Abstract. In the present study we propose a methodology to estimate the spatial distribution of destabilizing rock glaciers, focusing on the French Alps. At first, using recent orthoimages (2000 to 2013) covering the study region, we mapped the geomorphological features that can be typically found in cases of rock glacier destabilization (e.g. crevasses and scarps). This database was then used as support tool to rate rock glaciers destabilization. The destabilization rating was assigned taking into account the evolution of the the destabilization geomorphological features and the surface deformation patterns of the rock glacier, observable by comparing the available orthoimages. The destabilization rating served then as database to model the occurrence of rock glacier destabilization in relation to terrain attributes and to predict the susceptibility to destabilization at the regional scale. Significant evidence of destabilization could be observed in 46 rock glaciers, i.e. 10% of the total active rock glaciers in the region. Modelling the occurrence of destabilization suggested that this phenomenon is more likely to occur in elevations around the 0°C isotherm (2700 – 2900 m.s.l.), on north-exposed, steep (25° to 30°) and flat to slightly convex topographies. Model performance were good (AUROC: 0.76) and the susceptibility map reproduced well the observable patterns. About 3 km^2 of creeping permafrost, i.e. 10 % of the surface occupied by active rock glaciers, had a high susceptibility to destabilization. Considering that only half of this surface is currently showing destabilization evidence, we suggested that a significant amount of rock glaciers are candidates for future destabilization.

1 Introduction

Warmer mean annual air temperatures (IPCC , 2013) are linked to a general trend of increasing permafrost temperature (e.g. Harris et al., 2003) and its water content (e.g. Ikeda et al., 2008) causing permafrost degradation, a phenomenon widely observed in the European Alps (Haeberli et al., 1993, 2010; Springman et al., 2013; Bodin et al., 2015). Permafrost degradation occurrence is dependent on the ground properties, snow cover interactions and permafrost ice content (Scherler et al., 2013) and is therefore an heterogeneous phenomenon. Permafrost grounds affected by degradation experience a loss in stiffness due to the increasing ice ductility and reduced internal friction caused by the warmer ice and increasing water content (Davies et al. , 2001; Haeberli et al., 1997; Harris and Davies , 2001; Nater et al., 2008; Huggel et al., 2010).Abnormal rockfall activity at high

elevations (e.g. Ravanel and Deline , 2010) and increasing rock glaciers displacement rates (Delaloye et al., 2008) are often assumed as indicators of this change of state in the mountain permafrost. These processes may trigger mass movements that, in specific topographic conditions, may represent an hazard to alpine communities. Therefore, is a growing need to understand the occurrence of these phenomena at a regional scale to allow a targeted risk assessment and land use planning (Haeberli et al., 2010).

In this context, rock glaciers experiencing destabilization recently gained interest. While active rock glaciers commonly present moderate interannual velocity variations that correlate with the ground temperature (Delaloye et al., 2008; Kellerer-Pirklbauer and Kaufmann , 2012; Bodin et al., 2009), destabilized rock glaciers are characterized by a significant acceleration that can bring the landform, or a part of it, to abnormally high velocities (Delaloye et al., 2013; Roer et al., 2008; Scotti et al., 2016; Lambiel, 2011; Eriksen et al., 2018). During this acceleration phase, morphological features typical of sliding processes, as crevasses and scarps, appear and grow on the rock glacier surface. This suggests that the destabilization consists on the onset of a basal sliding process over the normal creep of the rock glacier (Roer et al., 2008; Schoeneich et al., 2015). In this sense, crevasses and scarps are interpreted as the possible transition between the creep-driven and the sliding sections of the landform (Roer et al., 2008). This acceleration phase, also referred as "surge" (Schoeneich et al., 2015) or "crisis" (Delaloye et al., 2013), may last decades and it commonly resolves in a deceleration or inactivation of the landform. Exceptionally, destabilized rock glaciers may reach complete failure and collapse in a landslide (Bodin et al., 2016).

Since destabilization and increased displacement rates may precondition significant mass movements that in particular topographic setting may represent an hazard (Kummert and Delaloye , 2018), it is relevant to understand its genesis and occurrence. An overload on the glacier surface caused by a landslide or glacio-isostatic uplift can cause a compressive wave that propagates through the landform increasing its displacement rates and consequent destabilization (Delaloye et al., 2013; Roer et al., 2008). Warmer climate and linked permafrost degradation on the other hand, is assumed to cause an increase of water content in the permafrost body and the onset of water saturated shear layers where sliding may occur, possibly triggering the crisis (Lambiel, 2011; Schoeneich et al., 2015; Eriksen et al., 2018). The onset of crevasses and scarps can increase the predisposition of the landform to trap meteoric water percolating into the permafrost body, causing a positive feedback process of destabilization (Ikeda et al., 2008). Nevertheless, not all rock glaciers experiencing permafrost degradation or mechanical overload are, or will be, destabilized. Permafrost degradation generally causes permafrost thaw in the landform and consequent inactivation (Scapozza et al., 2010). Destabilization was observed only in rock glaciers presenting a topographical predisposition to mass movements, as steep slopes and flow across a convex section (Roer et al., 2008; Delaloye et al., 2013). This suggests that there is a terrain predisposition of the rock glaciers to the onset of a destabilization phase.

The purpose of this study was to obtain regional-scale insights into the issue of destabilizing rock glaciers in the French Alps. In this region periglacial environment is abundant and occurrence of rock glacier destabilization was observed (Echelard , 2014; Bodin et al., 2016; Serrano , 2017; Schoeneich et al., 2017). Periglacial hazards therefore may exist and, given the dense urbanization of this region, the need for tools allowing a comprehensive risk assessment is crucial (Bodin et al., 2015). To do so, the present study proposed a two step methodology to (i) identify the rock glaciers showing evidence of destabilization and (ii) model the occurrence of this phenomena in relation with local terrain attributes. At first, geomorphological features

observed in destabilization cases, here called "surface disturbances" were mapped by multi-temporal aerial image interpretation based on expert field knowledge (Section 2.2). Surface disturbances were then used as support tool to assign a destabilization rating ranging from 0 to 3 to each active rock glacier (Section 2.2.1). Rock glaciers classified with higher destabilization rating presented typical geomorphological characteristics reported in known cases of destabilization, as pronounced surface

5 disturbances that increased by number and size in the past decades. These rock glaciers were suggested to be potentially destabilized while, on the other hand, rock glaciers not presenting surface disturbances were classified with lower ratings of destabilization (i.e. stable rock glaciers). Evidence of presence/absence of rock glacier destabilization was used to model rock glacier stability in relation to terrain parameters by using a statistical approach similar to landslide science (Goetz et al., 2011) (Section 2.3). This allowed to better understand the relationship between destabilization occurrence and terrain predisposition

10 and to compute a destabilization susceptibility map which provides an overview of potentially destabilizing landforms at the regional scale (Section 2.3.1). Strengths and limitations of the methodology are widely discussed in the manuscript, as well as the contribution of the study to the knowledge concerning rock glacier destabilization.

2 Methods

2.1 Study area and rock glacier inventory

15 The French Alps cover an area approximately 50-75 km wide and 250 km long, located between 44° and 46°S and 5.7° to 7.7°W (Figure 1). Apart from the noticeably high Mont Blanc massif (peaking at 4810 m.a.s.l.), mountain ranges commonly peak between 3000 and 4000 m.a.s.l.. The lithology is heterogeneous across the region. The Northern French Alps, can be roughly divided into the West side, dominated by granite and gneiss (ranges of Mont Blanc, Belledonne, Ecrins and Grandes Rousses), while on the East side ophiolites and schists are more common (ranges of Vanoise, Thabor and Mont Cenis). In the

20 Southern French Alps ophiolites, limestone and mica schists are the most common lithology (ranges of the Ubaye), while a the crystalline range of Mercantour can be found at the southernmost end of the region. Dominant geology is described the BRGM (2015) at 1/ 1 000 000 scale, and the vectorial version of this map is used in this study to observe destabilization occurrence in relation to lithology.

In this region permafrost is estimated to cover up to 770 km^2 (Boeckli et al., 2012; Marcer et al., 2017). The 0°C annual

25 isotherm at the end of XX century ranged from 2500 m a.s.l. in the Southern ranges down to 2300 m a.s.l. in the Northern sectors (Gottardi , 2009).The periglacial landforms of the region were inventoried by the "Office national des forêts" (ONF: the National Forest Office) (Roudnitska et al., 2016). This inventory compiled between the years 2009 – 2016 by inspecting aerial imagery in Geographical Information System (GIS)and revised by Marcer et al. (2017), revealed the high incidence of active rock glaciers in the region (i.e. 493 landforms). This inventory was used in the present study to identify active rock glaciers

30 locations and investigate the occurrence of destabilization.

