Stage 1 (Fig. 2a). A water pocket grows below the centre of the silicon layer and raises its
 192 surface by 2 mm. Above the water pocket, the silicon accelerates ($V_{\text{surface}} \geq 35 \cdot 10^{-3} \text{ mm.s}^{-1}$), and
 193 is decoupled from the substratum ($\frac{V_{\text{base}}}{V_{\text{surface}}} = 75$ to 80%). Below the rest of the silicon layer,
 194 lower velocities ($V_{\text{surface}} = 8 \cdot 10^{-3} \text{ mm.s}^{-1}$, $\frac{V_{\text{base}}}{V_{\text{surface}}} = 40$ to 50%) indicate higher basal friction.
 195 These results are consistent with inferences that meltwater ponding can form pressurised
 196 subglacial water pockets associated with basal decoupling, surface uplift, and ice flow
 197 acceleration in natural ice sheets (*Elsworth and Suckale, 2016; Livingstone et al., 2016*). In the
 198 experiment however, these effects are restricted to an approximately circular region and are not
 199 sufficient to produce channelised ice streaming.

200 Stage 2 (Fig. 2b). The water pocket expands and migrates towards the margin of the silicon
 201 layer. The lack of channels incised in the substratum indicates that this displacement occurs as
 202 distributed water drainage not accomplishing erosion. In the silicon layer, the region of surface
 203 uplift, basal decoupling and acceleration ($V_{\text{surface}} = 18 \cdot 10^{-3} \text{ mm.s}^{-1}$, $\frac{V_{\text{base}}}{V_{\text{surface}}} = 75$ to 85%)
 204 expands and migrates downstream with the water pocket. Similar migrations of pressurised
 205 subglacial water pockets have been observed or inferred under modern and ancient ice sheets
 206 (*Fricke et al., 2007; Carter et al., 2017*), sometimes associated with migrations of regions of
 207 ice surface uplift and ice flow acceleration (*Bell et al., 2007; Stearns et al., 2008; Siegfried et*

208 *al., 2016*). The experiment suggests that these water pockets can migrate by distributed drainage
209 and can contribute to the emergence of ice streams.

210 Stage 3 (Fig. 2c). When the water pocket reaches the margin of the silicon layer, it drains
211 suddenly. This marginal outburst flood is still fed by distributed drainage and conveys sand
212 particles eroded from the substratum towards a low-angle marginal sedimentary fan (Fig. S3).
213 Simultaneously, the silicon flow focuses in a stream (20 cm wide at the margin) that propagates
214 upstream from the silicon margin to the water injection area. This stream immediately peaks in
215 velocity ($V_{\text{surface}} = 80 \cdot 10^{-3} \text{ mm} \cdot \text{s}^{-1}$, 16 times higher than the surrounding silicon) and is entirely
216 decoupled from its substratum ($\frac{V_{\text{base}}}{V_{\text{surface}}} > 90\%$). Although similar relations between outburst
217 floods and ice flow accelerations have been suspected in modern (*Alley et al., 2006; Bell et al.,*
218 *2007; Stearns et al., 2008*) and past (*Livingstone et al., 2016*) ice sheets, they have been
219 documented for valley glaciers only (*Kamb, 1985*): there, they can produce sudden meltwater
220 discharges that exceed the capacity of distributed subglacial meltwater drainages and promote
221 basal decoupling and ice flow acceleration (*Magnússon et al., 2007*). The experiment confirms
222 that outburst floods can promote basal decoupling and trigger ice streaming in ice sheets
223 (*Fowler and Johnson, 1995*).

