## Abstract

The mass balance of the Greenland Ice Sheet (GrIS) in a warming climate is of critical interest in the context of future sea-level rise. Increased melting in the GrIS percolation zone due to atmospheric warming over the past several decades has led to increased mass loss at lower elevations. Previous studies have hypothesized that this warming is accompanied by a precipitation increase, as would be expected from the Clausius-Clapeyron relationship, compensating for some of the melt-induced mass loss throughout the Western GrIS. This study tests that hypothesis by calculating snow accumulation rates and trends across the Western GrIS percolation zone, providing new critical accumulation estimates in regions with sparse *in situ* data or data that does not span the recent accelerating surface melt. We present accumulation records from sixteen 22 – 32 m long firn cores and 4436 km of ground penetrating-radar, covering the past 20 – 60 years of accumulation, collected across the Western GrIS percolation zone as part of the Greenland Traverse for Accumulation and Climate Studies (GreenTrACS) project. Trends from both radar and firn cores, as well as commonly used regional climate models, show decreasing accumulation and precipitation of  $2.4 \pm 1.5 \% \text{ a}^{-1}$  over the 1996 – 2016 period, which we attribute to shifting storm-tracks related to stronger atmospheric summer blocking over Greenland. Changes in atmospheric circulation over the past 20 years, specifically anomalously high summertime blocking, have reduced GrIS surface mass balance through both an increase in surface melting and a decrease in accumulation.

## 1. Introduction

Greenland Ice Sheet (GrIS) mass loss has accelerated over the past few decades, with modern mass loss rates more than double those from Antarctica (van den Broeke et al., 2016). The 2010-2018 GrIS mass loss was calculated as  $286 \pm 20 \text{ Gt a}^{-1}$  (Mouginot et al., 2019), contributing  $0.7 \pm 0.2 \text{ mm a}^{-1}$  of sea level rise. Over the past 20 years, the largest warming rates (Hanna et al., 2012) and fastest mass loss have occurred in Western

34 Greenland ( $26 \pm 7$  GT a<sup>-2</sup> in basins F + G of Sasgen et al., 2012). Here, regional scale models calculate a  
35 surface mass balance (SMB) decrease ranging from 31.1% (European Centre for Medium Range Weather  
36 Forecasting downscaled; ECMWFd) to 76.5% (Modèle Atmosphérique Régional; MAR) over the 1996 –  
37 2008 period (Vernon et al., 2013) as a result of higher surface melt and runoff (van den Broeke et al., 2009,  
38 2016). Modern surface melt rates are at their highest levels of at least the last 450 years across Western  
39 Greenland (Graeter et al., 2018) and more broadly throughout Greenland (Trusel et al., 2018). In particular,  
40 ice core records from Western Greenland show an abrupt increase in surface melt rates beginning in the  
41 middle-late 1990's due to a combination of higher North Atlantic sea surface temperatures, enhanced  
42 summertime blocking highs, and anthropogenic warming (Graeter et al., 2018).

43  
44 Enhanced GrIS surface melt is driven fundamentally by rising Greenland summer temperature trends  
45 upwards of  $0.135 \pm 0.047$  °C a<sup>-1</sup> from 1982 – 2011 (Hall et al., 2013; Reeves Eyre and Zeng, 2017). Basic  
46 physics implies that rising temperatures should cause an increase in accumulation over the ice sheet due to  
47 the Clausius-Clapeyron relationship – warmer air has a higher saturation vapor pressure, potentially leading  
48 to more precipitation (Box et al., 2006; Buchardt et al., 2012). The Coupled Model Intercomparison Project,  
49 phase 5 (CMIP5) predicts precipitation increases of 20 – 50% over the GrIS by the end of the 21<sup>st</sup> century  
50 (Bintanja and Selten, 2014), partially offsetting mass loss and sea-level rise from enhanced summer melt and  
51 runoff. However, most *in situ* records of Greenland snow accumulation do not span the modern period of  
52 rapid warming since the mid-1990s, making it difficult to determine whether accumulation has been  
53 increasing with warming temperatures as predicted. For example, the Program for Arctic Regional Climate  
54 Assessment (PARCA) campaign collected accumulation data from a network of 49 ice and firn cores in 1997-  
55 1998 (Mosley-Thompson et al., 2001), just at the onset of accelerated surface melting (Graeter et al., 2018).  
56 There have been no published *in situ* accumulation records from the Western GrIS percolation zone for the  
57 past decade. Updated *in situ* snow accumulation data are needed from this region to assess recent changes in  
58 accumulation during this period of warming and SMB loss from melt and runoff.

59  
60 In addition to measuring snow accumulation with ice cores and automated snow depth sensors, several studies  
61 have used ground-based and airborne radar to calculate GrIS accumulation rates and trends (e.g. Medley et  
62 al., 2013; Spikes et al., 2004; Hawley et al., 2014; Koenig et al., 2016). We build upon these previous studies  
63 by collecting GPR data across the lower percolation zone of Western Greenland, where airborne radargrams  
64 are often obscured by refrozen melt percolation (Nghiem et al., 2005). The *in situ* GPR used in this study  
65 operates using a UHF pulsed radar, while other systems such as frequency modulated continuous wave  
66 (FMCW) radars use phase-sensitive antennas that include both amplitude and phase information. By having

67 our GPR antenna coupled with the snow, we avoid losing energy, and, therefore, penetration depth, from a  
68 strong reflection off of the snow-air interface.

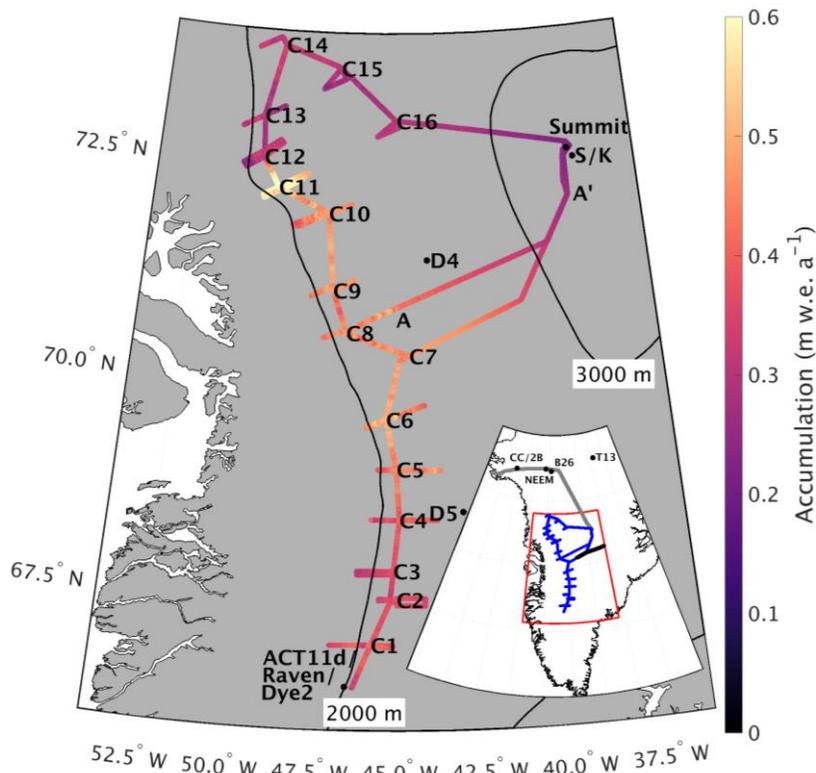

69

70 In addition to temperature-precipitation relationships through the Clausius-Clapeyron relationship, previous  
71 studies have analyzed the dynamic climate controls on Greenland precipitation. Mernild et al. (2014), Auger  
72 et al. (2017), and Lewis et al. (2017) have hypothesized that a positive Atlantic Multidecadal Oscillation  
73 (AMO) index correlates with rising accumulation over most of the GrIS interior, since higher sea surface  
74 temperatures increase moisture flux over the GrIS and induce greater snowfall. In addition, high pressure  
75 (blocking) systems east of Greenland tend to deflect eastward-moving storms over central Greenland and  
76 increase precipitation, whereas blocking directly over Greenland or in Baffin Bay has the potential to reduce  
77 accumulation over the GrIS by displacing the polar jet stream and corresponding storm tracks equatorward  
78 (Auger et al., 2017). Over the 1991 – 2015 period there has been particularly strong summertime Greenland  
79 blocking (Hanna et al., 2016), but its effects on GrIS accumulation have not been determined with *in situ*  
80 data.

81

82 Here we develop new accumulation records across the Western GrIS percolation zone using sixteen firn cores  
83 and 4436 km of GPR data collected during an over-ice traverse spanning two field seasons. We evaluate the  
84 veracity of the accumulation data through comparisons of our firn core time series with previous  
85 measurements. We quantify multi-year trends in accumulation across Western Greenland to test the  
86 hypothesis that precipitation has recently increased from the Clausius-Clapeyron relationship and higher GrIS  
87 temperatures. Further, we assess the ability of RCMs to capture the year-to-year variability and multi-year  
88 trends in Western GrIS accumulation. Finally, we evaluate relationships between recent accumulation trends  
89 and atmospheric circulation patterns, particularly changes in storm tracks.

This study uses data from the 2016 – 2017 Greenland Traverse for Accumulation and Climate Studies (GreenTrACS), which measured accumulation and melt across the Western GrIS percolation zone over two summer snowmobile traverses (closely following the 2150 m a.s.l. elevation contour). The May – June 2016 season traversed 860 km from Raven/Dye-2 northward to Summit Station, while the May – June 2017 traverse made a 1230 km clockwise loop starting and ending at Summit Station (**Error! Reference source not found.**Figure 1). This manuscript focuses on accumulation rates derived from 400 MHz GPR data collected along the entire traverse path, as well as sixteen shallow (22 – 32 m deep) firn cores spaced 40 – 100 km apart along the backbone of the traverse (Figure 1). Firn Cores 1 – 7 were collected in 2016 and Cores 8 – 16 were collected in 2017. We returned to the Core 7 location at the beginning of the 2017 traverse to recover a weather station and to connect the two season’s GPR data. Additionally, we collected GPR data ~30 – 70 km east and west of each core site, hereafter called “spurs”, to measure changes in accumulation along strong elevation gradients (see Figure 1).

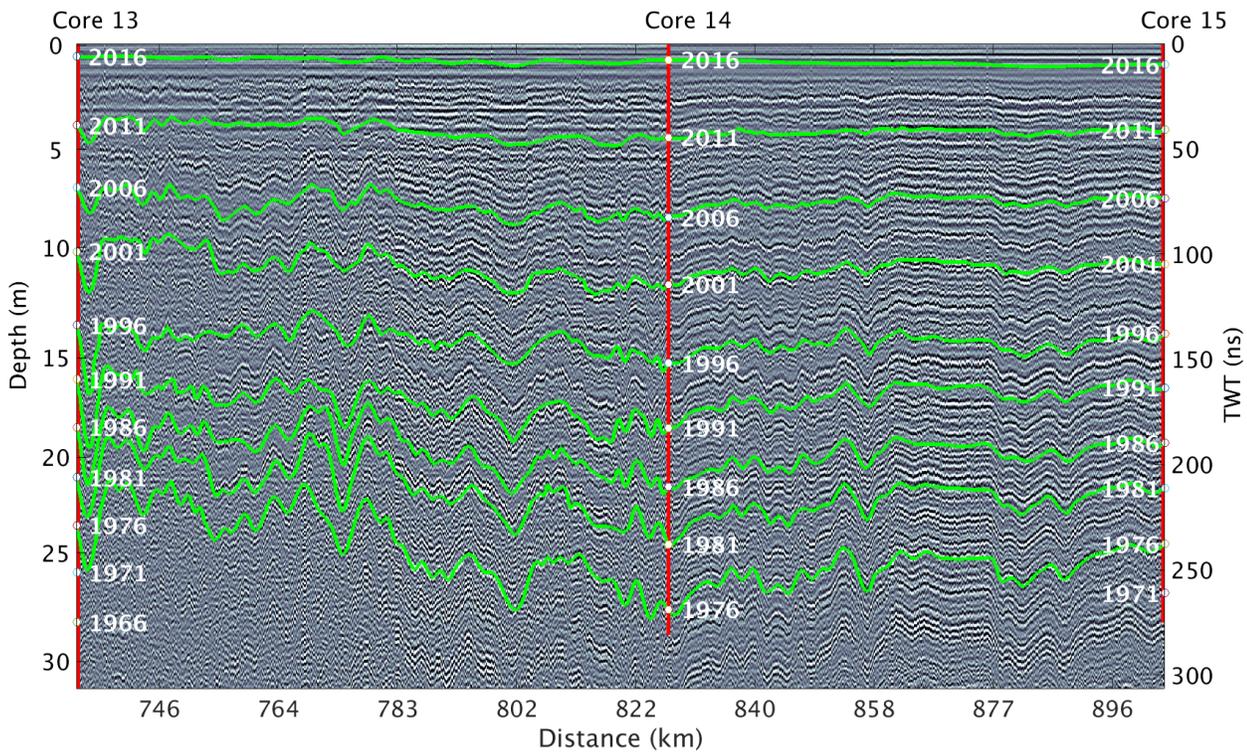

## 2.1. GPS Positioning

During the 2016 traverse we collected GPS data using a Trimble NetR8 reference receiver with a Zephyr Geodetic antenna mounted to a Nansen sled ~5 m in front of the GPR antenna. For each spur and the tail ends of each transect between core sites we performed differential corrections to the GPS data using RTKLIB 2.4.1 and a Trimble NetR8 base station near the core site. Between spurs, when not operating a base station, we post-processed GPS data in precise point positioning mode (Zumberge et al., 1997). Estimated root-mean-square horizontal errors were generally between 13 and 18 cm from standard deviations calculated during stationary periods at the end of spurs. To co-register GPR and GPS data, we used time stamps embedded in the two data streams and locations where we stopped to save GPR files, approximately every 15 km. The time drift in the GPR logger is negligible over these durations.