According to Auer et al. (2007),mean annual air temperature increased by up to 1.4°C in the European Alps during the $20^{t}h$ century, and this rate has been accelerating in recent decades. This climatic warming is suspected to have caused some quantifiable effects on the permafrost characteristics in the region. The only deep permafrost borehole in the region, located

in the Ecrins massif in temperate permafrost (-1.3°C) with low ice content, showed a temperature increase rate of 0.04°C per decade between 2010 and 2014 (Schoeneich et al., 2012), similarly to many sites in Switzerland where data series are longer (PERMOS , 2016) . The increase of the Laurichard rock glacier velocity since the late 1990s is also suggested to be linked to this phenomenon (Bodin et al., 2009). At the same time, several cases of rock glacier destabilization were observed. In 2006 the Berard rock glacier collapsed causing a landslide of 250 000 m^3, a very exceptional event that was possibly linked to the rare characteristics of this site, e.g. uncommonly fine grained debris (Bodin et al., 2016). Echelard (2014) identified another case of a striking destabilization, the Pierre Brune rock glacier, which was developing a series of deep crevasses while also accelerating. In 2015, a debris flow that was triggered by a concentrated flow at the front of a destabilized rock glacier, the Lou rock glacier, reached the town of Lanslevillard, damaging some infrastructures (Schoeneich et al., 2017). In a first attempt to get a regional overview, Serrano (2017) mapped destabilized rock glaciers in the Maurienne valley, Vanoise national park and Ubaye valley, highlighting the high incidence of destabilized rock glaciers in these areas.

2.2 Mapping rock glacier destabilization

The first step to identify destabilized rock glaciers was mapping surface disturbances on rock glaciers. Previous studies that described destabilized rock glaciers showed that these landforms present a wide variety of geomorphological features (e.g. Roer et al., 2008). Here, we followed a methodology similar to Serrano (2017), which consisted of defining a catalogue of typical surface disturbances that can be found on destabilized rock glaciers. Surface disturbances on rock glaciers were classified in three distinct categories, depending on their morphology and triggering causes: cracks, crevasses and scarps. Surface disturbances are described in detail in Table 1 and illustrated in Figure 2.

In this study, surface disturbances were mapped for the inventoried rock glaciers based on interpretation of a set of multi-temporal high-resolution aerial imagery for the French Alps. This orthoimagery collection was obtained from the Institut géographique national (IGN, National Institute of Geography), which is freely available from the official website (www.geoportail.fr) or can be accessed as a Web Mapping Service (IGN , 2011a, 2013). The IGN orthoimagery collection consists of orthomosaics covering all of France for three different collection periods. The first orthomosaic is composed of images taken from 2000 to 2004, the second from 2008 to 2009, and the third from 2012 to 2013. All images are of high-resolution: 50 cm x 50 cm for the most recent mosaic and slightly lower values (1 m x 1 m at its lowest) for the older mosaics, depending on the location. This resolution was sufficient to identify the smallest features to be mapped, i.e. the surface cracks (Figure 2a). Nevertheless, several limitations during the mapping process were encountered, as image distortion or illumination, and will be discussed in section 4.4.1.

Using a single orthoimage to map surface disturbances can lead to misinterpretations in the case of poor illumination of the terrain and snow patches covering the ground (Serrano , 2017). Indeed, as the surface morphology of a rock glacier is naturally shaped according to spatially varying creep patterns, it is easy to mistake actual surface disturbances to compression features, as furrows, depending on image quality. Therefore, surface disturbances, i.e. those morphological features not related to the creeping of the ice-rich permafrost, were mapped using all three available orthoimages in order to check that actual strain occurred where surface disturbances are located and to overcome limitations related to poor quality of an individual image.

2.2.1 Rating the degree of destabilization

After the rock glacier surface disturbances were mapped, a rating of the degree of destabilization was assigned to each rock glacier. This rating was given not only to provide some insight to the observed levels of destabilization in the French Alps, but also to provide a confidence rating to describe a rock glacier as stable or unstable for the spatial distribution modelling of rock glacier destabilization.

Assigning a rating to quantify the degree of destabilization of a rock glacier required the definition of the characteristics of the "typical" destabilized rock glacier that can be observed on multiple orthoimages. To do so, we investigated the recurrent the features of destabilized rock glaciers that could be observed by orthoimagery interpretation. The Berard rock glacier showed a crevasse since 1947, which did not evolve until the early 2000s (Bodin et al., 2016). In 2003 the crevasse seemed to deepen and a new one formed a few tens of meters further east of the original. The rock glacier collapse took place where these crevasses were located. In the Pierre Brune (Figure 2b), Roc Noir (Figure 2a) and Hinteres Langtalkar rock glaciers a series of scarps and crevasses cut the whole body and divided the rock glacier into two zones with different velocities (Echelard , 2014; Serrano , 2017; Roer et al., 2008). Although surface disturbances could be observed in aerial imagery since the 1940s to the 1960s (Figure3) evolution in terms of quantity and size were linked to the increased displacement speed of the sectors of the rock glacier downstream the surface disturbance, which occurred since the 1990s. Earlier, the rock glacier seemingly creeped uniformly. A similar pattern was observed on the Plator, Grosse Grabe and Gänder rock glaciers, where a scarp marked the sharp transition from displacement speeds in the order of 0.1 – 0.9 m/y to displacements speeds of the order of several meters per year (Scotti et al., 2016; Delaloye et al., 2008).

These observations suggested that the presence of surface disturbances was a necessary but not sufficient condition to the occurrence of destabilization, as rock glaciers may present surface disturbances but be stable for decades. Also, high speeds may not be a necessary feature, as some destabilized rock glaciers, e.g. Lou and Furggwanghorn, moved at a "normal" rate of around 2 m/yr (Schoeneich et al., 2017; Roer et al., 2008). On the other hand, the agreement between the discontinuity of the surface deformation pattern of the rock glacier and the surface disturbances was suggested to be a key pattern in destabilization. The co-occurrence of these two conditions was found in every known case of destabilization here analyzed. Considering this, we proposed a rock glacier destabilizing rating that varied from 0 (stable rock glaciers) to 3 (rock glaciers potentially destabilized), explained in Table 2. For each active rock glacier, a rating of the degree of destabilization was assigned by observing the combination of surface disturbances and a qualitative assessment of recent deformation patterns. This rating was applied using a standardized workflow (Figure 4). Temporal evolution was assessed by observing the IGN orthoimagery collection.

Potentially destabilized rock glaciers were ultimately classified into two different categories according to the type of surface disturbances observed. Most of the destabilization cases observed by previous studies described rock glaciers characterized by surface disturbances that may reach several meters of depth, i.e. crevasses and scarps, and therefore suggested to split the permafrost body. These surface disturbances can be observed in coarse grained (i.e. blocky, sensu Ikeda and Matsuoka (2006)) rock glaciers. Nevertheless, in the French Alps many active rock glaciers are fine grained and some destabilization cases, e.g.

the Lou (Schoeneich et al., 2017) and Iseran (Serrano , 2017) rock glaciers, were observed to be characterized by the presence of cracks only. These surface disturbances are shallower than crevasses and scarps and therefore suggested to affect only the upper layer of the rock glacier. As these observations were relatively recent, at present there is still not enough knowledge concerning the significance of these shallow cracks in the context of rock glaciers destabilization. We therefore decided to separate rock glaciers showing shallow surface disturbances from rock glaciers showing deep surfaces disturbances into two distinct classes in order to make the reader aware of this gap in knowledge.

2.3 Modelling rock glacier stability

Modeling the rock glacier stability aims to identify the terrain attributes that may precondition rock glacier destabilization. The modelling followed a statistical approach similar to previous spatial prediction studies on landslides (Goetz et al., 2011) and arctic permafrost slope failures (Rudy et al., 2017) that used the Generalized Additive Model (GAM) with logistic link function (R package "mgcv"). GAM was selected because of its flexibility in modelling non-linear interactions between dependent and predictor variables. The logistic link function allows to model the occurrence of a categorical response variable as a function of continuous variables (predictor variables). All numeric predictors were represented using spline-based smooths, for which we chose a maximum basis dimension of 4 in order to limit their flexibility and reduce overfitting. The actual degree of smoothness of the spline smooths is determined by a generalized cross-validation procedure (Wood , 2017).