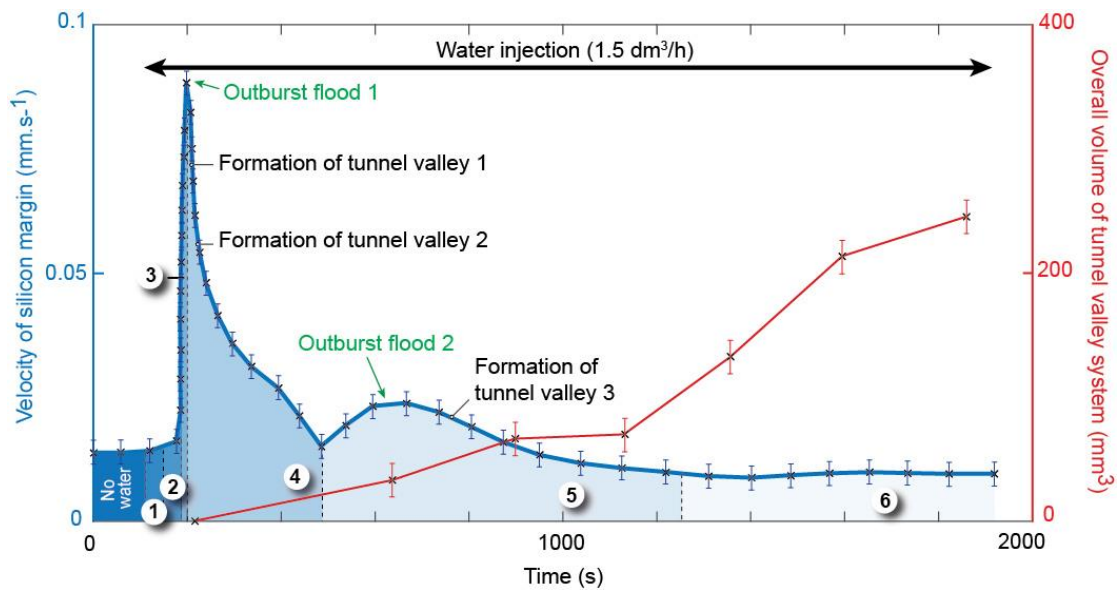

224 Stage 4 (Fig. 2d). The distributed subglacial drainage system starts to channelise: two valleys
225 (TV1 and TV2) appear below the margin of the silicon layer and gradually expand by regressive
226 erosion of the substratum. These valleys, with their constant widths, undulating long profiles
227 and radial distribution, are analogue to natural tunnel valleys in their dimensions, shapes and
228 spatial organization (*Lelandais et al., 2016; Fig. S4*). They are fed by distributed water drainage.
229 The sand eroded from the substratum transits through these valleys and accumulates in high-
230 angle marginal sedimentary fans, higher in elevation than the valley floors (Figs. 4 and S3-4).
231 In response to progressive channelisation of the water drainage into the expanding valleys, the
232 silicon stream narrows and slows down (12 cm wide at the margin; $V_{\text{surface}} = 24 \cdot 10^{-3} \text{ mm} \cdot \text{s}^{-1}$).
233 The silicon stream, still channelised, is still flowing 8 times faster than the rest of the silicon
234 layer and is still decoupled from the substratum ($\frac{V_{\text{base}}}{V_{\text{surface}}} > 85\%$). These results are consistent
235 with inferences that channelisation of hitherto distributed subglacial water drainage systems
236 can occur and reduce ice flow velocity after outburst floods (*Magnússon et al., 2007; Kamb,*
237 *1987; Retzlaff and Bentley, 1993*), and can be responsible for narrowing and deceleration of ice
238 streams (*Raymond, 1987; Retzlaff and Bentley, 1993; Catania et al., 2006; Beem et al., 2014;*
239 *Kim et al., 2016*). At this stage of the experiment, this transition, which corresponds to the
240 initiation of tunnel valleys, is not sufficient to stop ice streaming however.