During the 2017 traverse we used GPS data from a Garmin 19x GPS receiver wired directly to the GPR instrument, which recorded position data at every radar sample with RMS values of 3 m. During radar processing we average 75 adjacent traces, corresponding to a distance of ~20 m, so errors in GPS positioning have a negligible effect on the final dataset.

## 2.2. Ground-penetrating radar

We develop a spatially continuous record of accumulation using GPR profiles collected with Geophysical Survey Systems Inc. (GSSI) SIR-3000 (during 2016) and SIR-30 (during 2017) radar units with a 400 MHz antenna (following Hawley et al., 2014). The antenna was towed on the snow surface in a small plastic sled ~5 m behind a wooden Nansen sled and ~15 m behind a snow machine. We recorded 2048 samples (2016) and 4096 samples (2017) per trace over a range window of 800 ns (Figure 2). The 400 MHz short-pulse radar has a range resolution (ability to resolve distinct features) of  $0.35 \pm 0.1$  m in firn, which is fine enough to resolve Internal Reflecting Horizons (IRHs) that have been shown to represent isochrones (Medley et al., 2013; Rodriguez-Morales et al., 2014; Spikes et al., 2004; Hawley et al., 2014). We recorded 10 traces per second, which at the snowmobile's average travel speed of approximately  $2.75 \text{ m s}^{-1}$  results in ~3.6 traces recorded per meter. Note that this spacing between traces varies with vehicle speed.

**Figure 2. Radargram showing the top 32 m of the transect along the main 2017 traverse from Core 13 to Core 15. Cores are indicated as red lines down to their final depth, with dates plotted every 5 years at corresponding depths. Traced internal reflecting horizons are shown as isochronous green lines. The depth scale on the vertical axis is calculated from the TWT-depth conversion (see Section 2.4) for Core 13, although there is no visual difference in depth scale across this radargram.**

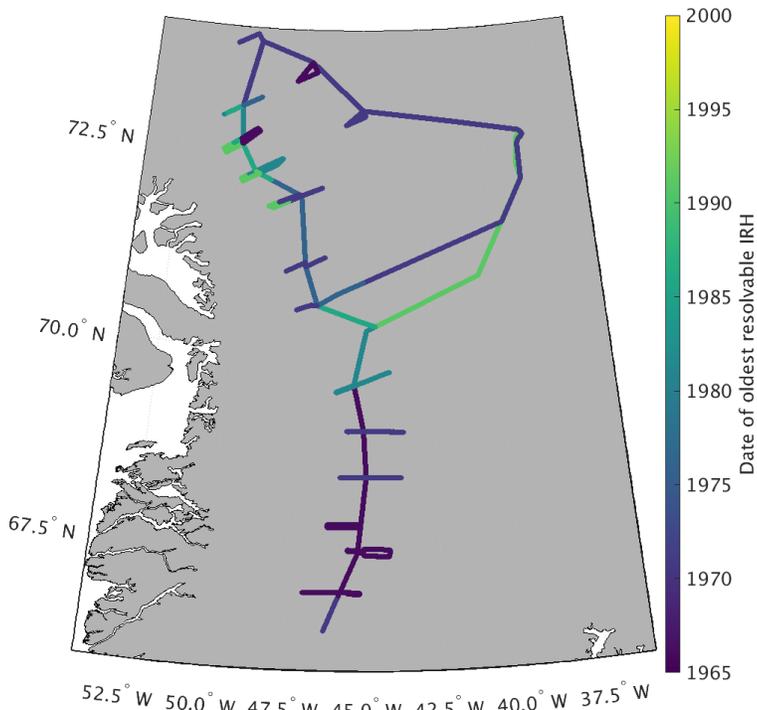

141 Depending on signal attenuation within the firn column, IRHs can be traced to a depth of 20 – 50 m (Figure  
142 2), providing accumulation records over the past 20 – 60 years (Figure 3). For areas with high attenuation  
143 (i.e. shallow penetration of the radar signal), such as lower elevation regions with more refrozen melt layers,  
144 we calculate accumulation results for shorter time periods. We are not able to trace as many IRHs to the west  
145 of Cores 10 – 13 compared to the east due to higher signal attenuation, resulting in slightly different (less  
146 than  $0.03 \text{ m w.e a}^{-1}$ ) average accumulation values on either side of these core locations (Figure 3). Likewise,  
147 we experienced an equipment malfunction at the end of the 2016 traverse, reducing the number of observable  
148 IRHs from Core 7 to Summit Station (Figure 3). We have less confidence in calculated accumulation  
149 throughout this section of the traverse due to this malfunction, although the 2017 Summit to Core 8 interval  
150 overlaps nicely with the last 140 km of the problematic 2016 interval, and provides high quality accumulation  
151 measurements for this section near Summit Station.

152

153 We reduce the GPR data volume and signal noise by averaging 75 adjacent traces, which has the effect of  
154 suppressing random noise by the principle of trace stacking (Yilmaz, 2001). We apply a combination of  
155 median trace filtering, residual mean filtering (Gerlitz et al., 1993), and bandpass filtering using a butterworth  
156 design (Selesnick and Sidney Burrus, 1998) between 200 – 800 MHz. For data visualization, we apply an  
157 automatic gain control (Yilmaz, 2001) to give the interpreter more confidence when picking IRHs.

176

The amount of snow mass and the time span between IRHs are necessary to calculate accumulation rates from the GPR profiles. The accumulation rate is a function of the depth-age scale, travel time-depth conversion rate, and the firn density profile. We obtain the depth-age and depth-density scales from each of the shallow firn cores collected along the GreenTrACS traverse, and from density models based on temperature and accumulation rate data.

The sixteen firn cores were drilled using an Ice Drilling Program hand auger with a Kyne sidewinder attachment (see Graeter et al., 2018). We sampled the firn cores for chemical measurements using a continuous ice core melter system with discrete sampling (Osterberg et al., 2006). We used an Abakus (Klotz) laser particle detector to measure microparticle concentrations and size distribution from the continuous ice core meltwater stream, a Dionex Model ICS5000 capillary ion chromatograph to measure major ion ( $\text{Na}^+$ ,  $\text{Mg}^{2+}$ ,  $\text{Ca}^{2+}$ ,  $\text{K}^+$ ,  $\text{NH}_4^+$ ,  $\text{Cl}^-$ ,  $\text{NO}_3^-$ ,  $\text{SO}_4^{2-}$ ) and methanesulfonic acid concentrations, and a Picarro L1102-I and

177 a Los Gatos Research Liquid Water Isotope Analyzer to measure oxygen and hydrogen isotope ratios ( $\delta^{18}\text{O}$ ,  
178  $\delta\text{D}$ ; Graeter et al., 2018).

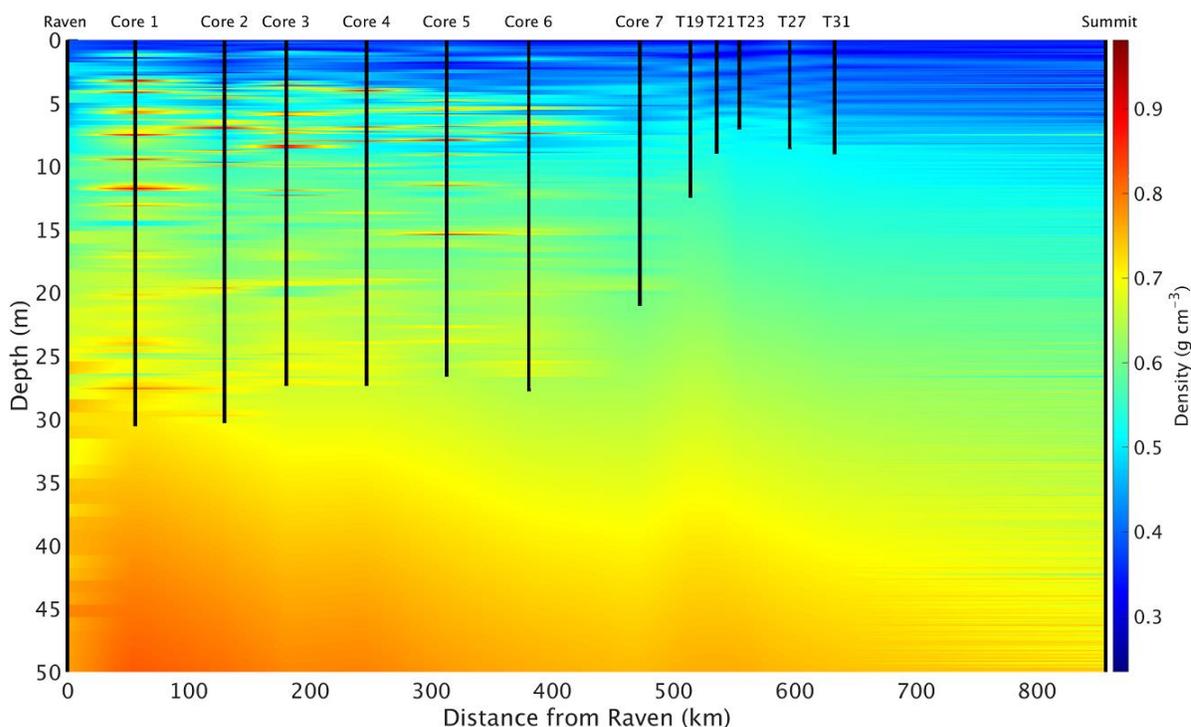

179  
202 We determine depth-age curves for each core by identifying annual layers based on seasonal oscillations in  
203  $\delta^{18}\text{O}$  and the concentrations of major ions and dust, consistent with previous ice core studies in this region  
204 (Graeter et al., 2018; Mosley-Thompson et al., 2001; Osterberg et al., 2015). While meltwater percolation  
205 smooths the signal of some of these tracers, we can still confidently determine the depth-age curve using  
206 nearly unperturbed oscillations in  $\delta^{18}\text{O}$  and dust. We combine the depth-age scales with measured density to  
207 calculate annual accumulation rates at the firn core sites.

208  
209 At each firn core and at the ends of each spur, we measured the density in the top meter of snow using a 1000  
210  $\text{cm}^3$  SnowMetrics cutter. To calculate density profiles from the firn cores, we measured the mass, length, and  
211 diameter of 0.03–1 m long core segments in the field and again after transporting the cores to the Dartmouth  
212 College Ice Core Laboratory. Additionally, we measured melt layer thickness in the laboratory following  
213 Graeter et al. (2018). To calculate accumulation rates at Raven/Dye-2, we use density data from a 119.6 m  
214 long firn core collected in 1997 (Bales et al., 2009) and a 19.3 m long core collected from the same location  
215 in 2015, which did not include accumulation data (Vandecrux et al., 2018). For this location we use the most  
216 recent density data for the near-surface and the older densities for depths below the 2015 core. Likewise, we  
217 use a density profile from a 109 m long firn core collected from Summit in 2010 (Mary Albert, personal  
218 communication, 2015). We also incorporate density data from measurements along the EGIG traverse at T19,  
219 T21, T23, T27, and T31 to improve the density profile between Core 7 and Summit (Morris and Wingham,  
220 2014).