In this study, rock glacier stability was hypothesized to be preconditioned by a series of local terrain attributes. In particular, rock glacier destabilization grouped by either presence or absence was the response variable, while terrain attributes describing local topography and climate were used as predictor variables. The multiple variable models were computed using different combinations of predictor variables. Different models were compared using the Akaike Information Criterion (AIC), which is a measure of goodness of fit that penalizes more complex models. The best multiple variable model was selected by iterating a backward-and-forward stepwise variable selection, aimed to identify which combination of predictors was better at describing the response variable by means of lower AIC. Finally, the best model performance was estimated using the Area Under the Receiver Operating Characteristic (AUROC) (Hosmer and Lemeshow , 2000). The AUROC estimates the ability of the model to discriminate stable and unstable areas.

The predictive power of the model was estimated by spatial cross-validation (R package "sperrorest"). The method selected was the k-means clustering, which consisted in dividing the database in k spatially contiguous clusters (Ruß and Brenning , 2010a). All but one clusters were used to train the model, while the remaining cluster was used to test the predictive power of the model. This process was repeated until each cluster was used at least once in both training and test sets. Here, we divided the database into $k = 5$ clusters of equal size per run and used 100 repetitions. Performance indicators were evaluated on the respective test sets, and the overall model performance was evaluated using the average and standard deviation over all partitioning clusters.

The variable importance was assessed using permutation-based variable importance embedded in the spatial cross-validation (Ruß and Brenning , 2010b). This method consisted of permutating the values of each predictor variable one at a time and calculating the reduction in model performance caused by the permutations. One thousand permutations were performed for

each spatial cross-validation repetition. Predictor variables causing higher deviations while permutated were considered the most important ones in the model.

2.3.1 Model response variable

Surface disturbances of potentially destabilized rock glaciers were used as evidence of creeping permafrost destabilization. This was done under the hypothesis that surface disturbances were the geomorphological expression of destabilized rock glaciers. However, many surface disturbances could be observed on rock glaciers that were classified as unlikely destabilized or as suspected of destabilization. On the other hand, in potentially destabilized rock glaciers surface disturbances could be observed to increase in time by number and size, creating a discontinuity in the deformation pattern, suggesting a stronger evidence of destabilization. Therefore, only surface disturbances located in potentially destabilized rock glaciers were considered as solid evidence of rock glacier destabilization.

As surface disturbances were digitized as linear features, they were buffered and merged into an "unstable areas" polygon database. A buffer distance of 30 m was chosen. The model was found to be insensitive to changes in buffer size up to 90 m. All remaining areas within the polygons of stable and likely stable rock glaciers were used as "stable areas". Polygons of both unstable and stable areas were sampled using a 25 m x 25 m point grid in order to assign the response variable to the modelling database. The point values were then used as binary response variable with values of 0 for stable areas of (likely) stable rock glaciers, while 1 was assigned for unstable areas of potentially destabilized rock glaciers in the modelling stage.

Since the rock glacier inventory counted a relatively small number of potentially destabilized cases (46 individuals), selecting only one point per rock glacier would have caused large uncertainty in the model outcome. It was therefore performed a simple exploratory analysis aimed to identify a proper amount of points per rock glacier to be used in modeling. Multiple points, from one to ten, were randomly selected within each rock glacier perimeter and used to compute a model. This was repeated ten times per each point sample size, in order to measure the variability of the model performance in relation to randomness of the points locations. Since model performances were found to stabilize for more than five points selected per rock glacier, this number of points was randomly extracted per rock glacier for modelling. Overall, the model was computed using 225 evidence of instability and 1785 evidence of stability.

2.3.2 Model predictor variables

Terrain attributes used in modelling need to be selected to represent as proxies of the processes that precondition destabilization. Although destabilization is found to occur in different conditions, some topographical features seem to be recurrent. Destabilization is observed to occur on steep slopes, as high slope angles increase the internal shear stress (Delaloye et al., 2013). Surface disturbances are often located in convex bedrock which causes an extensive flow pattern and a thinning of the permafrost body (Delaloye et al., 2013). Solar exposure also may be significant in the destabilization occurrence as, for example all known cases of destabilized rock glaciers in the French Alps are North facing. Solar exposure can also be a proxy of the snow cover duration, as north facing slopes are more prone to conserve longer snow patches through the summer, mak-

ing meltwater available through the summer. Elevation as well is a proxy of snow cover duration as well as mean annual air temperature, possibly affecting permafrost characteristics.

Terrain attributes were derived from the BD Alti DEM, 25 m × 25 m spatial resolution (IGN , 2011a). Slope angle and downslope curvature (Freeman , 1991) were evaluated using the Morphometry Toolbox in SAGA GIS (version 2.2.2, Conrad et al. 2015). Negative values of curvature indicate concave topography, while positive values indicate convex topography. Also Potential Incoming Solar Radiation (PISR) was calculated using the Terrain analysis toolbox in SAGA as the sum of the computed direct and diffusive components of the radiation (Wilson and Gallant , 2000). Clear-sky conditions, a transmittance of 70 %, and absence of a snow cover were assumed in the calculation of the annual total PISR.

Finally, it was decided to evaluate the relation between rock glacier destabilization and the spatial distribution of degrading permafrost in order to give an insight on the significance of the warming climate with respect to the destabilization phenomena. The spatial distribution of degrading permafrost was evaluated following the method already presented by other studies (Hoelzle and Haeberli , 1995; Lambiel and Reynard , 2001; Damm and Felder , 2013), which consisted in artificially shifting a permafrost map proportionally to the estimated climate warming occurred between the period of validity of the map and the current climate. Here, as permafrost distribution map of the region we used the Permafrost Favourability Index (PFI) map (Marcer et al., 2017). The ¨PFI map was calibrated using active rock glaciers as permafrost eviedence and it represents the permafrost conditions during the cold episodes of the Holocene, e.g. Little Ice Age (LIA). The climate warming between the years 1850-1920 and 1995-2005 was determined using the HISTALP database (Auer et al., 2007) over the region. A permafrost distribution map was then recomputed taking into account of these temperature variations and represented the theoretical permafrost distribution in equilibrium with the current climate. By comparing this theoretical permafrost distribution and the PFI, it was obtained the Potential Thawing Permafrost zone (PTP, i.e. the so-called "melting area" in Lambiel and Reynard (2001)). In order to use the PTP as predictor variable, it was represented by an index ranging between 0, i.e. no thaw expected, and 1, i.e. potential thaw.

It is emphasized that PTP is only a proxy of permafrost degradation, which occurs at all the elevations while the PTP zone consists in a belt of 250 to 300 meters elevations that affects about 50% of the lower margins of the permafrost zone (Figure 5). PTP is used under the hypothesis that degradation is more intense at the lower margins of the permafrost zone as permafrost may be temperate, richer in water and more sensitive to climate variations.

2.3.3 Susceptibility modelling

The model was used to predict the occurrence of degrading permafrost over the French Alps, obtaining the susceptibility map (e.g. Goetz et al., 2011). This was done using the R package RSAGA and the raster images of the predictor variables maps, which allowed to extrapolate the relationships between rock glacier stability and terrain attributes at the landscape scale. It is emphasized that, being the model calibrated on destabilized rock glaciers, the susceptibility map is significant only for the processes relative to destabilization of ice-rich debris slopes. Therefore, in areas where creeping permafrost does not exist the map was extrapolated and it may fail or be meaningless. The model predicted a DEFROST index which was classified into five

susceptibility zones using the 50, 75, 90, and 95 percentiles (Rudy et al., 2017; Goetz et al., 2011). These zones described very low (<50), low (50 – 75), medium (75 – 90), high (90-95) and very high (>95) susceptibility to permafrost destabilization.

3 Results

3.1 Destabilized rock glaciers inventory

5 More than 1300 surface disturbances were digitized, involving 259 active rock glaciers (Figure 6). Overall, more than the 50% of the active rock glaciers may be affected by some degree of destabilization as 46 rock glaciers (9.7%) showed potential destabilization, 86 (17.0%) were suspected of destabilization and 127 (25.7%) were unlikely destabilized. Only 13 potentially destabilized rock glaciers presented deep surface disturbances.

Potentially destabilized rock glaciers were mainly located in in the Vanoise National Park and in the Queyras and Ubaye
10 mountain ranges. In these areas, densely jointed lithologies, as ophiolites and schists, dominate. Rock glaciers in crystalline lithologies, i.e. gneiss and granite, were found showing low rates of destabilization, i.e. only two rock glaciers rated as possibly destabilized over a population of 55 (Table 3).