241 Stage 5 (Fig. 2e). A new transient water pocket grows below the silicon layer, migrates and
242 drains as an outburst flood, thus forming a new low-angle marginal sedimentary fan with at
243 lateral offset of 4 cm with respect to TV1. This induces the activation of a second stream (V_{surface}
244 $= 40 \cdot 10^{-3} \text{ mm} \cdot \text{s}^{-1}$) decoupled from its substratum ($\frac{V_{\text{base}}}{V_{\text{surface}}} = 80\%$) and the initiation of a new
245 radial valley (TV3), in a hitherto slow-moving region of the silicon cap. Simultaneously, the
246 first silicon stream switches off ($V_{\text{surface}} = 10 \cdot 10^{-3} \text{ mm} \cdot \text{s}^{-1}$), recouples to its substratum ($\frac{V_{\text{base}}}{V_{\text{surface}}} =$
247 30%), but water and sand still flow through TV1 and TV2. This result is consistent with

248 inferences that natural ice streams can switch on/off, surge or jump in location in response to
 249 changes in subglacial water drainage reorganization (Beem et al., 2014; Hulbe et al., 2016;
 250 Catania et al., 2012; Le Brocq et al., 2013). The experiment further suggests that this complex
 251 behaviour is controlled by the growth and migration, in various possible directions, of transient
 252 pressurised subglacial water pockets that form successively as long as the discharge capacity
 253 of tunnel valleys systems is not sufficient to drain efficiently the available meltwater.

254 Stage 6 (Fig. 2f). Since their initiation, TV1, TV2 and TV3 have progressively increased in
 255 width, depth and length. Their overall volume and discharge capacity have thus increased (Fig.
 256 3). In response to this increased drainage efficiency, the second stream gradually decays (V_{surface}
 257 $= 5 \cdot 10^3 \text{ mm} \cdot \text{s}^{-1}$), recouples to its substratum ($\frac{V_{\text{base}}}{V_{\text{surface}}} = 35\%$), and the silicon layer ultimately
 258 recovers a radial flow pattern (Fig. 2f). This result is consistent with the inference that ice
 259 streams may decelerate and even switch off in response to reduction of subglacial water
 260 pressures when efficient subglacial water drainage systems develop (Retzlaff and Bentley, 1993;
 261 Beem et al., 2014; Livingstone et al., 2016; Kim et al., 2016). In the experiment, this
 262 development is governed by the expansion of tunnel valley networks.

263

264

265 **Figure 3.** Progressive expansion of overall volume of tunnel valleys system vs. velocity of silicon
 266 margin through the experiment. The circled numbers correspond to the six-stages of the proposed ice
 267 stream lifecycle.

268 4. Proposed lifecycle of transitory ice streams

269

270 The experiment demonstrates that, on flat and homogenous beds, ice streams may arise,
 271 progress and decay in response to mechanical interactions between ice flow, subglacial water
 272 drainage and bed erosion. On uneven or heterogeneous beds, these interactions may additionally
 273 be enhanced or disturbed by spatial variations in the subglacial topography, geology and
 274 geothermal heat flux (Bourgeois et al., 2000; Winsborrow, 2010). The complex rheology of
 275 glacial ice and subglacial till (both generally soften with increasing strain rate, temperature,

276 water content and anisotropy) may also enhance these interactions by increasing velocity
277 contrasts between ice streams and their slower-moving margins (see methods for further
278 details). This may lead to the development of narrower ice streams with higher velocities and
279 sharper lateral shear margins in natural ice sheets than in the experiment (*Raymond, 1987; Perol*
280 *et al., 2015*).

281 Although the complexity of glacial systems cannot be fully modelled using the present
282 experimental setup, our results highlight the critical connection between ice streams and tunnel
283 valleys. This relation was suspected from the occurrence of tunnel valleys on palaeo ice stream
284 beds (*Keheew et al., 2012; Ravier et al., 2015*), but raised a contradiction: subglacial meltwater
285 pressures are classically believed to be high below ice streams (*Bennett, 2003*), while they are
286 suspected to be low in tunnel valleys (*Marczinek and Piotrowski, 2006*). Our results provide a
287 solution to this apparent contradiction: they demonstrate that ice streaming, tunnel valley
288 formation, release of marginal outburst floods and subglacial water drainage reorganization
289 may be interdependent parts of a single lifecycle that involves temporal changes in subglacial
290 meltwater pressures (Fig. 4).