221  
222 After collecting each firn core, we measured borehole temperature for 24 – 48 hours using a 20 m long  
223 thermistor string. We estimate mean annual temperature from the deepest thermistor on the twenty-  
224 thermistor-string. These measurements agree with MODIS satellite derived mean annual temperature (Hall  
225 et al., 2012) to within  $\pm 1$  °C for each firn core location. For the location of each firn core, we use the depth-  
226 density data from that core and calculate a Herron and Langway (1980) depth-density model for depths below  
227 the core using our measured mean annual temperature, firn core mean annual accumulation, and top-meter  
228 snow density. Likewise, we calculate Herron-Langway profiles for the ends of each spur using MODIS  
229 satellite derived mean annual temperature (Hall et al., 2012), MAR modeled accumulation (Burgess et al.,  
230 2010), and the measured snow density in the upper meter of each of the spur’s snow pits. Finally, we  
231 interpolate depth-density profiles both between firn cores and along radar spurs to estimate the depth-density

232 matrix everywhere along our traverse (Figure 4). Final calculated accumulation rates are insensitive to the  
233 input accumulation parameter we use to calculate our Herron-Langway models (Lewis et al., 2017).

234  
235 As shown in Figure 4, ice layers within several firn cores are extrapolated laterally along the traverse,  
236 although these dense lenses are typically both localized and heterogeneous at these elevations (Brown et al.,  
237 2011; Rennermalm et al., 2013). Numerous studies have documented the heterogeneity of firn throughout  
238 the percolation zone and the complications of calculating SMB due to ice pipes and lenses (Brown et al.,  
239 2011, 2012; De La Peña et al., 2015). Here we attempt to accurately calculate accumulation using interpolated  
240 firn cores and *in situ* GPR throughout this complicated region. Our ice lens density interpolation is as accurate  
241 as possible between firn cores without additional *in situ* data, and this estimation does not significantly alter  
242 our results, as discussed in Section 2.6, since the ice layers represent a small fraction of the total depth to  
243 IRHs.

244  
245 **Figure 4. Depth-density profile along the main 2016 traverse used for calculation of electromagnetic wave velocity and accumulation in**  
246 **this study. Densities are linearly interpolated between the two nearest cores and are modeled using Herron-Langway profiles below the**  
247 **depth of each core. The left and right boundary data come from the Raven/Dye-2 and Summit firn cores, respectively. Ice layers in Cores**  
248 **1 – 5 are clearly visible as red lenses, but their extent is, in reality, likely more localized.**

#### 249 250 **2.4. Travel-time to depth conversion**

251 We convert the radar travel time to depth by iteratively multiplying the velocity of the electromagnetic wave  
252 by the signal’s one-way travel time to each IRH. The electromagnetic speed of the radar wave,  $v$  ( $\text{m s}^{-1}$ ), is

253 calculated from the relative dielectric permittivity,  $\epsilon_r$  (dimensionless), and the speed of light in a vacuum,  $c$   
254 ( $3 \times 10^8 \text{ m s}^{-1}$ ), from  
255  $v = \frac{c}{\sqrt{\epsilon_r}}$  (1).

256 In turn, we calculate the relative dielectric permittivity from the density,  $\rho$  ( $\text{g cm}^{-3}$ ), of snow and ice at depth,  
257 as shown in Figure 4, for each radar trace at every range bin (following Kovacs et al., 1995) by  
258  $\epsilon_r = (1.0 + 0.845 * \rho)^2$  (2).

259 We calculate the depth of each subsequent radar sample for each trace in the profile using the radar travel  
260 time and velocity profile from equations 1 and 2, following Hawley et al. (2014) and Lewis et al. (2017).

261

## 262 **2.5. Internal reflecting horizons**

263 We manually select 10 clear, strong IRHs spaced approximately 5 years apart to consistently trace from  
264 Raven/Dye-2 to Summit Station and throughout the 2017 main traverse (Figure 2). We trace each layer  
265 manually by visually identifying strong amplitude peaks throughout the radargram, starting with the 2016  
266 layer and working downwards. We use a spline interpolation between manual picks to trace each layer along  
267 large amplitude reflections every  $\sim 500 - 700$  m along the traverse. When a layer appears to bifurcate due to  
268 changes in accumulation, we continue to trace the layer based on the trajectory of surrounding IRHs. Each  
269 horizon is traced throughout the traverse, except in areas where the attenuated signal makes it too difficult to  
270 interpret (Figure 3). We trace layers for each spur starting at the depth of each layer at the corresponding firn  
271 core location. We can trace layers below the depth of some firn cores by tracing them from cores that are  
272 deeper or have lower accumulation rates.

273

274 We trace layers between cores using a connect-the-dots approach using the depth-age scale at each firn core.  
275 We trace layers from one firn core to the next before checking that we intersect that core location at the  
276 proper depth for the age of our traced IRH. Note that the depths of several layers at Cores 2 – 16 are located  
277 below the bottom depth of those cores. Since these layers are isochronous, they are used to calculate  
278 accumulation over appropriate time epochs by using dates obtained from intersections with other cores (see  
279 Figure 3).

280

## 281 **2.6. Accumulation calculations and uncertainty**

282 Finally, we calculate snow accumulation using the firn core depth-age scales, measured and interpolated  
283 depth-density profiles (Figure 4), and traced IRHs (Figure 2). We calculate the water equivalent accumulation

284  $\dot{b}$  (m w.e. a<sup>-1</sup>) between adjacent IRHs from the depth  $z$  (m) and age  $t$  (year) of each layer, the average density  
285  $\rho$  (kg m<sup>-3</sup>) between layers, and the density of water  $\rho_w$  (1000 kg m<sup>-3</sup>):

$$286 \quad \dot{b} = \frac{1}{t_2 - t_1} \int_{z_1}^{z_2} \frac{\rho(z)}{\rho_w} dz \quad (3).$$

287  
288 We correct for layer thinning using a Nye (1963) model. The thinning factor has an average value of 0.9993  
289  $\pm$  0.0003 and is multiplied by the accumulation rate for each radar trace. For each radar trace, the thinning  
290 factor,  $\lambda(z)$ , is calculated from the average accumulation  $\dot{b}$  (m w.e. a<sup>-1</sup>) of each epoch, average age of the  
291 epoch  $a$  (year), and water equivalent thickness of the GrIS  $H$  (m), from Morlighem et al. (2014):

$$292 \quad \lambda(z) = e^{-\frac{\dot{b}}{H}a} \quad (4).$$

293  
294 Accumulation uncertainty can arise from independent errors in tracing IRHs, errors from incorrectly dating  
295 firm cores, and/or errors in the densities used for converting from separation distance to water equivalent  
296 accumulation. To reduce tracing errors, we retraced each IRH along the two main traverse paths four times  
297 apiece. Close inspection of the IRHs reveals that the peaks defining IRHs are within  $\pm 2$  radar samples (within  
298 at most  $\pm 0.12$  m), and incorrectly jumping to the next IRH would result in an error of at most  $\pm 10$  samples  
299 (within  $\pm 0.55$  m). We chose an epoch between IRHs of 5.0 years from the firm core chemistry depth-age  
300 scales, which corresponds to a maximum tracing error of  $\sim \pm 0.11$  m a<sup>-1</sup> for each epoch, or a maximum error  
301 of  $\pm 0.061$  m w.e a<sup>-1</sup> given an average firm density of 0.55 g cm<sup>3</sup> across this dataset.

302  
303 We perform a leave-one-out cross validation to calculate accumulation errors at locations where we do not  
304 have firm core density profiles. Here we choose one of the sixteen firm cores, in addition to the Raven/Dye-2  
305 and Summit cores, to omit from our density interpolation (Figure 4), so that we interpolate density profiles  
306 between adjacent firm cores and a Herron-Langway profile at the missing core location. We find maximum  
307 single-epoch errors of 0.079 m w.e. a<sup>-1</sup> and maximum RMS (1971 – 2016) errors of 0.046 m w.e. a<sup>-1</sup> (Table  
308 1) at the location of missing cores. These differences are approximately twice as large at Cores 1 – 6 than  
309 Cores 7 – 16 due to larger differences between measured and interpolated density profiles, likely a result of  
310 meltwater percolation and ice lenses (Graeter et al., 2018).

311  
312 Similarly, we perform a leave-out-out validation by omitting a firm core density profile location entirely and  
313 interpolating density profiles over a larger distance (e.g. between Core 1 and Core 3). In this case we find  
314 maximum single-epoch errors of 0.057 m w.e. a<sup>-1</sup> and maximum RMS (1971 – 2016) errors of 0.033 m w.e.  
315 a<sup>-1</sup>. Throughout this study, we use our measured density profiles to calculate accumulation at core locations,  
316 rather than rely on Herron-Langway density models that would result in larger uncertainties.

317

326  
327  
328  
329

We conservatively take our accumulation error from missing density measurements to be 0.079 m w.e. a<sup>-1</sup>. This error highlights the importance of our firn core spacing between 40 – 100 km along the traverse and confirms that the accuracy of future remotely sensed radar accumulation (e.g. IceBridge snow and accumulation radars) estimates depend on precise field-based *in situ* density profiles for accurate accumulation history in the percolation zone. Overly et al. (2016) calculated accumulation in the dry snow zone using Herron-Langway profiles within 3.5% of accumulation calculated using neutron-probe density profiles. However, here we show that *in situ* measurements, or accurate meltwater percolation modeling (Meyer and Hewitt, 2017), are required to correctly calculate SMB in the percolation zone.

**Table 1. Difference between accumulation rates at each GreenTrACS core site calculated using Herron-Langway profiles and firn core density information.**

Core	RMS average difference (m w.e. a <sup>-1</sup> )	Max epoch difference (m w.e. a <sup>-1</sup> )	Max Epoch difference (% of acc.)
1	0.046	0.079	20.1
2	0.025	0.061	16.2
3	0.037	0.074	19.9
4	0.028	0.045	10.7
5	0.026	0.054	11.5
6	0.038	0.052	10.0
7	0.015	0.026	5.4

330  
331  
332  
333  
334  
335

We assume uncertainty in dating the firn cores from annual variations in chemistry to be  $\pm 0.5$  years (Buchardt et al., 2012). At the lowest accumulation locations, the smallest distance between layers is 0.15 m w.e. over an epoch of 4.91 years. This gives an uncertainty in accumulation due to dating of at most  $\sim \pm 0.03$  m w.e. a<sup>-1</sup>. The error associated with measuring *in situ* firn density has been estimated to be 1.4% (Karlöf et al., 2005). However, following Hawley et al. (2014) and Lewis et al. (2017), we conservatively assume that our

336 measurements have a density measurement error of up to twice this large, corresponding to a maximum  
337 accumulation error of  $\pm 0.014$  m w.e.  $a^{-1}$ .