The predominant surface disturbance observed were cracks, which were present on 187 of the active rock glaciers (Table 4). Crack clusters also had a high number of observed cases (152), while the deep surface disturbances occurred in about 15% of
15 all the examined rock glaciers. In general, the occurrence of surface disturbances were dependent on the destabilization rating. Scarps and crevasses were found in about 10% on unlikely destabilized landforms. The observation of each surface disturbance was highest for potentially destabilized rock glaciers with deep surface disturbances, indicating that in these landforms multiple surface disturbances coexist.

3.2 Modelling

20 Following a stepwise backward and forward selection, the chosen model included PISR, slope angle, elevation and curvature as predictors. The mean cross-validated AUROC was 0.76 on the test set, indicating a good performance (Hosmer and Lemeshow , 2000). The predictors having most influence on the response variable were the PISR (AUROC change = 0.162), curvature (AUROC change = 0.068), slope angle (AUROC change = 0.031) and elevation (AUROC change = 0.018).

The model transformation functions revealed the relations between terrain attributes and rock glacier stability (Figure 7).
25 Surface disturbances were more likely to occur in an altitudinal range between 2700 and 2900 m a.s.l. Slope angles ranging between 25 and 30° were associated with higher predisposition to destabilization. Slightly negative to positive curvature was also favourable to destabilization. PISR was negatively correlated with the destabilization probability, indicating that rock glacier destabilization was more likely to occur on north-facing slopes. For higher PSIR, i.e. around 2000 kWh/m² destabilization predisposition is found to grow again. Although not used in the final model and therefore reported for exploratory purposes
30 only, the PTP was positively correlated with the destabilization.

3.3 Susceptibility map

The susceptibility map highlights creeping permafrost areas susceptible to destabilization based on regional-scale model predictions (examples shown in Figure 8). The susceptibility map reproduced well the previously known cases of destabilization. The destabilized areas of the Iseran, Roc Noir and Pierre Brune were predicted to be at high susceptibility to destabilization coherently to field observations. The susceptibility predicted high destabilization susceptibility in areas belonging to stable rock glaciers.

Rock glacier surfaces were investigated with respect to each susceptibility class (Table 5). About 75% of the creeping permafrost was found at low or very low susceptibility to destabilization. Creeping permafrost at high and very high susceptibility to destabilization accounted 10% of the total creeping permafrost surface, i.e. 2.9 km^2. While about one third of this surface was located in potentially destabilized rock glaciers, more than 1.4 km^2 of stable and unlikely destabilized rock glaciers were found at high and very high destabilization susceptibility.

4 Discussion

4.1 Rating rock glacier destabilization

The present study provided the first comprehensive assessment of rock glacier destabilization for the French Alps, suggesting the high prevalence of the phenomena in this area. Destabilized rock glaciers were more likely located in the Vanoise, Queyras and Ubaye ranges. In these areas the densely jointed lithology was suspected to generate mainly pebbly rock glaciers (Matsouka and Ikeda , 2001; Ikeda and Matsuoka , 2006). This suggested that destabilization may be more likely to develop in pebbly rock glaciers, as observed in the Berard, Roc Noir and Lou rock glaciers. Also, no rock glacier developed in crystalline lithology showed potential destabilization. However, recognizing surface disturbances on pebbly rock glaciers may be easier than in "blocky" rock glaciers, as smaller cracks are more evident. This may create a bias which should be studied more in detail by investigating geomorphological features of destabilization occurring on blocky rock glaciers.

The majority of rock glaciers showing potential destabilization were characterized by shallow cracks (33 cases versus 13). Although, this is suggested to be partially due to the high incidence of rock glaciers located in densely jointed lithology, there is a number of questions that still need to be answered in this context. At present, we are unsure about the significance of these surface disturbances in the context of destabilization. Cracks may either be a "mild" evidence of destabilization as they affect only the upper layer of the landform or a typical surface disturbance occurring on destabilized pebbly rock glaciers. In the first case, using cracks as destabilization evidence could lead to an over-interpretation of the destabilization severity of the landform. On the other hand, it was observed that destabilization may occurred when only these type of surface disturbances occurred (Schoeneich et al., 2017; Serrano , 2017). Concerning this issue, this study suggested that these landforms deserve more attention due to their high incidence on the regional territory.

Overall, rock glacier destabilization rating can be a relevant tool for the local authorities to assess risks related to the degradation of the periglacial zone, as we identified all rock glaciers presenting signs of destabilization in the region. The destabilization

rating, jointed with displacement rates assessment and landform connectivity, suggests the severity of the potential hazard and can help identify actions that should be undertaken to deal with the problem. In general rock glaciers with low destabilization rating are currently evolving slowly or are stable, and consequently monitoring based on remote sensing may be sufficient. Suspected or potentially destabilized rock glaciers require more caution and in-situ monitoring is recommended.

4.1.1 Uncertainties in rating rock glacier destabilization

A potential source of uncertainty in this study was the subjectivity that can occur while mapping surface disturbances and rating the degree of destabilization. These activities were based on expert knowledge; however, it is possible that mapping and rating results vary depending on the operator. For example, the operators in charge of the digitization process were requested to interpret surface features that in many cases have small dimensions with respect to the resolution of the orthoimages, making the identification challenging. Also, although surface disturbances were inventoried into the catalogue in an attempt to standardize the classification, destabilized rock glacier morphology is complex, and its identification requires intense training. In many cases the boundaries between the different typologies proposed were not sharp. Personal knowledge of the process evolved through the inventory compilation, requiring various iterations to review the work.

Another issue was that the operator's metrics of judgment was subjected to the "prevalence induced concept change" (Levari et al., 2018), as the classification might get stricter (or looser) when the operator deals with a series of destabilized (or stable) rock glaciers. The ratings were compiled and revised by different operators in an attempt to mitigate these effects. Some cases were subject of debate, highlighting significant individual biases. These biases can influence the resulting susceptibility model (Steger et al., 2016). It is therefore strongly recommended to integrate the inventory with in situ observations when possible and to maintain a critical attitude towards the data. At present time France does not have a LiDAR-based high-resolution DEM covering the study region. Such data could be used to revise in the inventory in the future in order to reduce errors due to poor quality of the orthophotos. In particular, high resolution DEM could avoid issues related to the differentiation between isolated crack and crevasse, as the judgment based on orthoimages may vary depending on the lightning.

Although observing aerial orthoimagery or high resolution DEMs could not replace the relevance of a proper in-situ survey, it provides us with data and resulting insights that would normally not be possible with in-situ surveys alone, a characteristic that fitted with the aim of the study. Additionally, the use of orthoimagey has been proved to be a useful approach for mapping rock glacier surface disturbances by Serrano (2017), where the results of field observation were compared to observations from orthoimagery. Although Serrano (2017) investigated a limited number of sites, those results were encouraging, showing that the method was relevant. The use of multiple orthoimages was believed to successfully reduce subjectivity-related issues in most of the cases. Observing the movements of the landforms was a valuable decision support tool, as surface disturbances could be related or not to discontinuities in a pronounced displacement field. Also, the use of multiples orthoimages reduced potential errors due to bad lighting that may enhance features that may be unrelated to destabilization processes (Serrano , 2017).

4.2 Modelling the predisposition to rock glacier destabilization

Despite the various limitations of the database, results were encouraging. The spatially cross-validated model had a good performance, suggesting that the method is valuable in the context of modeling rock glacier stability. The relationships with predictor variables were found to be consistent with topographic settings observed in known cases of destabilization. High slope angles are suggested to increase internal shear, making the landform more susceptible to destabilization (Schoeneich et al., 2015). Convex slopes cause an extensive flow pattern as creep velocity is higher downslope the convexity (Delaloye et al., 2013). This is suggested to cause a thinning of the permafrost body and the generation of traction forces that may enhance the occurrence of surface disturbances. The PTP was found to be a significant predictor of potential destabilization. In particular, increasing potential in permafrost thaw was linked to increase susceptibility of destabilization, indicating that destabilization was more likely to occur where the permafrost zone was expected to be thawing. This seems to be consistent with the relation between destabilization and elevation, as potentially destabilized rock glacier as more often located around 2800 m.a.s.l., which roughy coincides with the lower margins of the regional permafrost zone.