291 1. Ice stream seeding. A prerequisite to the activation of ice streams is the formation of
292 pressurised subglacial pockets by meltwater ponding in ice sheet hinterlands. Approximately,
293 circular regions of surface uplift and accelerated ice flow develop above these transient water
294 pockets.

295 2. Ice stream gestation. Pressurised water pockets migrate downstream by distributed water
296 flow. Regions of surface uplift and accelerated ice flow migrate accordingly.

297 3. Ice stream birth. Once water pockets reach ice sheet margins, they drain as outburst floods.
298 At that time, ice streams switch on, peak in velocity and propagate towards ice sheet hinterlands
299 as decoupled corridors of accelerated ice flow underlain by pressurised distributed water
300 drainage.

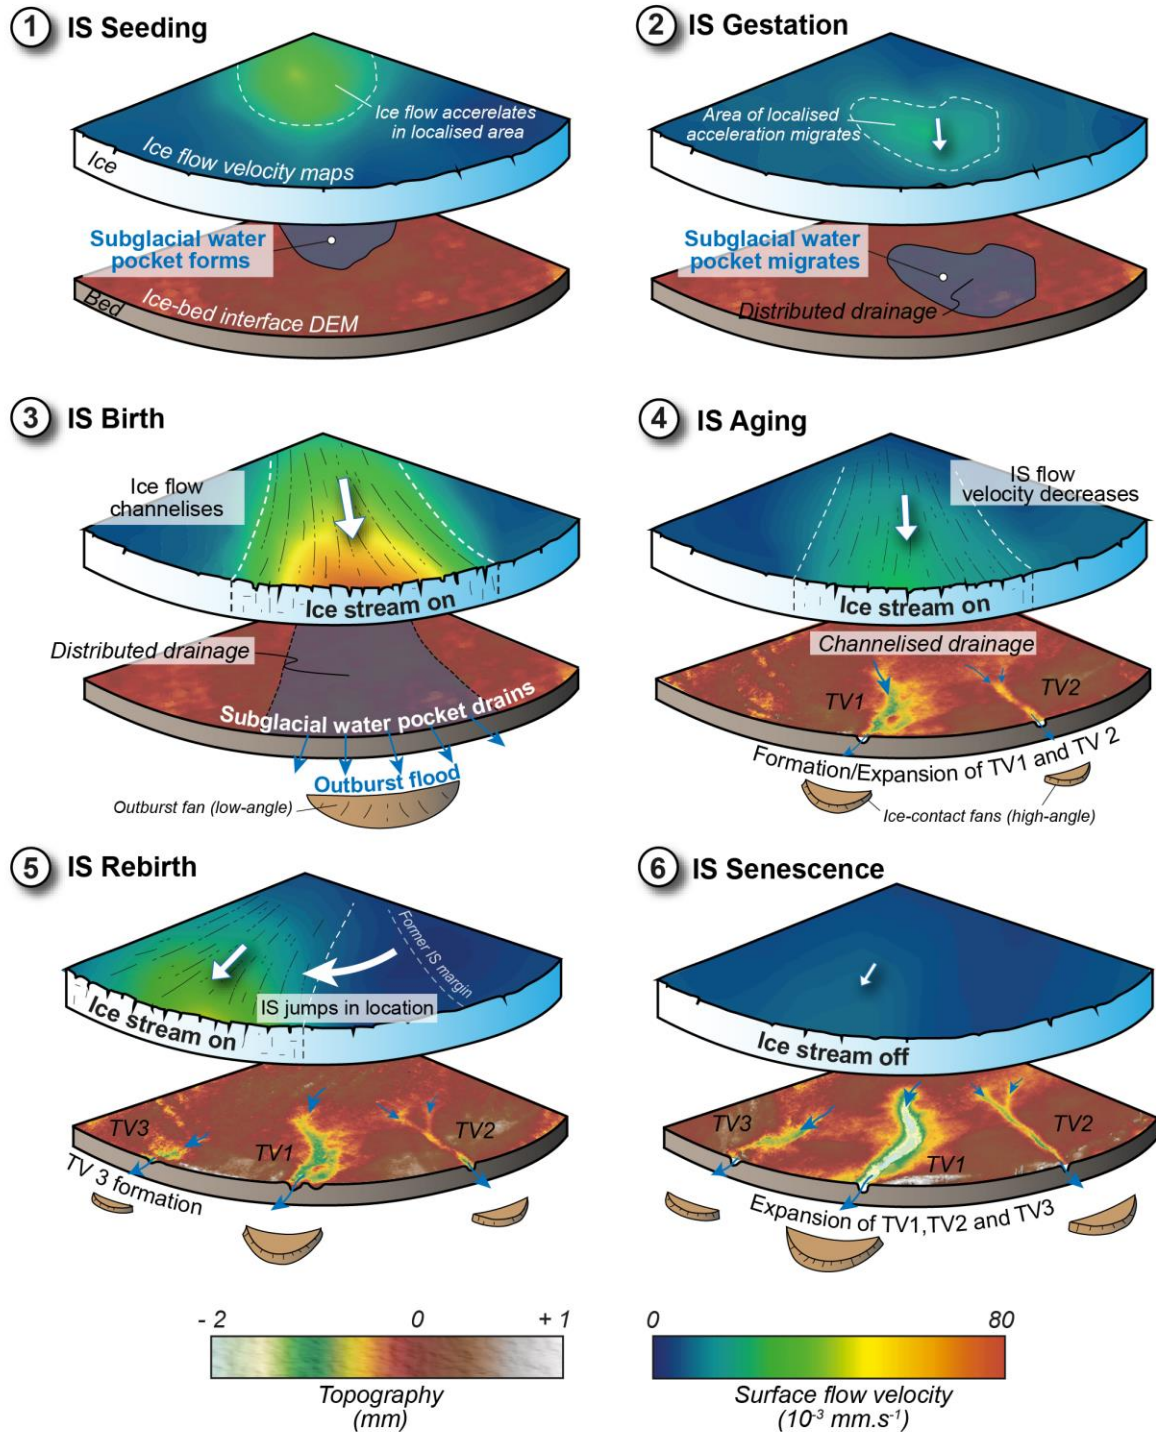

301 4. Ice stream aging. Subglacial water drainage then channelises gradually: tunnel valleys fed by
302 pressurised distributed drainage start to form at ice stream fronts. Subsequent expansion of
303 tunnel valleys by regressive erosion progressively increases their overall discharge capacity,
304 lowers subglacial water pressures and provokes gradual ice stream recoupling and deceleration.

305 5. Ice stream rebirth (relocation or surge). As long as tunnel valley systems keep low drainage
306 capacities, successive pressurized subglacial water pockets can form, migrate and drain as
307 marginal outburst floods. On even and homogeneous ice sheet beds, subglacial water drainage
308 is controlled by the surface topography of ice sheets: subtle temporal changes in this topography
309 may thus be able to produce consecutive generations of ice streams and tunnel valleys at
310 different locations and with different flow directions. These jumps in locations and directions
311 may be responsible for the formation of independent, but sometimes intersecting, ice streams
312 corridors and tunnel valleys networks on some palaeo ice sheet beds (*Jørgensen and Piotrowski,*
313 *2003; Fowler and Johnson, 1995*). By contrast, if subglacial water routes and ice flow are
314 constrained by bed heterogeneities, migration of successive subglacial water pockets along
315 predetermined paths may induce sequential ice stream surges (*Fowler and Johnson, 1995;*

316 *Hulbe et al., 2016*) and participate in the gradual development of complex tunnel valley systems
317 at fixed places, like the Dry Valleys “Labyrinth” in Antarctica (*Lewis et al., 2006*).