338

339 We calculate the total uncertainty from formal error propagation (following Bevington and Robinson, 1992)  
340 from the average accumulation rate  $\dot{b} = 0.385$  m w.e.  $a^{-1}$ , average thickness between IRHs  $\Delta h = 3.56$ ,  
341 uncertainty in tracing  $\delta h$ , average firm density  $\rho$ , uncertainty in density measurements  $\delta\rho$ , average time  
342 period between IRHs  $\Delta t$ , and uncertainty in core dating  $\delta t$ . We find the total accumulation rate uncertainty  
343 for each epoch to be  $0.0709$  m w.e.  $a^{-1}$  from equation 5.

$$344 \sigma_{epoch} = \sqrt{\dot{b}^2 \left( \left( \frac{\delta h}{\Delta h} \right)^2 + \left( \frac{\delta t}{\Delta t} \right)^2 + \left( \frac{\delta \rho}{\rho} \right)^2 \right)} \quad (5)$$

345

346 Due to the random and non-systematic nature of these errors, we can assume that they are unlikely to  
347 contribute to a regional or temporal accumulation bias. To calculate uncertainty for accumulation averaged  
348 over multiple epochs ( $\sigma_{n-epochs}$ ) we divide our uncertainty  $\sigma_{epoch}$  by the square root of the number of traced  
349 layers ( $n$ ) at that location.

$$350 \sigma_{n-epochs} = \frac{\sigma_{epoch}}{\sqrt{n}} \quad (6).$$

351

## 352 **2.7. Model comparison**

353 We compare our GreenTrACS accumulation results with annual outputs from Box et al. (2013; hereafter  
354 “Box13”; 1840 – 1999), the Fifth Generation Mesoscale Model (Polar MM5; 1958 – 2008; Burgess et al.,  
355 2010), MAR (1948 – 2015; Fettweis et al., 2016), and the Regional Atmospheric Climate Model (RACMO2;  
356 1958 – 2015; Noël et al., 2018) over common time periods. Grid cell sizes for these model outputs are 5 km,  
357 3 km, 5 km, and 1 km, respectively. For each radar trace we calculate statistically significant differences (at  
358  $\alpha = 0.05$ ) using a two sample t-test with the GreenTrACS accumulation records for each epoch and RCM  
359 accumulation for each common year. Additionally, we compare our GreenTrACS accumulation with an  
360 accumulation map kriged from 295 firm cores and 20 coastal weather stations (Bales et al., 2009; hereafter  
361 “Bales09”). We perform the same two sample t-test with the reported Bales09 uncertainty of  $0.092$  m w.e.  $a^{-1}$   
362 (Bales et al., 2009).

363

## 364 **2.8. Accumulation trends**

365 To investigate recent changes in GrIS accumulation, we calculate trends in accumulation across our GPR and  
366 GreenTrACS firm core dataset. We fit a linear model to the accumulation time series for each radar trace and

367 analyze the trend for both slope and statistical significance. Likewise, we calculate trends and their statistical  
368 significance for total precipitation (snowfall + rainfall) for MAR and RACMO2 grid cells from 1996 through  
369 the end of both models' temporal coverage. We can compare these results with our accumulation trends since  
370 precipitation and accumulation are nearly identical above the equilibrium line altitude, due to zero runoff and  
371 negligible sublimation within the percolation zone.

## 372 **2.9. Storm track changes**

373 To investigate the potential role of changing storm tracks in precipitation changes over the Western GrIS, we  
374 utilize the updated Serreze (2009) storm track database. This database contains six-hour interval positions of  
375 extratropical cyclone storm centers on a  $2.5^\circ$  grid. These centers are defined when a gridpoint sea level  
376 pressure is surrounded by gridpoints at least 2 mb higher than the central point (Serreze, 2009). We calculate  
377 the total number of days in which a storm center is located within our region of interest for each season. To  
378 determine statistical significance, we run a two sample t-test on the number of storms in our region of interest  
379 between 1958 – 1996 compared with 1996 – 2016.

## 380 **3. Results and discussion**

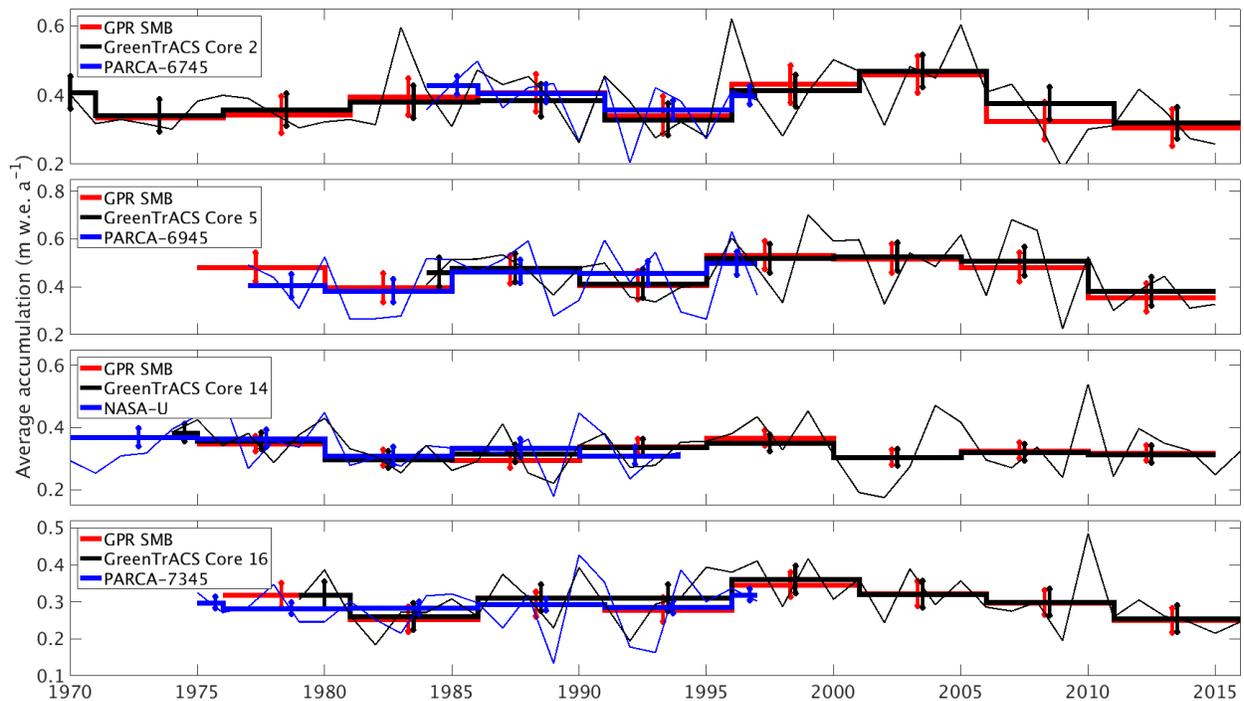

### 381 **3.1. Firn core and GPR accumulation records**

382 Figure 1 displays the mean accumulation at each location along the traverse route, with higher accumulation  
383 rates in the southwest and lower accumulation rates at higher elevations of the ice sheet interior, broadly  
384 consistent with previously published accumulation compilations (e.g. Bales et al., 2009) and RCM output  
385 (Box et al., 2013; Burgess et al., 2010; Fettweis et al., 2016; Noël et al., 2018). We analyze localized  
386 differences between GPR derived accumulation and these RCMs in Section 3.3. There is an especially high  
387 accumulation zone near Core 11 ( $0.685 \text{ m w.e. a}^{-1}$ ), nearly double the accumulation at Core 10 ( $0.453 \text{ m w.e.}$   
388  $\text{a}^{-1}$ ) and Core 12 ( $0.327 \text{ m w.e. a}^{-1}$ ), respectively situated only 43 km northwest and 73 km southwest of Core  
389 11. In the GPR data, the number of traceable IRHs is highest towards the interior of the ice sheet and lowest  
390 in warmer areas towards the coast and in the south, where refrozen percolated melt water from enhanced  
391 surface melt attenuates the radar signal and reduces the number of observable IRHs (Brown et al., 2011;  
392 Figure 3).

### 393 **3.2. Validation with past measurements**

394 We validate our accumulation record with published core records from the PARCA campaign and  
395 accumulation data from the NASA IceBridge program. The locations of GreenTrACS Core sites 2, 5, 9, 10,  
396 11, 14, 15, and 16 were chosen to reoccupy PARCA core locations 6745, 6945, 7147, 7247, 7249, NASA-

397 U, 7347, and 7345, respectively. These GreenTrACS cores overlap with the accumulation history of each  
 398 PARCA core and extend the record from 1997/1998 to 2016/2017. Accumulation rates derived from  
 399 GreenTrACS firm cores are within error of those determined from corresponding PARCA cores during the  
 400 period of overlap. Figure 5 compares the accumulation records from PARCA sites 6745, 6945, 7345, and  
 401 NASA-U to their corresponding GreenTrACS cores, demonstrating that each pair of cores has similar long-  
 402 term mean accumulation and nearly identical decadal variability. Thus, we have confidence in firm core  
 403 derived accumulation rates that are used in subsequent GPR calculations of accumulation rates throughout  
 404 the GreenTrACS traverse.  
 405

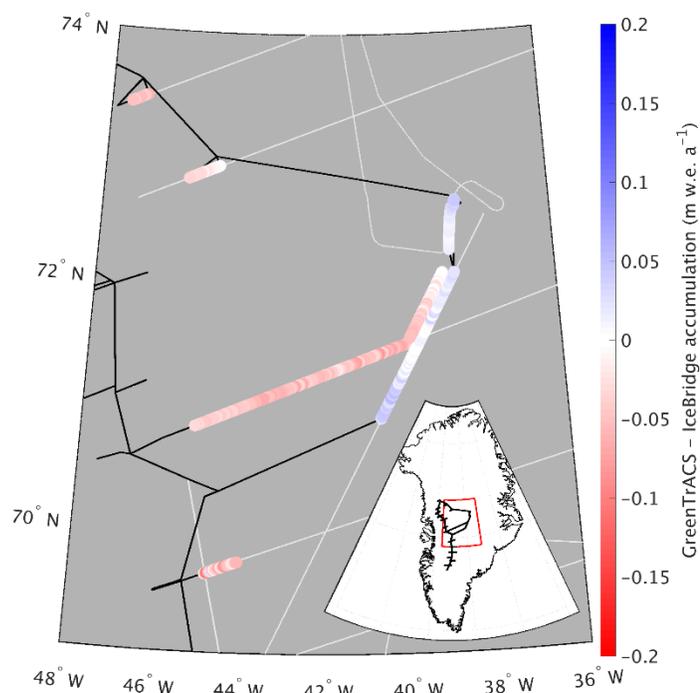

406  
 407 **Figure 5. Accumulation from GPR and collected firm cores (this study) compared with cores from the PARCA Campaign. Thin lines**  
 408 **represent annual PARCA (blue) and GreenTrACS (black) firm core accumulation, while thick lines are 5-year averages over**  
 409 **corresponding GPR epochs. Error bars represent one standard deviation over each epoch. GPR and PARCA accumulation averages**  
 410 **and decadal trends are statistically indistinguishable.**

411  
 412 Average (1966 – 2016) GPR accumulation is statistically indistinguishable with average (1962 – 2014)  
 413 IceBridge Accumulation Radar measurements analyzed by Lewis et al. (2017), with an RMS difference of  
 414  $0.0387 \pm 0.0327$  m w.e.  $a^{-1}$  along a total of 562.5 km of overlap (Figure 6). The disagreement is largest at  
 415 lower elevations, where Herron-Langway profiles used in Lewis et al. (2017) differ the most from  
 416 GreenTrACS firm core density profiles in the upper 30 m of firm, demonstrating the importance of field  
 417 observations for calibration and validation. The close agreement at higher elevations is illustrated in Figure  
 418 7a, where our GreenTrACS accumulation measurements are statistically indistinguishable from the IceBridge

419 radar-derived accumulation (Lewis et al., 2017) along the 285 km A – A' transect on Figure 1. Notice that  
420 the uncertainty in GreenTrACS accumulation progressively decreases higher in the percolation zone and into  
421 the dry snow zone (towards the right in Figure 7) along this transect as density becomes less heterogeneous  
422 from fewer melt layers (Graeter et al., 2018) and IRHs become easier to trace.

423  
424 Similarly, our 2011-2016 accumulation is statistically indistinguishable from average 2009 – 2012 IceBridge  
425 snow radar measurements analyzed by Koenig et al. (2016), with an RMS difference of  $0.0489 \pm 0.0961$  m  
426 w.e.  $a^{-1}$  along a total of 69.7 km of overlap (not shown). Koenig et al. (2016) use a different radar system on  
427 an airborne platform and are able to calculate annual accumulation at elevations below 2000 m a.s.l., however  
428 the GreenTrACS accumulation record covers a longer temporal duration than the data from that study.