PISR had the most importance in the model, suggesting that rock glacier destabilization was primarily more likely to occur on north facing slopes. We cannot offer a convincing explanation of this phenomenon as, at the present state of the art, there is no systematic study comparing rock glacier characteristics in relation to their solar exposure. Nevertheless, we suggest that a possible explanation resides in the variability of meltwater input of the rock glaciers with respect to solar exposure. Ikeda et al. (2008) suggest that high water input can boost destabilization by reducing internal friction. Considering that snow patches tend to last longer in North exposed slopes, meltwater inputs may be more significant than in south exposed slopes.

4.3 Susceptibility map

Overall, permafrost destabilization was adequately described, as indicated by the cross-validated performance, in most of the observed cases of destabilization. Although cases of potential destabilization were inventoried, rock glaciers that have a low rating of destabilization and are located in areas with high susceptibility should be identified as having a high potential of showing future destabilization. Results indicated that these rock glaciers had a large area of high predisposition to destabilization and should be monitored for risk assessment. In particular, the Laurichard rock glacier is a site currently under monitoring which was found to present a low to medium susceptibility to destabilization in this study (Bodin et al., 2008). The comparison of the future evolution of this landform with respect to the DEFROST susceptibility map is therefore recommended.

5 Conclusions

The present study aimed to give insights into the extent of the phenomeon of destabilizing rock glaciers in the French Alps. This was done by mapping and modelling rock glacier destabilization in the region using orthoimagery collection, 25 m x 25 m resolution DEM and statistical modelling. This methodology carried several limitations, due to subjectivity and modelling issues. Therefore, absolute model performance and the appearance of the susceptibility map may not be exact and further work

is strongly encouraged. Integrating the observations with high resolution LiDAR DEM and with new field-observations could spot possible systematic biases in the destabilization rating attribution and significantly reduce uncertainty.

Despite the limitations of this methodology, the study contributes to the knowledge related to permafrost degradation in the French Alps. Rock glacier destabilization potentially involves 47 active landforms, uniquely located in non-crystalline

5   lithologies, which are typically densely jointed as ophiolites and schist. Shallow surface disturbances, i.e. cracks, had the highest incidence in potentially destabilized rock glaciers. At present, there are several questions concerning the destabilization of pebbly rock glaciers presenting these shallow surface disturbances, as only few studies tackled the subject. Therefore, considering the high incidence of these landforms in the region, it is suggested to dedicate more attention to the issue in the future.

10   The destabilization of creeping permafrost was found to be a widespread phenomenon which involves more than 10% of the total surface of active rock glaciers, i.e. 3 km^2 ca. Only half of this surface was attributed to rock glaciers currently showing a relevant degree of destabilization, suggesting that several stable rock glaciers have a significant degree of susceptibility to experience destabilization in the future. Rock glacier destabilization was found to be more likely at the lower margins of the permafrost zone, i.e. were permafrost thaw due to climate warming is expected to be more intense. This suggests that

15   climate warming may have increased the predisposition of creeping permafrost to slope failure. In this context, the present study contributes by having mapped potentially destabilized rock glaciers and areas considered susceptible to destabilization, allowing to focus future monitoring efforts. In this sense, we suggest that the modelling framework proposed is relevant and further efforts to better acknowledge the phenomena are strongly encouraged.

Code and data availability.   The R code to model rock glacier stability and database is available and built in RGUI version 3.4.4. Shape files
20   for surface disturbances (one file per feature type. Data are in .shp format) and PTP and DEFROST susceptibility maps are available (.tiff format). Data are in referenced in EPSG : 2154.

Competing interests.   Herby we declare that no competing interests is present for this study

