

Response to reviewer 1 (JF Lemieux)

Dear Jean-François,

Thank you very much for your helpful comments. We will respond to them below.

Review of Presentation and evaluation of the Arctic sea ice forecasting system neXtSIM-F by Williams et al.

In this paper the authors present and evaluate a new sea ice forecasting system based on the neXtSIM sea ice model. They have evaluated drift, sea ice thickness and concentration against different datasets and show that the forecasts, in general, show good agreement with the observations. Being also in the business of ice-ocean predictions, I recognize the amount of work that was done by the authors to develop and evaluate this kind of forecasting system.

I have, however, two major concerns about the paper.

The first one is easy to address. I think the authors need to do a better literature review. We have the impression there are currently only two sea ice forecasting systems (Topaz and GOFs) in the world and that neXtSIM-F is the third one to be proposed. For example, the Danish meteorological institute, the UK Met office, ECMWF, Environment and Climate Change Canada (ECCC) all have operational sea ice forecasting systems. Note also that we (ECCC) have, a few years ago, developed a similar system as neXtSIM-F: a stand alone sea ice model coupled to a slab ocean model (with MLD and SSS initialized from a coupled ice-ocean prediction system and SST from an analysis...). It is not used anymore as it has been replaced by a coupled ice-ocean forecasting system but I think, given the similarities between the two systems, that it should be mentioned. You could then describe what is different (e.g. the ocean heat flux correction you propose...which is interesting by the way.)

We agree that our discussion gives the wrong impression of the field, and are quite sorry about this. We have now scaled back our discussion to refer to the papers of Tonani et al (2015), and also the more recent one by Hunke et al (2020, <https://link.springer.com/article/10.1007/s40641-020-00162-y>) which also gives an idea about trends in the systems. Thanks for the reference about the ECCC stand-alone sea ice forecast RIPS that you sent - we have included it in our introduction as well.

The second major concern I have is that neXtSIM-F was evaluated for only half a year. And especially, the evaluation was done during the winter months, that is at a time when there is almost no navigation in the Arctic. I would understand why you would choose this period if your system was designed specifically for the Baltic Sea or the Gulf of St-Lawrence (where there is a lot of navigation during winter). I have the impression that the authors have submitted their paper too early and that it would make more sense to show a complete seasonal cycle of the forecast scores. You mention, anyway, that neXtSIM-F will be operational in November of this year...this is coming soon. This means you will soon have the evaluation for the summer months? Then I really think you should include these.

We agree that this was a major short-coming of the previous version of the paper, and have now completed evaluation for a period of 20 months. neXtSIM-F finally went operational in July 2020, and will be updated in December with the version evaluated in the present paper.

This paper will be an important contribution to the field of sea ice forecasting but first the authors need to address these concerns and the minor comments given below.

1 Minor comments

1) p.5 line 19. *I guess you use a turning angle for the ocean-ice stress? Please mention it.*

Yes, it is 25 degrees. Added to paper (section 4.2)

2) p.5 line 22. *this is already mentioned above.*

We have simplified this section and added it to section 4.1, where the slab ocean is introduced.

3) sections 3.6-3.7. *What is this the atmospheric forcing you will use once the system becomes operational? I hope it will be the same one used for the evaluation because then it does not make sense.*

The forcing we will use is the ECMWF forecast described in section 3.6. A line has been added to clarify this.

4) p.8 lines 7-9. *You give information that is not needed. We don't need to know that it was first coded in Matlab. Just say that the version of neXtSIM used for neXtSIM-F is described in Rampal et al. 2016 and Samake et al 2017.*

OK - we have removed some of the history.

5) p.8 lines 13-14. *Mention that the MLD varies spatially and that this spatial field is fixed (I guess) during the 7 days of the forecast.*

It actually varies with time according to the ocean forecast. We have added a comment to clarify this.

6) section 4.2. *Mention how you initialize the sea ice velocity.*

We added a sentence about this: the ice velocity and also the damage are started from zero.

7) section 4.2. *What justifies the values of 0.2 and 0.8 for the initial thin and thick ice?*

This is a little arbitrary (necessarily so given the difficulty of determining the concentration of thin ice) but the model wasn't too sensitive to this.