429  
430

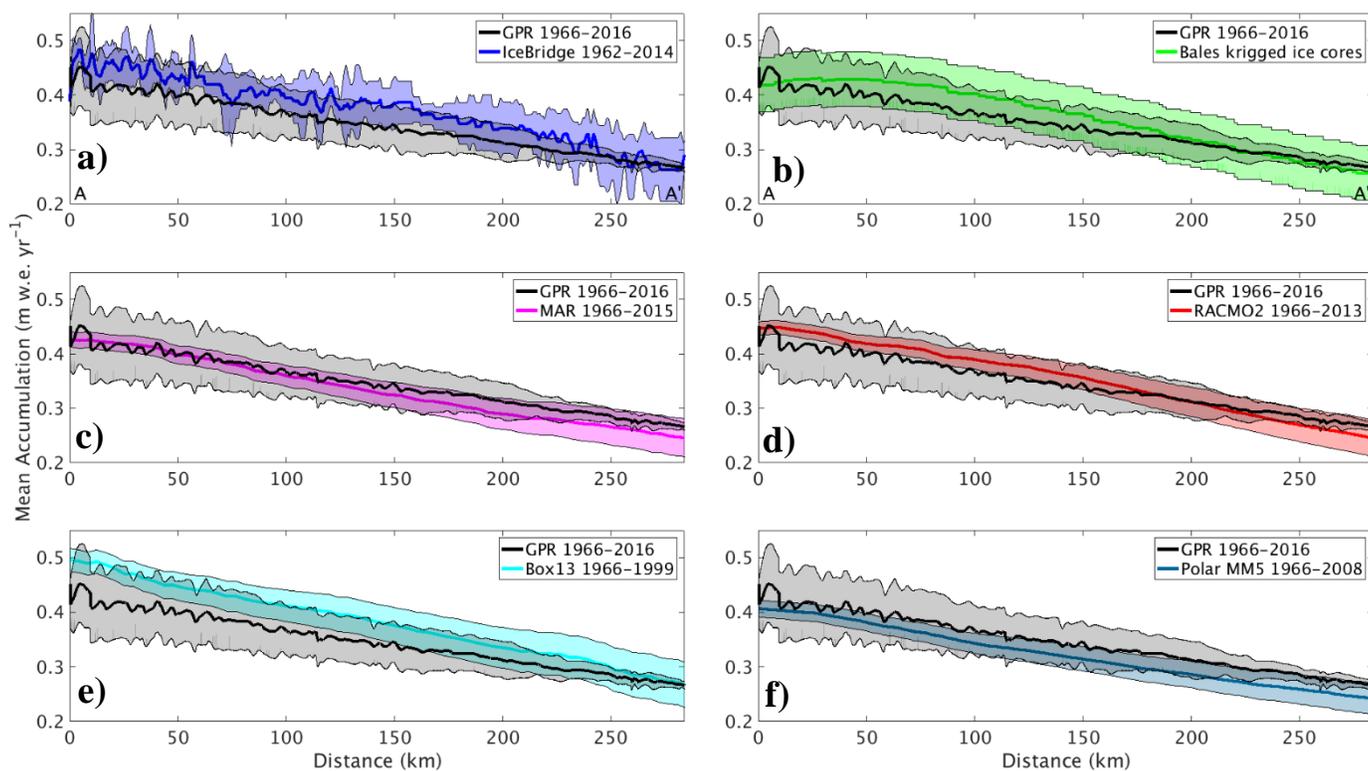

431  
432 **Figure 6. Difference between averaged (1966 – 2016) GreenTrACS accumulation and average (1962 – 2014) IceBridge Accumulation**  
433 **Radar rates from Lewis et al. (2017) across all 562.5 km of overlap. Spatially overlapping section of 2016 and 2017 traverses displayed**  
434 **as adjacent tracks. Also showing extent of GreenTrACS traverse (black) and IceBridge accumulation radar (grey). Inset shows map**  
435 **location with respect to GreenTrACS traverse (black).**

436

### 437 3.3. Comparison to modelled accumulation

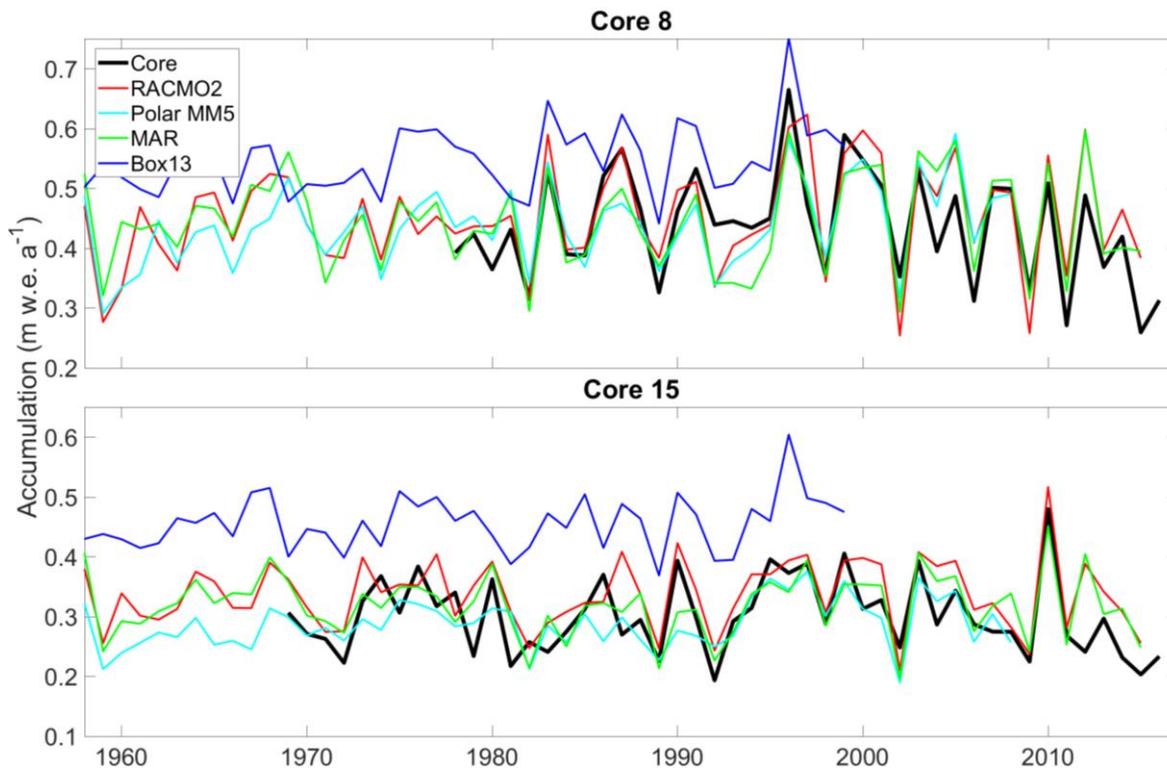

438 We assess differences between RCM accumulation output and GreenTrACS accumulation record at each firn  
439 core site, two of which are shown in Figure 8. In general, year-to-year correlations between GreenTrACS  
440 firn core accumulation records and RCM output for the corresponding grid cell are strong, positive, and

441 statistically significant (Table 2). On average, GreenTrACS firn cores' correlation coefficient with MAR  
 442 output is 0.718, with PolarMM5 is 0.701, with Box13 is 0.607, and with RACMO2 is 0.763. Every correlation  
 443 is statistically significant at  $p < 0.05$  except for Cores 7 and 11 with Box13. We do not report a correlation  
 444 coefficient for Core 11 and Box13 because they only share two common years. Temporal correlation  
 445 coefficients remain high even at locations with large magnitude differences between RCM output and firn  
 446 core accumulation. For example, the Box13 model overestimates accumulation at Core 15 by  $0.15 \pm 0.05$  m  
 447 w.e.  $a^{-1}$ , on average, but the model output has a correlation coefficient of 0.48 with Core 15 (Table 2) and  
 448 matches years of high accumulation (e.g. 1987, 1990, and 1996) and low accumulation (e.g. 1981, 1989,  
 449 1992).

450  
 451 **Figure 7. Average GreenTrACS GPR accumulation (black) compared with a) IceBridge accumulation radar, b) Bales09 krigged ice core**  
 452 **map, c) MAR, d) RACMO2, e) Box13, and f) Polar MM5. GPR measurements are statistically indistinguishable from each of the other**  
 453 **measurements along this 285 km transect in the dry snow zone (A – A' on Figure 1).**

454

455

456 **Figure 8.** Accumulation record at GreenTrACS Core 8 and Core 15 (black) compared with RCM output from RACMO2 (red), Polar  
 457 MM5 (cyan), MAR (green), and Box13 (blue). We find statistically significant Pearson correlation coefficients between GreenTrACS  
 458 and RCM accumulation rates for these cores (see Table 2).

459

460 **Table 2.** Pearson correlation coefficients between accumulation rate time series from firn cores and co-located RCM output over their  
 461 common time period<sup>#</sup>.

	Available data period	MAR	PolarMM5	Box13	RACMO2

462 <sup>#</sup>Statistically significant correlations ( $p < 0.05$ ) are bold

463

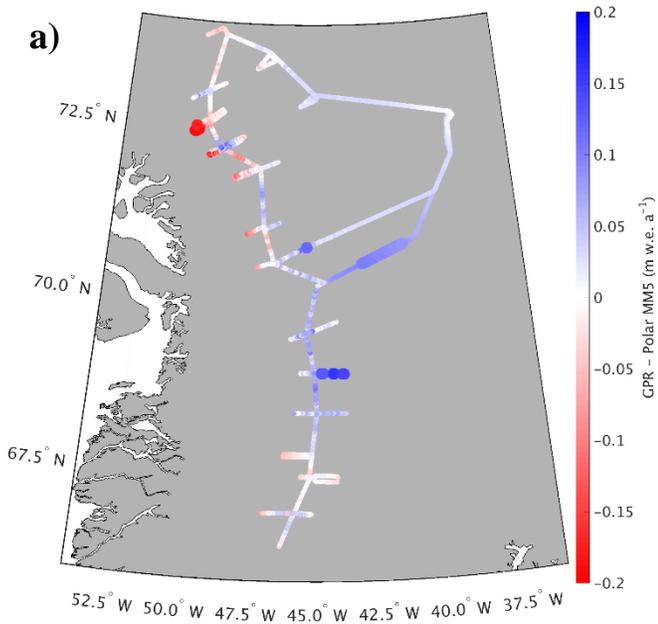

464 We also assess spatial differences between GreenTrACS accumulation and mean RCM accumulation  
 465 averaged over several decades (Table 2). Figure 9 shows that differences between GreenTrACS accumulation

466 and RCM output increase in magnitude, become more spatially heterogeneous, and vary by model at lower  
467 elevations of the ice sheet where topographic variations are larger and surface melt increases. Averaged over  
468 all 4436 km of the traverse, the RMS difference ( $\pm 1\sigma$ ) between each model and GreenTrACS accumulation  
469 over corresponding data periods (Table 2) is  $0.068 \pm 0.065$  (MAR),  $0.0562 \pm 0.0548$  (RACMO2),  $0.0822 \pm$   
470  $0.0702$  (Box13),  $0.048 \pm 0.045$  (Polar MM5), and  $0.0475 \pm 0.0445$  m w.e.  $a^{-1}$  (Bales09). We find that RCM  
471 differences from GreenTrACS accumulation are small in the dry snow zone (Figure 9). For example, Figure  
472 7 shows that average GreenTrACS accumulation measurements from 1966 – 2016 along the A – A' transect  
473 in Figure 1 are statistically indistinguishable from those derived from the Bales09 krigged ice core map  
474 (Figure 7b), MAR (1966 – 2015; Figure 7c), RACMO2 (1966 – 2013; Figure 7d), Box13 (1966 – 1999;  
475 Figure 7e), and Polar MM5 (1966 – 2008; Figure 7f).