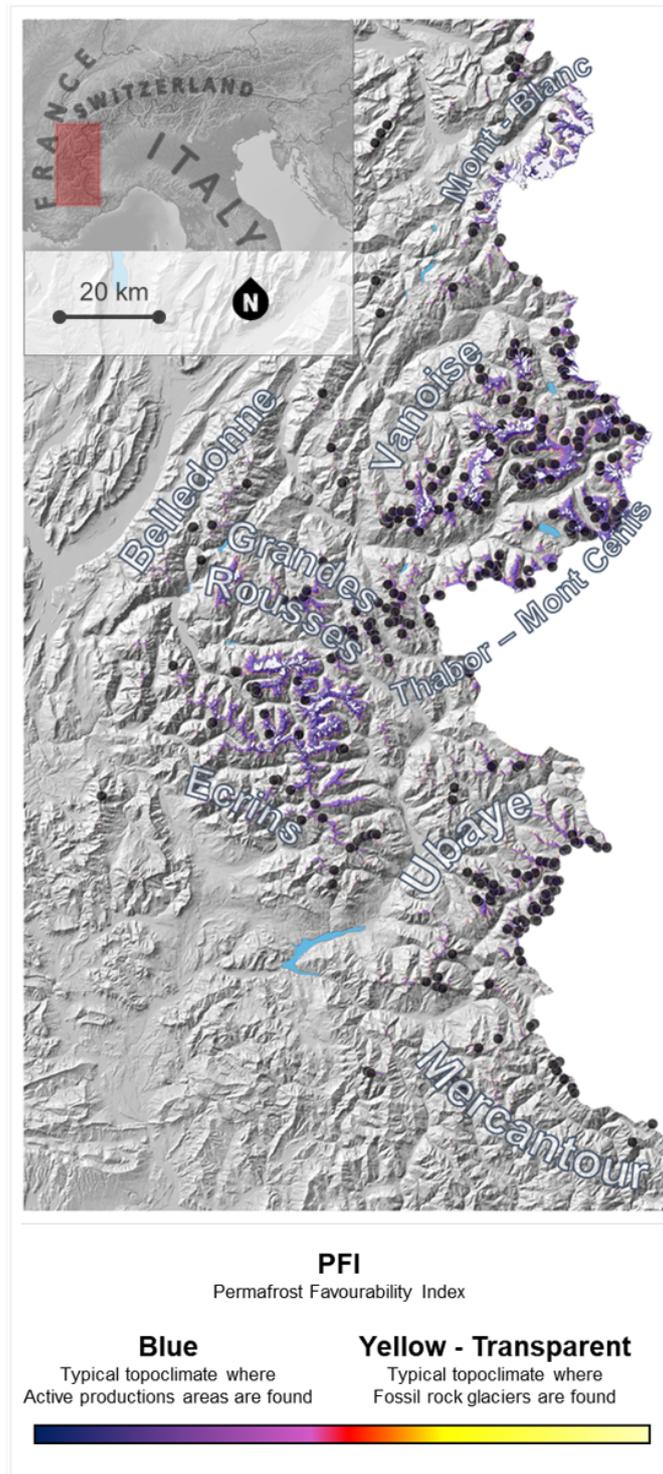

Figure 1. Isentification of the surdy area in the European Alps and overview of the periglacial environment. Permafrost distribution is represented by the PFI map (Marcer et al., 2017). Black dots identify active rock glaciers locations (Marcer et al., 2017)
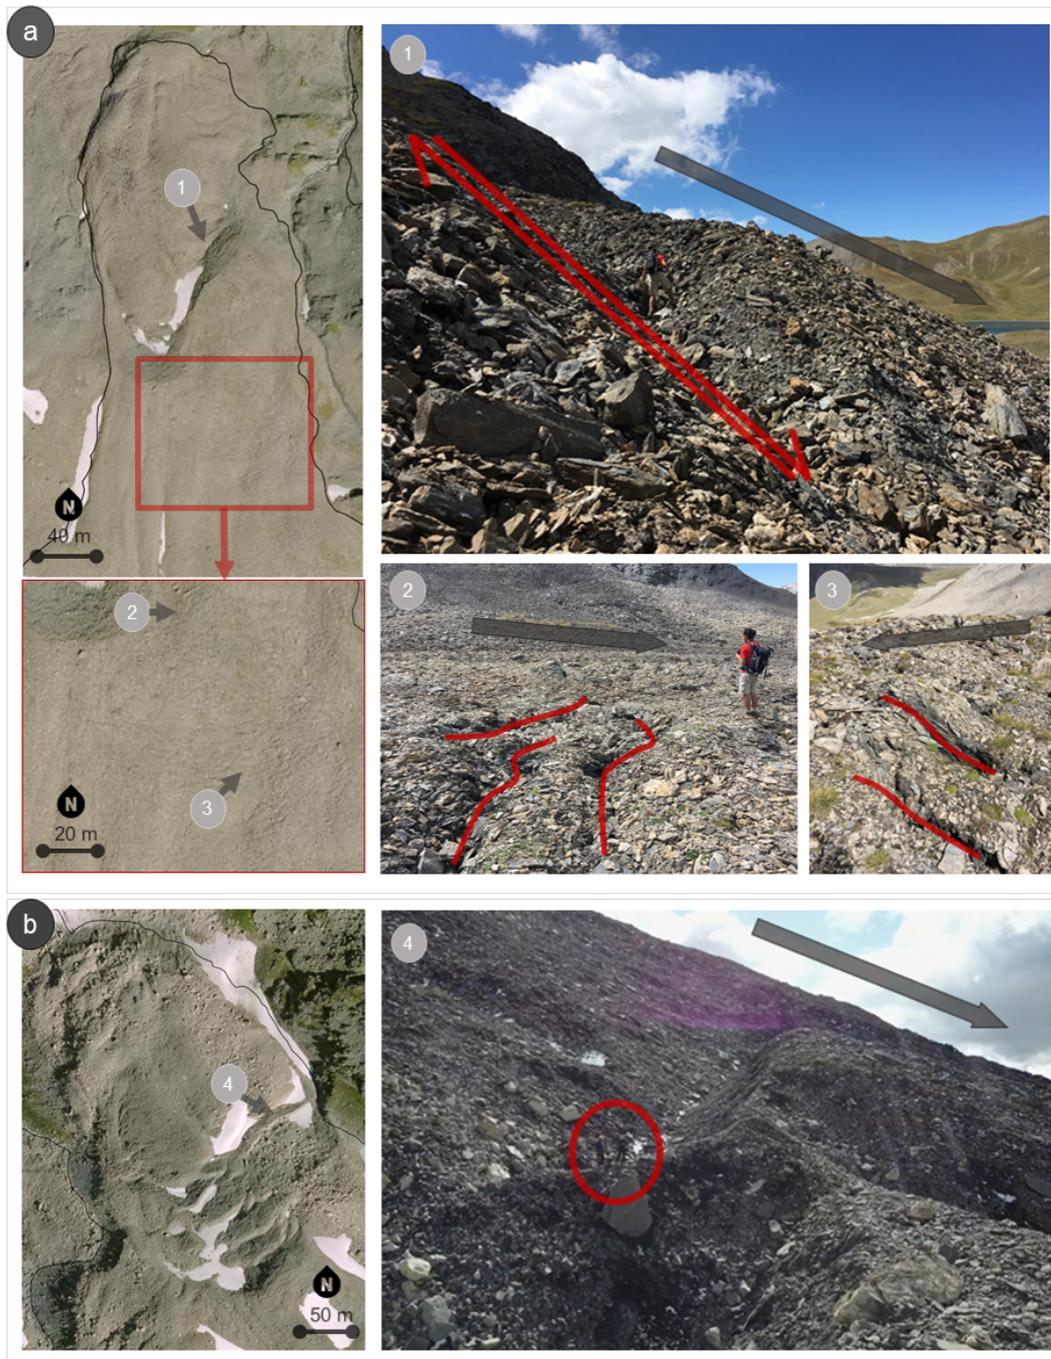

Figure 2. Examples of surface disturbances observable on the available orthoimages in comparison to field observations on (a) Roc Noir (Serrano , 2017) and (b) Pierre Brune (Echelard , 2014) destabilized rock glaciers. Black arrows on field pictures indicate rock glacier displacement direction. On Roc Noir rock glacier are observable a scarp (1) and cracks (2,3). On Pierre Brune rock glacier are observable large crevasses (4).
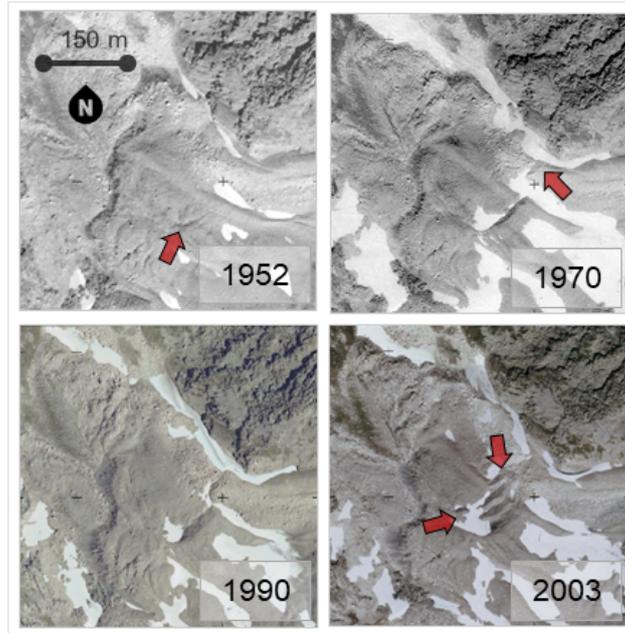

Figure 3. The evolution of the destabilization of the Pierre Brune rock glacier. The destabilization evidence, in this case a crack observable since 1952, evolved to a crevasse, observable in 1970. Afterwards, the landform was stable for 20 years as destabilization evidences did not further evolve. Between 1990 and 2003 the rock glacier experienced severe destabilization with the formation of new crevasses and scarp in the location of the 1952 crack.
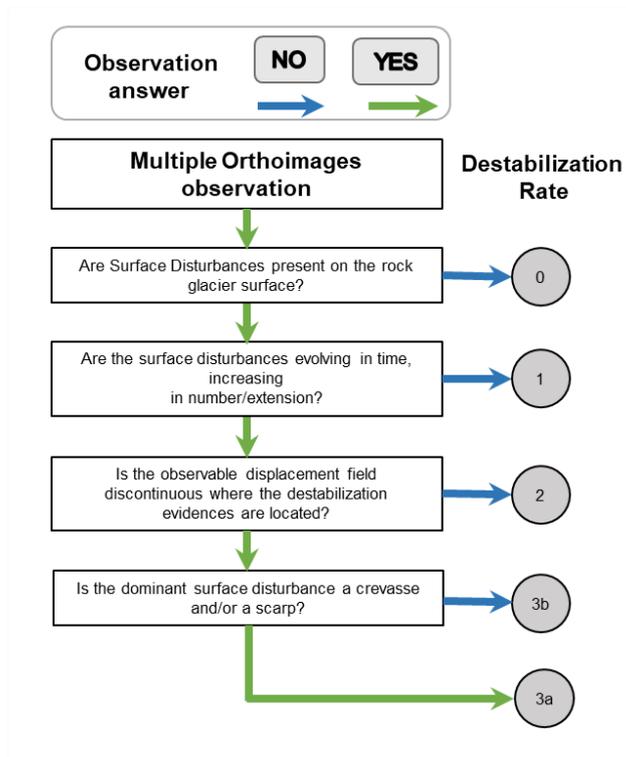

Figure 4. General pipeline used to rate rock glacier destabilization by observing surface disturbances and qualitative displacement field. Higher rates of destabilization indicate potentially unstable rock glaciers, while lower ratings indicate stable rock glaciers.
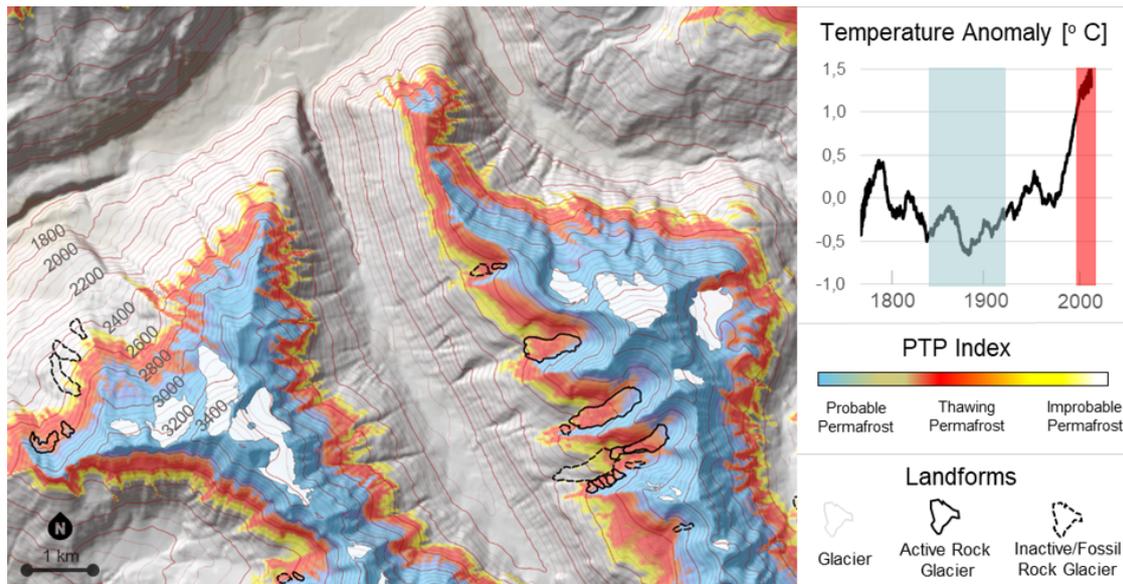