8) p.10 line 19. *The first condition (i.e. $ct > 0$) is not needed, right?*

Yes you are right - we have removed it.

9) section 5.1. *Clearly state how long (time period) is the free run.*

10) p. 11, line 6. *Typo "the no ice".*

Fixed.

11) Fig. 3. *Explain how you calculate the concentration and uncertainty. Is it the mean over the whole domain? Then it means you have many grid cells with a concentration of zero and many with a concentration close to 1.0. This means the signal you are interested in is kind of buried because most grid cells have a forecast concentration close to the observed one...which is not surprising.*

We actually average over the union of the ice masks. This still leaves the pack ice, which in our case is usually close to 1, while the observations is usually about 0.9-1. So this signal is less interesting since the observations are also uncertain. The extent is actually the main signal we would like to capture, but we present the comparison of the concentration also.

How do you deal with uncertainties when the concentration is 1 or 0...it cannot be gaussian, right?

This is a good question. It turns out that it was quite difficult to estimate uncertainties since we did not know the distribution of the observation errors. Therefore we removed the error shading from most of the plots. For the error plots we kept it as a rough reference level to show when our results were significantly different from the observations. Another interesting thing that came up from the uncertainty analysis was with the drift speed - adding noise to a given set of "true" drift values introduced a bias of $2\sigma^2$ to $\langle \text{drift}^2 \rangle$ where σ^2 is the variance of the drift. Hence one should be a bit careful when comparing drift speeds.

12) p. 13, lines 6-7 and Fig. 6. Is it possible the MEB rheology leads to too much convergence? (e.g. North of the CAA).

Yes. It is slightly improved with BBM, but there are still issues with this near the northeast coast of Greenland and the north coast of Svalbard. This has some unfortunate follow-on effects on the summer ice extent in the Greenland Sea especially.

13) p. 13, lines 18-24. Too many numbers given. I don't think you need to give all these values.

We have reduced the number of numbers inline throughout.

14) p. 13, line 27. What do you mean by "eroded"? Please clarify.

We mean that by setting a maximum threshold on the uncertainty in the ice drift we had masked the observations in some areas (mainly near the ice edge, coast, and the north pole). We now generally use a higher threshold (10 km/day) so that we can include evaluation in summer, but include a table where we use the lower threshold (1.25 km/day) for 2 winters and show it reduces our errors significantly. However some of the regions with higher errors (eg coast and MIZ) are regions where we have some problems with other variables like thickness and extent so masking them out can help for that reason too.

15) p. 13, line 33. I don't think the ice is landfast there but it is (very) slowly drifting.

Yes, you are right.

16) p. 14, line 1. remove "very respectable"...just give the number and that's it.

Fixed.

17) p. 14, line 10-14. Please clarify this paragraph. It is not clear here what are exactly the experiments (especially the sentence "...without assimilation, with assimilation of concentration and with assimilation of concentration and thickness.").

We have now reduced the number of experiments to one free run and one with assimilation of concentration/extent.

18) Fig. 9. I am not surprised persistence is doing so bad here because the beginning of November is a time when there is a lot of ice growth. No wonder the model performs so well. I think it would be good to show another case for example in March. Is it always true that the model beats persistence? Is it always true that assimilation improves the quality of the forecast?

Assimilation always improves the forecast concentration and extent compared to the free run (see the new figure 9). However it only beats the persistence in extent in the months Sep-Feb. We now have 4 examples (2 with positive skill (Jan, Sep) and 2 with negative skill (Mar, Jun)).

19) p. 16, lines 13-14: The captions in Fig. 10 and 11 do not match the text here about the dates.

Figs 10 and 11 have now been removed.

20) p. 18, line 1: *East Siberian and Chukchi seas...not obvious to me when I look at Figs 10 and 11.*

These figures and the discussion have now been replaced.

21) *Fig. 13 and 14 are not discussed. Are they really needed?*

They have in fact been replaced.

22) p. 19, lines 11-13: *Please rephrase...*

(This referred to the evaluation against SMOS thin ice thickness.) We decided to remove evaluation against SMOS since errors were dominated by difference in extent.