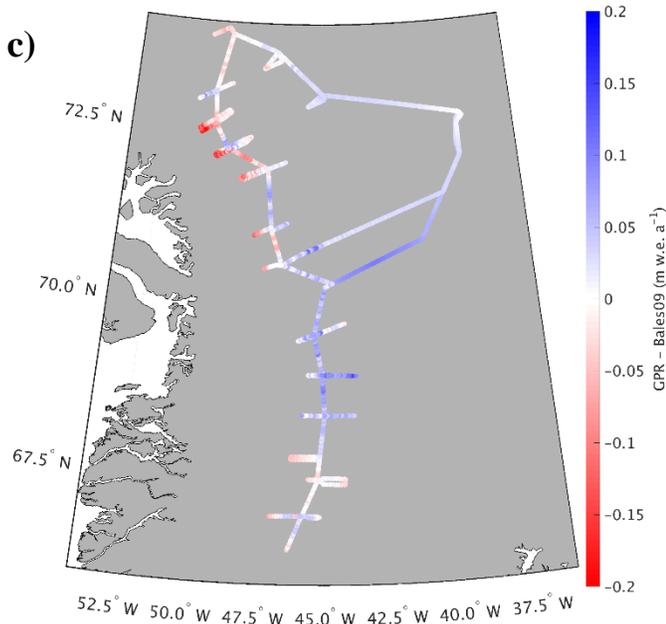

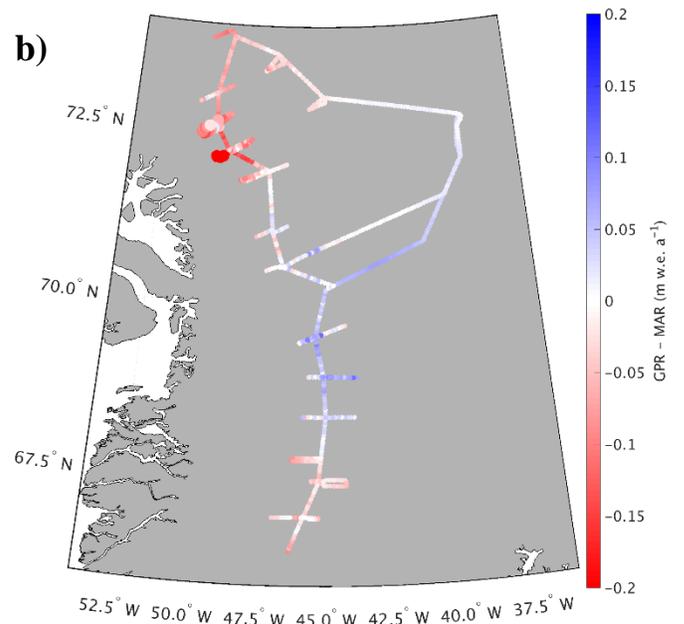

476  
477 However, the high spatial resolution of our dataset shows significant accumulation variability not captured  
478 in model output (Figure 9). For example, Polar MM5 and MAR both underestimate accumulation between  
479 Core 4 and Summit, while overestimating accumulation to the west of Cores 10 – 12. Likewise, RACMO2  
480 overestimates accumulation between Raven/Dye-2 and Core 5 by 0.03 to 0.08 m w.e.  $a^{-1}$  and shows  
481 statistically significant differences east of Cores 11 and 12. Bales09 accurately calculates accumulation along  
482 most of the 2016 traverse, but overestimates accumulation west of Cores 11 and 12 by  $0.135 \pm 0.041$  m w.e.  
483  $a^{-1}$ . Finally, Box13 overestimates accumulation along many of the western spurs and has statistically  
484 significant overestimations of 0.1 to 0.4 m w.e.  $a^{-1}$  between Cores 10 and 16. Box13 overestimates 67.8% of  
485 the data in the Core 10 – 16 region by at least 0.1 m w.e.  $a^{-1}$ , and 6.6% of that data by at least 0.2 m w.e.  $a^{-1}$ .

486  
487 Our study is almost entirely contained within drainage basin E from Vernon et al. (2013), who note that basin  
488 E is the only major Greenland drainage basin with no statistically significant differences in SMB between  
489 the four RCMs. However, differences of 0.1 to 0.4 m w.e.  $a^{-1}$  exist when we look at a local (sub-drainage-  
490 basin) scale for each model. All four of the RCMs overestimate accumulation along the western spur of Core  
491 11 and they all underestimate accumulation along the eastern spur of Core 5 (Figure 9).

492

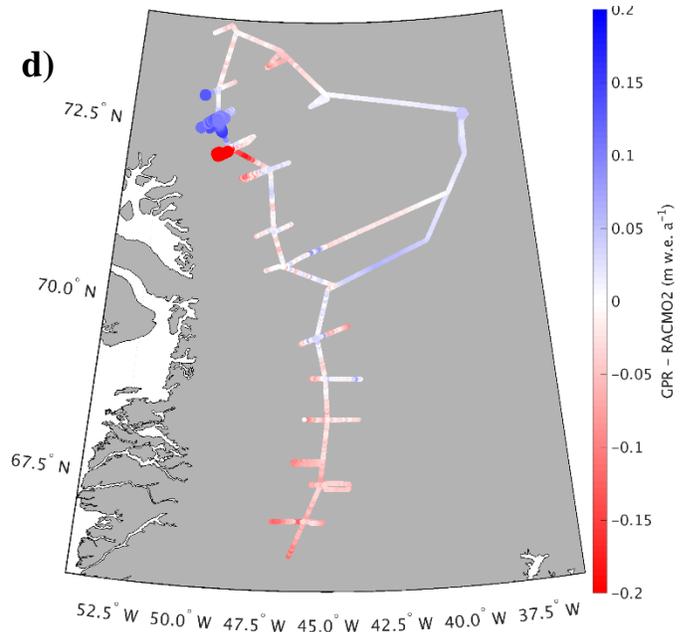

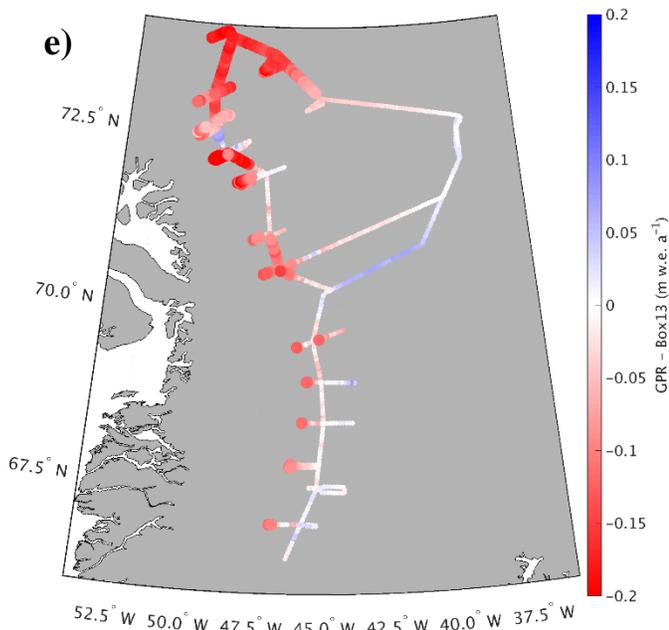

493

494

495

496  
 497 **Figure 9. Differences between GreenTrACS accumulation and a) Polar MM5, b) MAR, c) Bales09, d) RACMO2, and e) Box13**  
 498 **accumulation averaged over the corresponding time periods. Large dots show statistically significant differences from GreenTrACS**  
 499 **accumulation.**

500  
 501 In summary, the RCMs do an excellent job of calculating accumulation averaged over this drainage basin,  
 502 with RMS values between 0.048 and 0.0822 m w.e. a<sup>-1</sup>, but there are larger differences of 0.1 to 0.4 m w.e.  
 503 a<sup>-1</sup> between model and GPR accumulation on local scales. Differences between GreenTrACS and RCM  
 504 accumulation are largest in areas concurrent with the fewest, shortest, and/or most outdated *in situ*  
 505 measurements. For example, the GPR vs. model differences near Cores 11, 12, and 13 are relatively large for  
 506 all RCMs, despite Core 11 being co-located with PARCA 7249. However, the PARCA cores were collected  
 507 over 20 years ago, and Core 11 only spanned 7 years because of the high accumulation rate at that site. This  
 508 highlights the importance of collecting updated field-based measurements to calibrate remotely sensed data  
 509 and RCM output.

### 511 3.4. Accumulation temporal trends

512 In most locations, there are no statistically significant trends in the GreenTrACS accumulation record from  
 513 1966 through the mid-1990s. However, a changepoint analysis (Lavielle, 2005) reveals that accumulation in  
 514 the Western GrIS percolation zone changed significantly after the 1995 – 1996 accumulation year. Since  
 515 1996, our record indicates a statistically significant average accumulation decrease of  $0.009 \pm 0.005$  m w.e  
 516 a<sup>-2</sup>, or  $2.4 \pm 1.5$  % a<sup>-1</sup>, from 1996 to 2017. Although we observe fewer statistically significant accumulation  
 517 trends when we expand this analysis to include the entire temporal duration for each firn core, the sign of the  
 518 trend at each core site does not change.

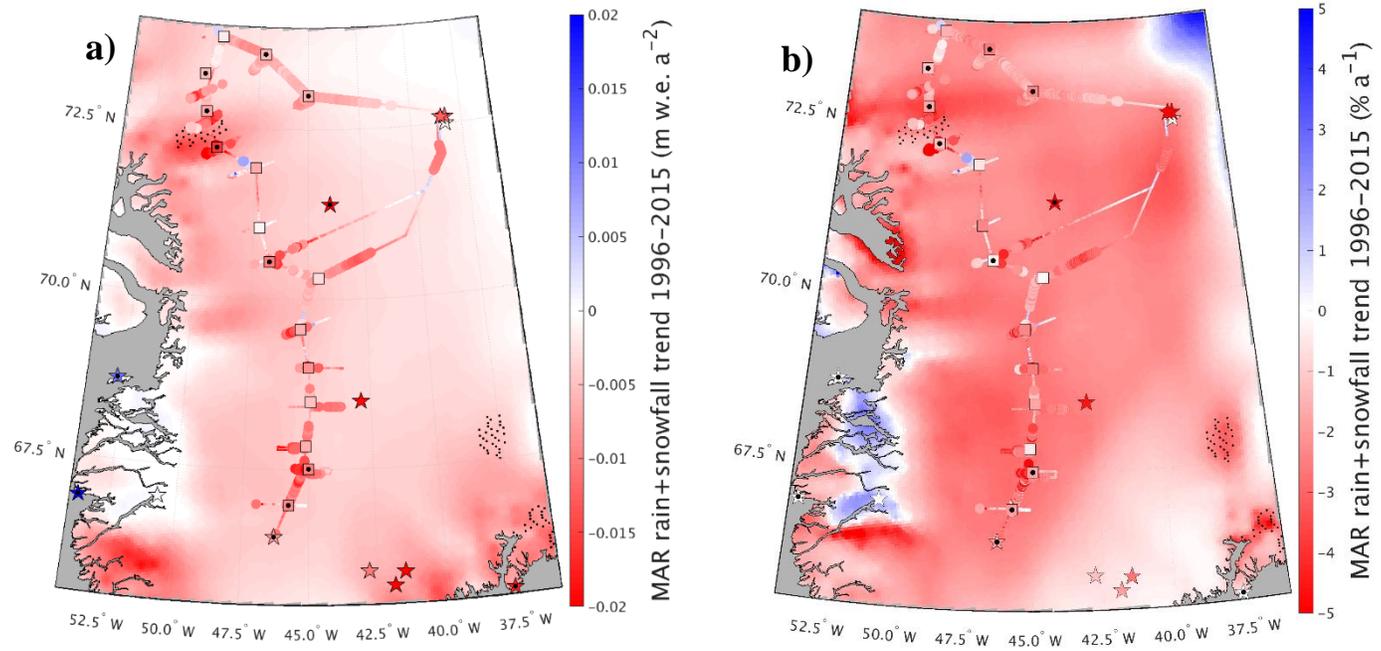

519

520 In Figure 10, we compare the negative accumulation trend in the GreenTrACS record (1996 – 2016) to best-  
521 fit linear trends in total precipitation (rain + snowfall) across the ice sheet in MAR and RACMO2 simulations  
522 over the 1996 – 2015 and 1996 – 2013 periods, respectively. Also shown in Figure 10 are 1996 – 2016  
523 accumulation trends for all 16 GreenTrACS firn cores (squares), accumulation trends from ACT10A (1996  
524 – 2010), ACT10B (1996 – 2010), ACT10C (1996 – 2010), D4 (1991 – 2002), D5 (1991 – 2002), Katie (1991  
525 – 2002), Sandy (1991 – 2002), and Summit 2010 (1991 – 2010) ice/firn cores (stars on ice sheet), and  
526 precipitation trends from coastal weather stations (Mernild et al., 2014; stars on coast). Statistically  
527 significant trends ( $p < 0.05$ ) in core data are indicated by black dots, while statistically significant trends in  
528 the MAR and RACMO2 output are stippled in black.