318 6. Ice stream senescence. Ice streams may ultimately switch off when drainage capacities of
319 tunnel valley systems are sufficient to limit subglacial water overpressures. Tunnel valleys and
320 ice streams are frequently found to co-exist and with the many examples reported from
321 the southern margin of the Laurentide Ice Sheet (*Patterson, 1997; Livingstone and Clark,*
322 *2016*). In one case, development of tunnel valleys has been suggested to have led to stagnation
323 of ice flow at an ice stream terminus (*Patterson, 1997*), a process that we have now
324 demonstrated by modelling. This further validates the hypothesis that tunnel valley
325 development can secure ice sheet stability by preventing catastrophic ice stream collapses
326 (*Marczinek and Piotrowski, 2006*), which could represent early stages of unstoppable ice sheet
327 disintegrations (*Hulbe, 2017*) In a global change context, this possible stabilisation however
328 requires that pre-existing and/or newly forming tunnel valley systems expand sufficiently fast
329 to accommodate increased meltwater production. The processes and rates of tunnel valley
330 development are thus major issues for predicting the forthcoming behaviour of present-day ice
331 sheets and for assessing their contribution to the release of ice and freshwater to the ocean,
332 which alters global sea level and oceanic circulations.

333

334

335 **Figure 4.** Chronological sequence with interpretative sketches illustrating the proposed ice
 336 stream lifecycle and the relations with tunnel valley development. Basal topography and surface
 337 flow velocity maps are derived from the experiment.

338

5. Conclusion

339

The transitory and mobile nature of ice streams may be understood in the framework of a model lifecycle that involves temporal changes in subglacial meltwater pressures and arises from interactions between ice flow, subglacial water drainage and bed erosion. In this model

341

342 lifecycle transitory ice streams arise, progress and decay in response to subglacial flooding,
343 changes in type and efficiency of subglacial drainage, and development of tunnel valleys. These
344 results are consistent with (and reconcile) a variety of otherwise detached observations
345 performed at different timescales and at different places, on modern and ancient natural ice
346 streams. One of the most novel outcomes of this study, is that subglacial tunnel valley
347 development may be crucial in controlling ice stream vanishing and perhaps, as a consequence,
348 in preventing catastrophic ice sheet collapses during periods of climate change. The processes
349 and rates of tunnel valley development are thus major issues for predicting the forthcoming
350 behavior of present-day ice sheets and for assessing their contribution to the release of ice and
351 freshwater to the ocean. The innovative experimental approach, used here opens new
352 perspectives on the understanding of subglacial processes controlling ice sheet dynamics and
353 destabilisation

354 **Author contributions:**

355 OB, RM, ER and SP conceived this research and gathered funding. TL designed and conducted
356 the experiments (setup, monitoring and post-treatment), with contributions by RM and PS. TL,
357 ER, OB, CDC, SP and RM contributed to the interpretation of the results and of their natural
358 implications. TL wrote the first draft of the manuscript; ER, OB, SP and CDC contributed
359 substantially to its present version.

360 **Competing interests:**

361 The authors declare that they have no conflict of interest

362 **Acknowledgements:**

363 This study is part of the DEFORm project (Deformation and Erosion by Fluid Overpressure)
364 funded by “Région Pays de la Loire”. Additional financial support was provided by the French
365 “Agence Nationale de la Recherche” through grant ANR-12-BS06-0014 ‘SEQSTRAT-ICE’
366 and the “Institut National des Sciences de l’Univers” (INSU) through the ‘Programme National
367 de Planétologie’ (PNP) and ‘Système Terre : Processus et Couplages’ (SYSTER) programs.