23) p. 20, line 1. *What drifters are we talking about here?*

Every day at 12:00 we place Lagrangian drifters at the grid points of the OSISAF drift product and advect them for 48h at the ice velocity. The total drift is then compared to the OSISAF drift product. We clarify this in the Data Sources section.

24) p. 25, lines 11-17. *I think it could also be the thermodynamic model itself. There is clearly too much ice growth...the model might require some tuning. This should be mentioned. What about the way the thin and thick ice categories are initialized? How does it affect the overestimation of the growth?*

We have now removed the comparison to SMOS.

25) p. 25, line 19. *What do you mean by "fragmentation"?*

Technically we mean damaging. We have changed this in the paper.

26) p. 25, line 23. *I thought neXtSIM is using our grounding scheme for landfast ice? Would it be worth tuning the k1 parameter?*

We now have the opposite problem of too much fast ice in the Laptev and East Siberian sea. We are currently tuning this parameter, but for this paper we were concentrating on the main parameters of the dynamics (cohesion, Pmax, drag)

27) p. 26, lines 20-22. *Is it a result you presented in this paper? Or I just don't understand the sentence. Please clarify this.*

Yes it is presented. We clarify the different runs better now (eg free run v forecasts)

Congratulations for your work on developing this new sea ice forecasting system.

Jean-François Lemieux

Thank you.

Anonymous Referee #2

Dear Reviewer 2,

Thanks very much for your helpful comments. We will respond to them below.

Interactive comment on “Presentation and evaluation of the Arctic sea ice forecasting system neXtSIM-F” by Timothy Williams et al.

Dear anonymous reviewer, thank you for your thorough review and helpful comments. We will respond to them below.

In this paper the authors introduce a new sea ice forecasting system neXtSIM-F based on the neXtSIM sea ice model and present an evaluation of the model over a single season - winter 2018-19.

I feel that this study will be worth publishing in The Cryosphere (although it would likely fit better in GMD than TC). However several changes will be required before this is possible.

General comments

1. *It is not made clear enough what the various runs and systems are that are assessed in this study. In particular there is also no mention of the “free run” before it is evaluated in Section 5.1. Section 3 contains information on the observational datasets used in this study but there is no equivalent for the model datasets. This study needs a summary of exactly which runs and systems are being evaluated with perhaps a table.*

This has now been clarified in a few places (introduction, start of results section, discussion and conclusions).

2. *Additionally the names neXtSIM and neXtSIM-F seem to be fairly inter-changeable in the manuscript. I guess the neXtSIM-F forecasting system uses the neXtSIM sea ice model. If so then I think the name of your forecasting system as neXtSIM-F is a bit confusing.*

This has now been clarified in a few places.

3. *The evaluation period is only a few months and does not include the late spring/summer period when many sea ice forecasting systems report their poorest performance. This means that it is hard to put the evaluation here into context with other operational systems. The conclusions of this study would be much strengthened if the authors could perform, and evaluate, a complete annual cycle (or preferably 2).*

This is a completely valid criticism and the run is now 20 months. We also have our worst performance in the summer months.

4. *In general I find that there are too many figures and stats in the paper, which makes it hard to understand what the take-home message is.*

We have removed some figures and tables, and replaced some others, and also tried to emphasise the main take-home message more, so hopefully the new figures and tables now help understanding rather than hinder it.

Specific comments

1. *In many places the language used in the paper is too informal and colloquial (i.e., in the abstract we have “. . .in our system, we obtain. . .” and on P9 we have “the observed ones”).*

We have tried to make the language more formal.

2. *You need to be careful to distinguish between “sea ice concentration”, which ranges from 0 to 100%, and “sea ice area fraction”, which ranges from 0 to 1 throughout this manuscript. For example in Figure 4 the caption says “concentration” but the scale is +/- 0.5%. This is either a low “concentration” or a high “area fraction”. I assumed the former to start with until I noticed that the text talks about an associated reduction in extent. With changes of +/- 0.5% concentration I wouldn't expect to see any departure to the 15% contour (extent) so is it actually “area fraction” plotted here?*

You are correct that it was actually area fraction - we have changed to using concentration with units of % everywhere.