Figure 5. Example of Potential Thawing Permafrost (PTP) distribution in the Mont Cenis range, indicating the extent of the permafrost zone not in equilibrium with the present climate (red colored areas). Temperature warming to compute the map is evaluated using HISTALP data (Auer et al., 2008) between the end of the Little Ice Age (light blue shade period in the temperature anomaly plot) and the current climate (red shade period).
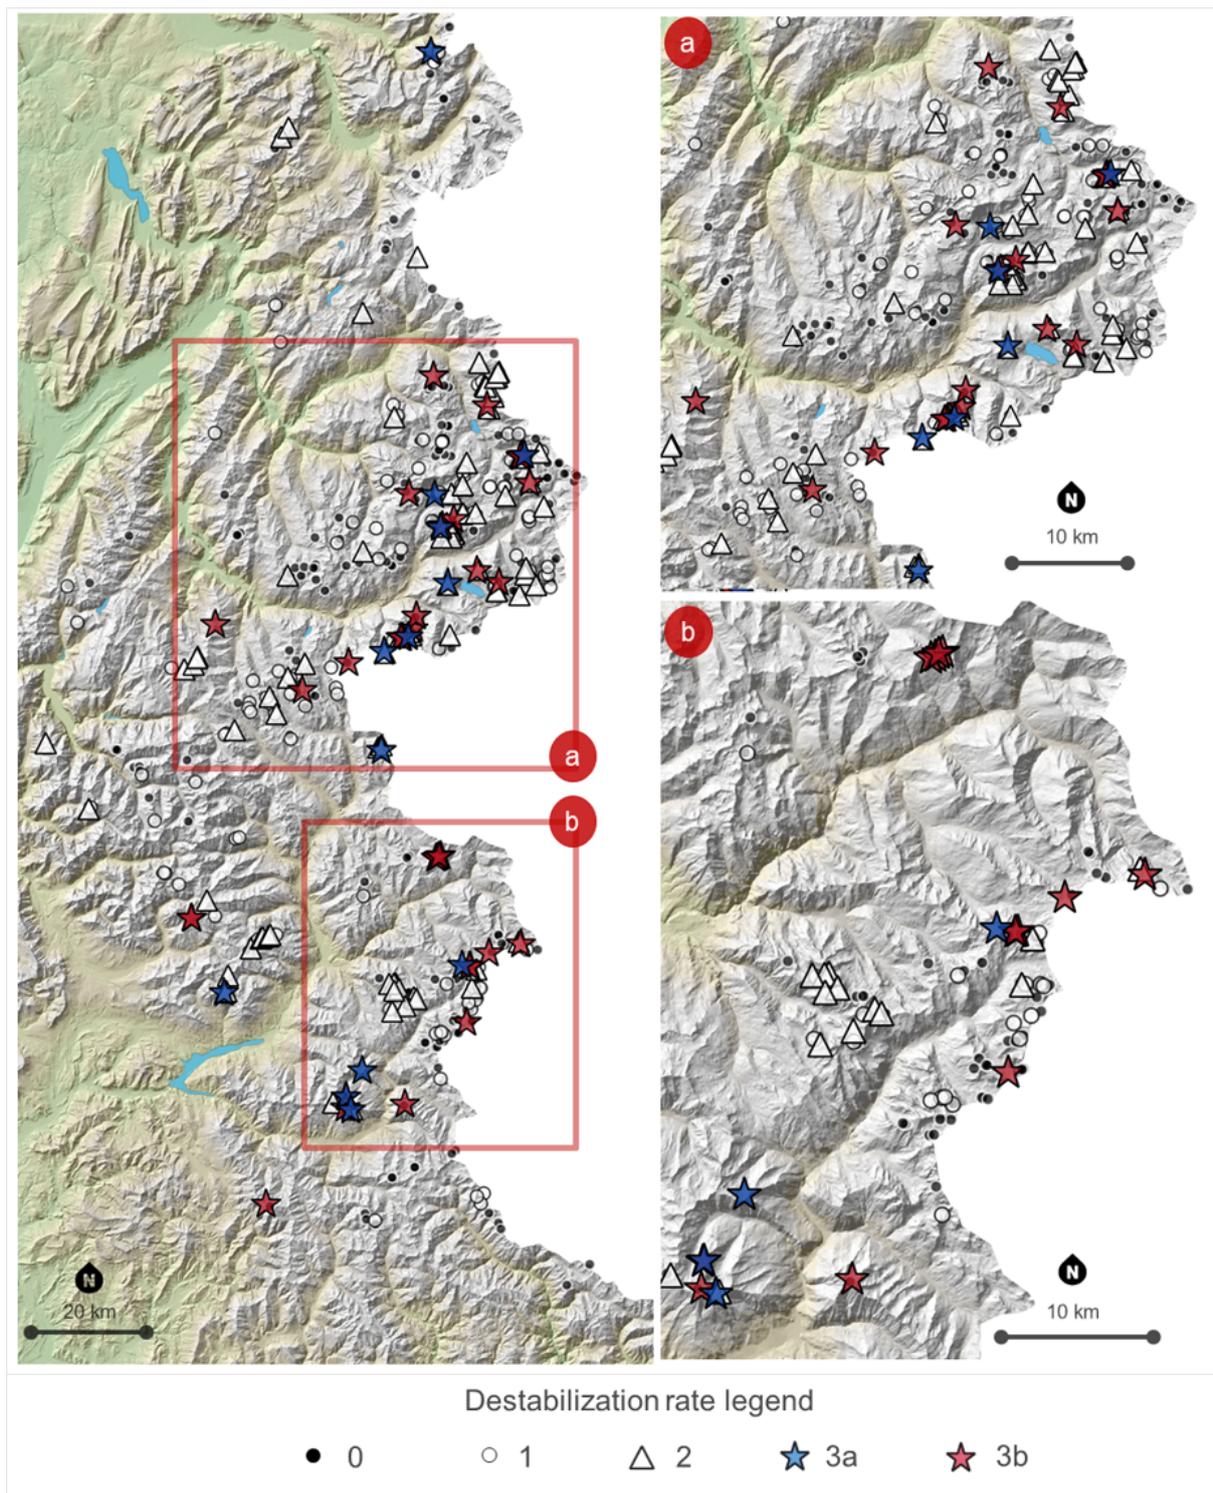

Figure 6. Map of active rock glaciers in France by rock glacier destabilization rating, with focus on the (a) Vaonise - Mont Cenis and (b) Ubaye ranges as most of potentially destabilized landforms were observed in these areas.
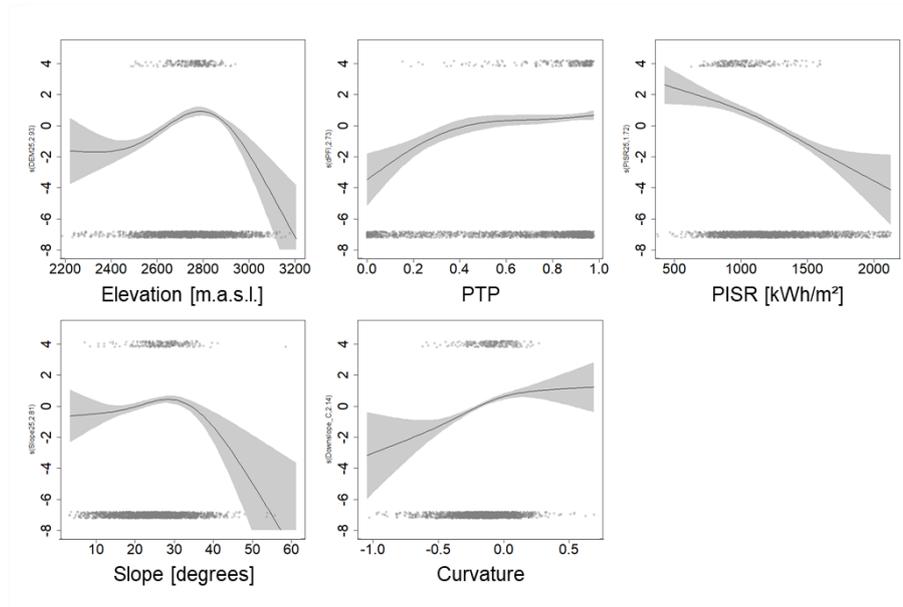