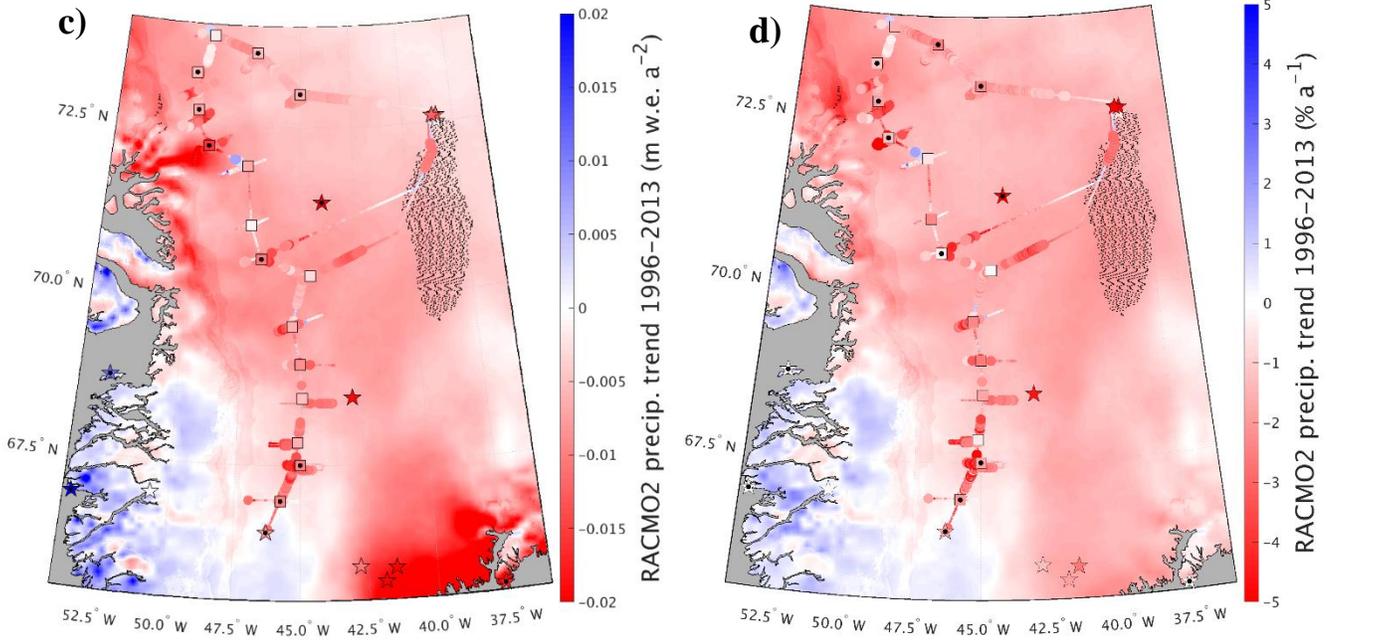

529

530 We find strong agreement between the accumulation decrease in the GreenTrACS record and widespread  
531 precipitation decreases in the RCMs over the study area (Figure 10). On average, the RCMs have a more  
532 negative precipitation trend than the GreenTrACS record by  $0.003 \pm 0.005$  for MAR and  $0.0016 \pm 0.0051$  m  
533 w.e.  $a^{-2}$  for RACMO2. Vernon et al. (2013) show a melt-driven decrease in SMB across this drainage basin  
534 of 31.1% (ECMWFd), 61.6% (RACMO2), 76.5% (MAR), and 33.5% (Polar MM5) for the 1996 – 2008  
535 period. The negative precipitation trends of  $2.4 \pm 1.5 \%$   $a^{-1}$  (Figure 10d) indicate a total of 2539.4 fewer Gt  
536 of precipitation and a total of 5159.1 additional Gt of melt (not shown) over 1996 – 2013 across the GrIS.  
537 Thus, our analysis suggests that a significant decline in snow accumulation contributes to declining SMB  
538 throughout the Western GrIS over recent decades, in addition to increasing surface melt from rising  
539 temperatures (van den Broeke et al., 2009, 2016).

540

541

542 **Figure 10.** Best fit linear trends for each grid cell showing magnitude (left) and percent (right) changes in total precipitation for a) and  
 543 b) MAR (1996 – 2015) and c) and d) RACMO2 (1996 – 2013). Statistically significant RCM grid cell trends are stippled black. Also  
 544 shown are accumulation trends for GreenTrACS firn cores (squares), ACT10A, ACT10B, ACT10C, D4, D5, Katie, Sandy, Summit 2010,  
 545 and Raven/Dye-2 cores (stars on ice sheet) and precipitation trends from Mernild et al (2014; stars on coast) with statistically significant  
 546 trends indicated by black dots.

547

548 **3.5. Effects of melt on accumulation trends**

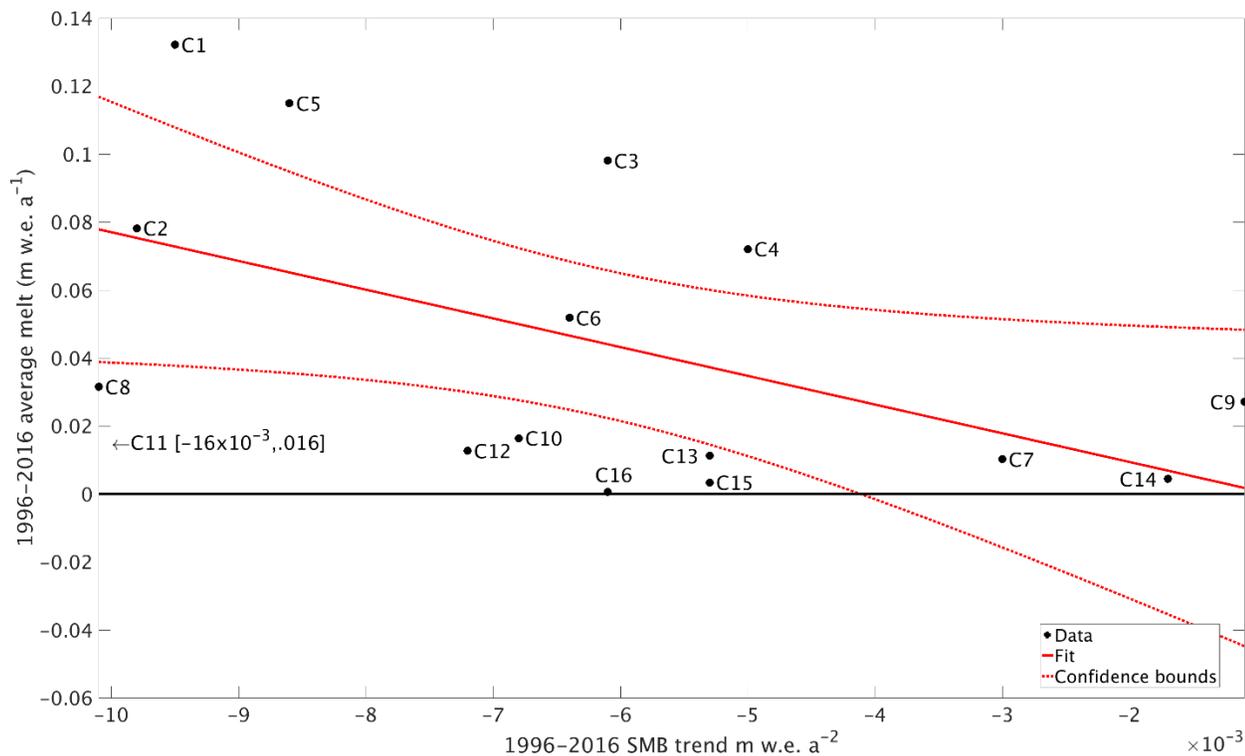

549 Increased melt throughout the 1996 – 2016 period is a confounding variable when analyzing trends in  
 550 accumulation. With increased melt over the past several decades in this region, meltwater percolates down  
 551 through several years of firm (Benson, 1962; Graeter et al., 2018; Harper et al., 2012; Wong et al., 2013).

552 This movement of mass into lower years can artificially increase the mass balance at depth and lower the  
553 mass balance during the most recent years, which have not experienced as much meltwater percolation from  
554 more recent annual layers. Therefore, it is necessary to evaluate the degree to which the recent accumulation  
555 decrease in the GreenTrACS record is biased by the recent increase in surface melt and percolation.

556  
557 Figure 11 compares the 1996 – 2016 mass balance trends with 1996 – 2016 average melt for each of the  
558 sixteen GreenTrACS firn cores. If we exclude Core 11 (which only dates back to 1997 and has a highly  
559 negative SMB trend), the linear regression is statistically significant with  $p = 0.04$  (Figure 11). Note that both  
560 the measured Core 11 SMB trend and RCM trends at that location are so negative, with that small amount of  
561 average melt, that the linear trend is no longer significant if that point is included in the calculations. On  
562 average, we find larger negative accumulation trends ( $-7 \times 10^{-3}$  to  $-10 \times 10^{-3}$  m w.e.  $a^{-2}$ ) at the lower latitude  
563 cores that experience more melt, supporting the hypothesis that meltwater percolation and refreezing are  
564 enhancing the negative accumulation trend.

565  
566 However, several other lines of evidence support a negative accumulation trend in the study area since 1996.  
567 First, we find statistically significant negative accumulation trends at Cores 10, 11, 12, 13, 15, and 16, each  
568 of which experience  $< 1.6$  cm  $a^{-1}$  of meltwater percolation on average (Figure 11). Additionally, we have  
569 confidence that GreenTrACS accumulation trends reported here are not artifacts of meltwater percolation  
570 because both MAR and RACMO2 have similar trends in precipitation (Figure 10). Finally, we evaluate the  
571 maximum effect meltwater percolation could have on GreenTrACS accumulation trends over 1996 – 2016.  
572 The largest measured melt layer from our sixteen ice cores occurred during 2003 – 2004 in Core 1 and  
573 contains 0.364 m of ice, equivalent to 0.333 m w.e. (Graeter et al., 2018). We add this percolation to nine  
574 years' of accumulation using a sine wave (percolation magnitude 0, 0.5, 1, 0.5, 0, -0.5, -1, -0.5, 0), square  
575 wave (0, 0, 0, 1, 1, 1, 0, 0, 0), and triangle wave (0, 0.25, 0.5, 0.75, 1, 0.75, 0.5, 0.25, 0) weighted kernel,  
576 before re-computing hypothetical accumulation trends over the same time period with additional meltwater  
577 percolation. Regardless of the wave-type choice, re-calculated trends remain within a factor of two of the  
578 original SMB trends and do not change sign with additional percolation.

579

580

581

582

**Figure 11. Relationship between 1996 – 2016 SMB trend and 1996 – 2016 melt for each of the 16 GreenTrACS firn cores (black circles). Red line shows linear best fit, dotted line shows 95% confidence boundary.**

583

### 3.6. Atmospheric circulation drivers of the recent accumulation decline

584

585

586

587

588

589

590

591

592

593

Our analysis indicates that snow accumulation has been declining in Western Greenland since 1996, despite significant warming and resulting increases in saturation vapor pressure from the Clausius-Clapeyron relationship. Instead, precipitation decreases over Western Greenland likely result from changes in atmospheric and/or oceanic circulation. Mernild et al. (2014) and Auger et al. (2017) found that the positive phase of the Atlantic Multidecadal Oscillation (AMO) is associated with a precipitation increase over interior and Southwestern Greenland based on ice core records and the Japanese Meteorological Agency 55 Year Reanalysis (JRA-55; Kobayashi et al., 2015), respectively. In direct contrast with these findings, the decline in Western Greenland accumulation documented in the GreenTrACS record began in the mid-1990s, contemporaneous with a switch to the AMO positive phase.