Figure 7. Transformation function plots of the GAM model showing the relationship between each predictor variable and destabilization occurrence. Data distribution with respect to predictor variables are indicated with dots on top (destabilization evidence) and on the bottom (stability evidence) of the plots.
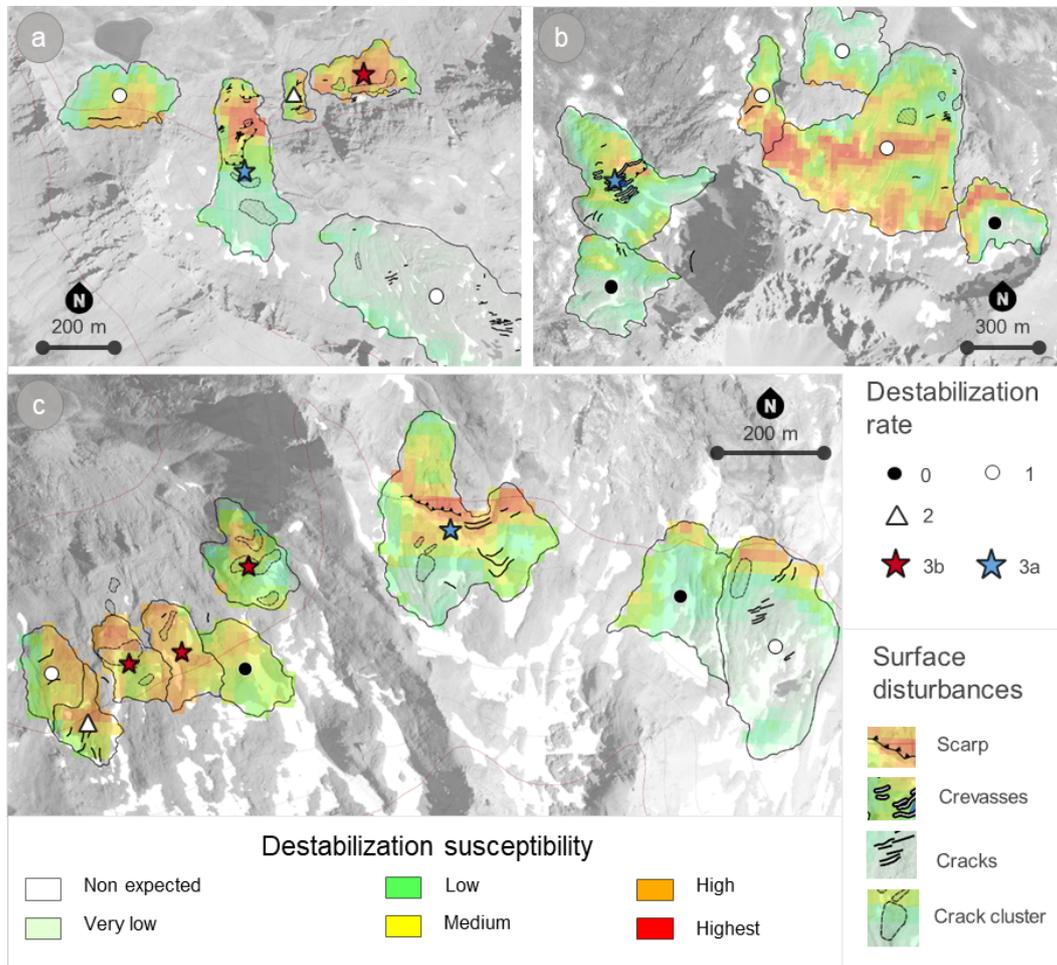

Figure 8. Examples of the susceptibility map in (a) Roc Noir, (b) Pierre Brune and (c) Iseran and Neighbouring rock glaciers. The susceptibility map successfully identifies instabilities observed on the potentially destabilized rock glaciers. Nevertheless, some predicted instabilities were observed in areas that appear stable by observing the orthomosaics.

Table 1. Description of surface disturbance features that could be observed in the field or from orthoimagery to identify signs of rock glacier destabilization

Feature	Description
Cracks	These are shallow linear incisions in the surface of an active rock glacier where a strain is applied (called "scars" in Roer et al. (2008)). Cracks can be several tens of meters long and occur either individually or in a great number, being spaced from each other of only few meters. In this case we define the feature as a "crack cluster" (translated from Serrano (2017)). Their proximity and shallowness lead to the assumption that they affect only the active layer of the landform. Nevertheless, this feature was found to be largely predominant on the Lou (Schoeneich et al., 2017), signal de l'Iseran (Serrano , 2017) and Tsate'-Mory (Roer et al., 2008; Lambiel, 2011) rock glaciers and therefore considered of interest in the context of the study.
Crevasses	These deep transverse incisions on the rock glacier surface can range in length from several meters to the entire landform width (Avian et al., 2005; Delaloye et al., 2008; Roer et al., 2008). Their depth is substantially larger than the active layer thickness, suggesting the presence of a shear plane sectioning the frozen body. Crevasses may be isolated or grouped. Spectacular crevasses can be found on Pierre Brune rock glacier (Fig. 1), where they are up to 7 m deep and 10 m wide, cutting across the entire landform (about 150 m). Similar dimensions are reported in the Furggwanghorn rock glacier (Roer et al., 2008).
Scarps	Described by Scotti et al. (2016) and Delaloye et al. (2008) as steep slopes (30 to 40°) several meters high cutting transversally the entire rock glacier. Scarps are associated with deep shear planes that disconnect the rock glacier into two bodies that creep at different speeds. Their activation is associated with a sudden acceleration of the downstream portion of the landform. One of the biggest scarp observable in the region is the one on Roc Noir rock glacier (Serrano , 2017). This S-shaped scarp, 20–30 m high and 40–45° steep, cuts transversally the whole landform (120 m) and the downstream lobe creeps about twice as fast as the upper part.

Table 2. Rating classes used to describe rock glacier destabilization

Rating	Label	Description
3	Potential destabilization, potentially destabilized rock glaciers	Surface disturbances are well recognizable and evolve in time, increasing in number and/or size. The deformation pattern of the rock glacier is discontinuous and some sectors move significantly faster than others. The source of the discontinuity may be located at the rock glacier's root and the whole landform may be affected by destabilization. Deformation pattern discontinuities are sharp and coincide with the presence of surface disturbances. Sectors moving appreciably faster may also present a series of surface disturbances. If the dominant surface disturbances are deep (i.e. crevasses and scarps), then it is attributed the rate **3a**. If the dominant surface disturbances are shallow (i.e. crack and crack clusters) then it attributed the rate **3b**
2	Suspected destabilization	In these landforms the surface disturbances are well recognizable and evolve in time, by increasing in number and/or size. The velocity field is continuous, i.e. there are no abrupt spatial differences in the velocity field. If there are sectors moving faster than others, their transition is smooth
1	Unlikely destabilization	In these landforms surface disturbances do not appear to evolve in time. The rock glacier presents a continuous deformation pattern, with no sectors moving substantially faster than others.
0	Non-observable destabilization	Active rock glaciers not presenting surface disturbances are considered as stable.

Table 3. Number of rock glaciers per dominant lithology in relation to destabilization rate.

Destabilization rate	Ophiolites	Schist	Sandstone	Mica-schist	Gneiss	Granite	Limestone	Totals
0	47	88	21	11	31	3	32	**233**
1	39	37	11	3	13	2	22	**127**
2	33	28	5	0	1	1	18	**86**
3b	18	7	1	3	0	0	4	**33**
3a	5	2	1	0	0	0	5	**13**

Table 4. Number of rock glaciers per destabilization rating showing a specific surface disturbance.

Destaibilization rating	Cracks	Crack clusters	Crevasses	Scarps
1	86	54	13	8
2	52	51	15	11
3b	23	29	0	0
3a	10	9	10	8
Totals	**187**	**152**	**40**	**27**

Table 5. Active rock glacier area per class of destabilization susceptibility.

Destabilization Rating	Surface per DEFROST susceptibility class [km^2]				
	Very Low	*Low*	*Medium*	*High*	*Very High*
0	8.09	3.21	1.70	0.43	0.37
1	4.03	2.16	1.29	0.42	0.38
2	2.18	1.50	0.93	0.34	0.30
3b	0.07	0.19	0.31	0.24	0.38
3a	0.17	0.27	0.17	0.05	0.05
Cumulative Surface	14.54	7.33	4.41	1.47	1.48