594

595

596

597

598

599

We hypothesize that the differences between our results and those of Auger et al. (2017) and Mernild et al. (2014) stem from different causes. Auger et al. (2017) validated the reanalysis data by demonstrating that JRA-55 precipitation at Nuuk, Greenland is significantly correlated with Nuuk station data from 1958 – 2013. Furthermore, coastal precipitation in Western Greenland is strongly and significantly ( $p < 0.05$ ) correlated with precipitation over the interior Western GrIS in the JRA-55 dataset (not shown). However, Mernild et al. (2014) found that coastal Greenland precipitation is anti-correlated with ice core accumulation records from

600 the interior GrIS from 1900 to 2000. This suggests that JRA-55 precipitation data, which is not constrained  
601 by ice core accumulation records, should be interpreted with caution over the interior GrIS. Mernild et al.  
602 (2014) concluded that positive AMO conditions favor higher precipitation over the interior GrIS based on  
603 the previous positive AMO phase (1920s to mid-1960s), contrasting with lower accumulation during the  
604 negative AMO phases (mid-1960s to mid-1990s and prior to the 1920s). However, Mernild et al. (2014) state  
605 that the ice core composite record in their analysis may be biased from 1995 – 2000, and they do not analyze  
606 precipitation trends after 2000. Thus, the decline in Western GrIS accumulation documented in the  
607 GreenTrACS cores during the latest positive AMO phase from 1996 to 2017 was not captured in the Mernild  
608 et al. (2014) analysis. Our results suggest that factors other than the AMO are behind the decline in Western  
609 GrIS accumulation since 1996.

610  
611 We find that the decrease in accumulation over the Western GrIS is associated with a significant decrease in  
612 the number of storm-days since 1996. The GreenTrACS region experienced an average of  $115.8 \pm 15.3$  storm-  
613 days per year over 1958 – 1996 and  $96.2 \pm 27.3$  storm-days per year over 1996 – 2016. A two sample t-test  
614 indicates that this 17% decline in storm-days is statistically significant ( $p < 0.001$ ). The largest decrease in  
615 storm-days (25%) over the GreenTrACS region occurred during summer, with  $56.4 \pm 6.1$  storm-days per  
616 summer from 1958 – 1996 and  $42.3 \pm 17.4$  storm-days per summer from 1996 – 2016 ( $p < 0.0001$ ; Figure  
617 12b). We also find an increase in the number of storm-days in the Northwestern GrIS near Thule (not shown).

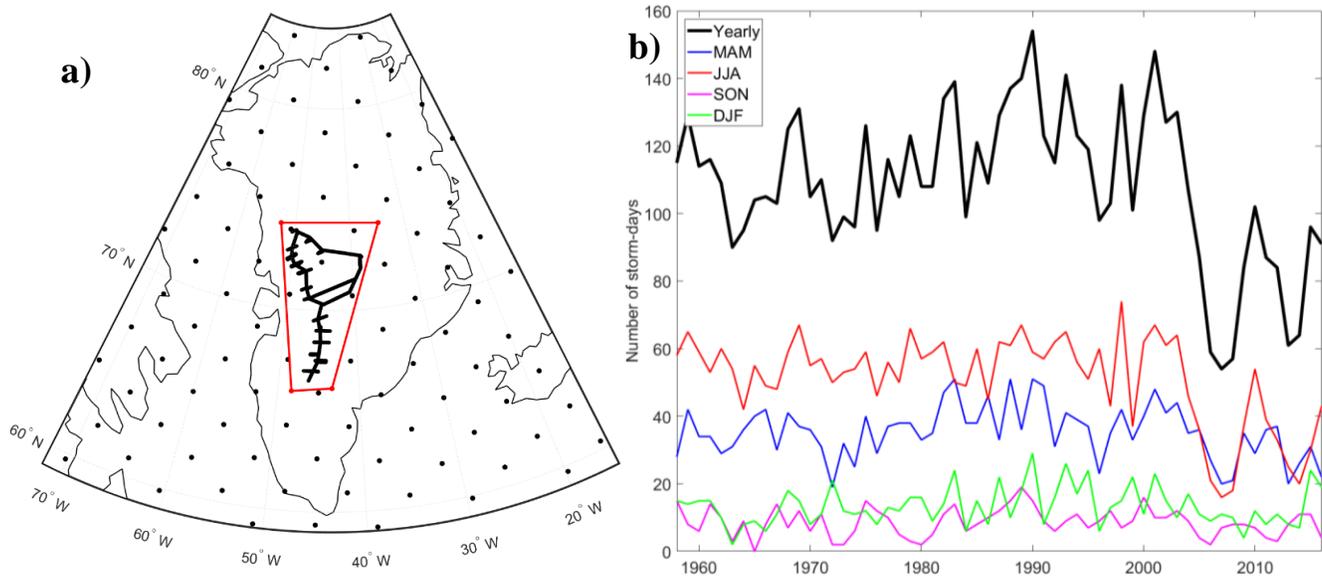

618  
619 The decline in summer storm-days indicates a relationship with well-documented stronger summer blocking  
620 over Greenland over the past two decades (Hanna et al., 2013; McLeod and Mote, 2016), with a positive  
621 Greenland Blocking Index (GBI) during 17 out of 21 summers between 1996 – 2016 (Hanna et al., 2016).  
622 The June – August GBI had a statistically significant positive trend of 1.87 (unitless; normalized to 1951 –  
623 2000) from 1991 – 2015 (Hanna et al., 2016). The summertime 500 mbar geopotential height increased 50 –  
624 70 m over the 1996 – 2016 period compared with the 1979 – 1996 baseline (Figure 12c), indicating stronger  
625 blocking that we suggest likely reduced precipitation over the central GrIS by deflecting storms poleward  
626 from the Greenland interior. This is consistent with an observed  $0.9 \pm 0.3\%$   $a^{-1}$  decrease in JJA cloud cover  
627 over Greenland from 1995-2009, with the largest decreases in the GreenTrACS region (Hofer et al., 2017).  
628 Furthermore, we find a strong negative correlation between ERA-Interim 1979 – 2015 June – August (JJA)  
629 GBI and JJA precipitation in both MAR (Figure 12d) and RACMO2 (not shown) across the central and  
630 southern GrIS. These results suggest that the blocking-induced accumulation decline observed in the  
631 GreenTrACS region is representative of a broader pattern over the GrIS, with the exception of Northwest  
632 Greenland where poleward blocking has increased storm-days (not shown) and accumulation (Figure 12d).

633

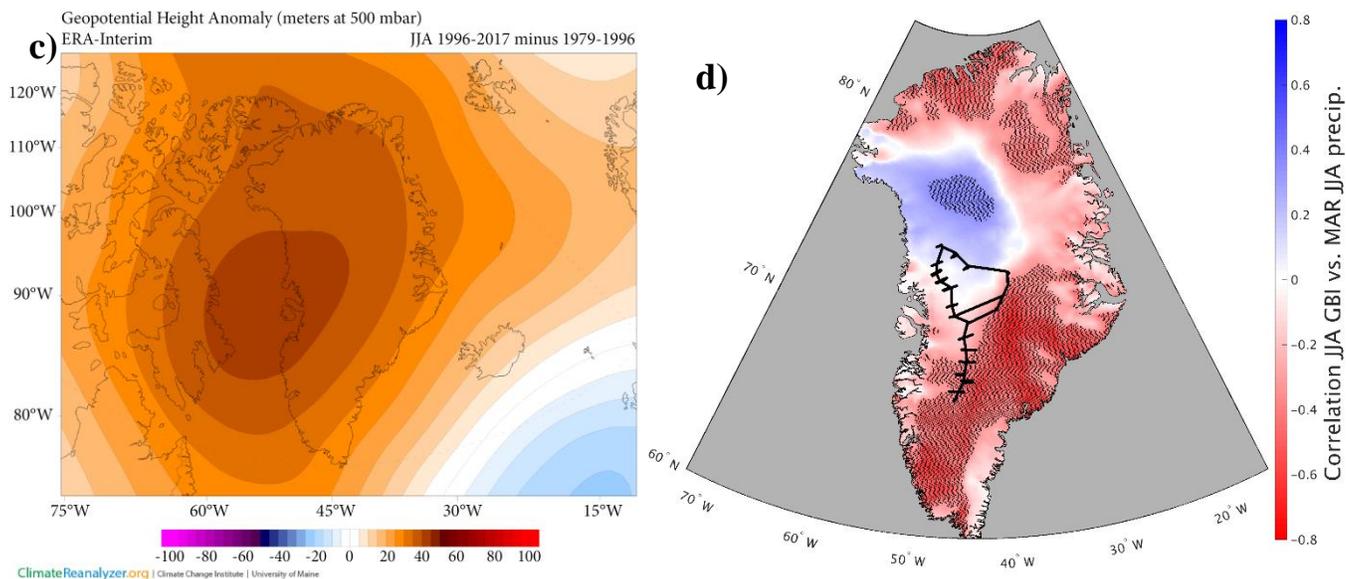

634

635 The effect of summertime Greenland blocking has previously been discussed primarily in the context of  
636 increasing surface melt (Hanna et al., 2013; Ballinger et al., 2017; Hanna et al., 2018; Hofer et al., 2017),  
637 while the effect of blocking on precipitation has received less attention (Hanna et al., 2013; McLeod and  
638 Mote, 2016). Our results highlight that stronger summer blocking reduces GrIS SMB through both an  
639 increase in surface melting and a decrease in accumulation. Stronger summer blocking has been tied to an  
640 observed increase in surface melt since 1996 across the Western GrIS percolation zone (Graeter et al., 2018),  
641 and to the July 2012 melt event, during which 98.6% of the GrIS experienced melt (Nghiem et al., 2012). We  
642 show here with *in situ* data that snow accumulation has declined in this same region as strong blocking has  
643 decreased the number of summer storm-days. Presently, none of the GBI outputs from the Coupled Model  
644 Intercomparison Project 5 (CMIP5) suite of global climate models accurately capture the recent summer GBI  
645 increase (Hanna et al., 2018). Improved predictions of summertime Greenland blocking under future  
646 anthropogenic forcing scenarios are therefore critical for accurately predicting Greenland SMB and its  
647 contribution to sea level rise.

648

649

Statistically significant RCM grid cell correlations are stippled black. GreenTrACS traverse is shown in black.

#### 658 4. Conclusions

659 We have developed a new dataset of accumulation rates over the western interior of the Greenland ice sheet  
 660 spanning the past 20 – 60 years, based on sixteen 22 – 32 m long firn cores and 4436 km of *in situ* GPR  
 661 accumulation data. This accumulation record is internally consistent across the dataset and is validated by  
 662 previous *in situ* field measurements and other radar-derived accumulation measurements (e.g Lewis et al.,  
 663 2017).

664  
 665 Overall, the Polar MM5 (Burgess et al., 2010), MAR (Fettweis et al., 2016), Box13 (Box et al., 2013), and  
 666 RACMO2 (Noël et al., 2018) Regional Climate Models accurately capture large spatial patterns in  
 667 accumulation over the GrIS, but show statistically significant differences from GPR accumulation on a  
 668 regional basis. The average RMS difference between each model and GreenTrACS accumulation is  $0.068 \pm$   
 669  $0.065$  (MAR),  $0.048 \pm 0.045$  (Polar MM5),  $0.0822 \pm 0.0702$  (Box13),  $0.0562 \pm 0.0548$  (RACMO2), and  
 670  $0.0475 \pm 0.0445$  m w.e.  $a^{-1}$  (Bales09). These differences are on the same order as the uncertainties in the  
 671 GreenTrACS and RCM accumulation estimates. While these average differences are small, we find  
 672 differences of 0.1 to 0.4 m w.e.  $a^{-1}$  when we investigate at a local scale for each model.

673

674 While global climate models predict a 21<sup>st</sup>-century increase in precipitation over the GrIS (e.g. Bintanja and  
675 Selten, 2014), we observe a decrease in precipitation across the Western GrIS from 1996 – 2016 using records  
676 from firn cores, GPR, and published RCMs. We believe this study is the first to identify widespread negative  
677 GrIS precipitation trends during this period of enhanced surface melt, evident in these RCMs and our field  
678 observations (Graeter et al., 2018).

679

680 We attribute the decrease in accumulation over the Western GrIS between 1996 and 2016 to more persistently  
681 positive Greenland blocking in the summer. We find a statistically significant 25% reduction in the number  
682 of summer storms that precipitate over the GreenTrACS region since 1996. While warming temperatures  
683 from anthropogenic forcing and enhanced summer blocking have increased melt across the western  
684 percolation zone, here we show that summer blocking has also contributed to declining precipitation over the  
685 past two decades. This has led to a strongly negative SMB trend on both the input and output sides of the  
686 SMB equation that may not be accurately captured in global climate models that are currently unable to  
687 reproduce the recent increase in blocking. This highlights the importance of improving GCM projections of  
688 future summer blocking to accurately forecast Greenland precipitation and melt rates under stronger  
689 greenhouse gas forcing.