3. *I find the abstract to be rather technical and not very abstract. It reads a bit more like a conclusions/summary section. I would encourage the authors to make the abstract more exciting to make the paper more inviting to potential readers.*

We have removed the numbers from the abstract and tried to make it more inviting.

4. *The introduction section (section #1) is rather disjointed. It starts with some motivation for sea ice forecasting (with background on changing climate) but then jumps straight in to say that neXtSIM-F is based on neXtSIM. It doesn't actually say that neXtSIM(-F) is a sea ice forecasting system! It would be better to include a couple of extra lines to say that this is the case. Perhaps to say something like “Here we introduce a new sea ice forecasting system, neXtSIM-F, that is based upon the neXtSIM model. . .”.*

Thanks - this is a good sentence that we have used in the introduction. Hopefully introduction is now less disjointed.

5. *I find the introduction to operational ocean forecasting systems in Section 2 to be, almost paradoxically, both too detailed and non-existent. I say too detailed because I am left wondering why there is such a thorough introduction provided to the GOFs system when it isn't really used in this study? Of course, GOFs is only one of many global operational ocean-sea ice forecasting systems and you don't mention any others apart from TOPAZ and neXtSIM. The Tonani et al. (2015) GODAE paper provides a nice reference describing the world's operational global forecasting systems. Although several of the systems have doubtlessly moved on since 2015, this reference provides evidence for the breadth of activity in the world. Tonani, M., Balmaseda, M., Bertino, L.,*

Blockley, E. W., Brassington, G., Davidson, F., Drillet, Y., Hogan, P., Kuragano, T., Lee, T., Mehra, A., Paranathara, F., Tanajura, C. A. S. and Wang, H.: Status and future of global and regional ocean prediction systems, *J. Oper. Oceanogr.*, 8, sup2, s201-s220, doi:10.1080/1755876X.2015.1049892, 2015.

We agree that our discussion gives the wrong impression of the field, and are quite sorry about this. We have now scaled back our discussion to refer to the papers of Tonani et al (2015), and also the more recent one by Hunke et al (2020, <https://link.springer.com/article/10.1007/s40641-020-00162-y>) which also gives an idea about trends in the systems.

7. The data sources section (#3) does not make it clear which datasets are used for assimilation and which are used for evaluation (and hence which are used for both). At the least it is important to note which datasets are independent from the assimilation.

A sentence has been added to the start of each data-source subsection to make it explicit which are used in assimilation and evaluation, and which are used in evaluation only.

8. Related to the above point I find the description of the blended SSMIS+AMSR2 product somewhat confusing. Is this done purely for the evaluation? If not why can't the DA do this blending by waiting the observations with their respective errors?

We now use this only for data assimilation, but it unfortunately became quite inconvenient to use it for evaluation due to missing sections of data in the AMSR2 product particularly.

We clarify this in section 2.3.

9. P3, L4: “. . . profiles from Argo floats.”. Why do you only use Argo floats (if that's true)? Why not CTD/XBT/seals etc.?

Here we were only describing what TOPAZ does. However, it also assimilates ice-tethered profiles as well. Other data like the ones you mention are available too late to assimilate in near-real-time. They are used in the TOPAZ reanalysis though (Laurent Bertino, *personal communication*).

10. I do not understand why a couple of weeks of CFSv2 is used in place of ECMWF. Surely you could get the replacement data from somewhere else (like ECMWF themselves for example)? If not then you should really consider the implications of using CFSv2. Specifically: is this the configuration with unrealistic ice growth caused by the fact that they turned off the stratus cloud formation to improve tropical temperatures and ENSO predictability (as described by Yang et al. 2017 and references therein)?

Yang, Q., M. Wang, J.E. Overland, W. Wang, and T.W. Collow, 2017: Impact of Model Physics on Seasonal Forecasts of Surface Air Temperature in the Arctic. *Mon. Wea. Rev.*, 145, 773–782, <https://doi.org/10.1175/MWR-D-16-0272.1>

We have now been able to access those missing forecasts and have rerun the free run and the relevant forecasts without needing to plug with CFSv2. This also allows us to delete the section describing CFSv2.

11. I don't like your “RMSE” for extent as it is exactly the Integrated Ice Edge Error (IIEE) of Goessling et al., (2016). You cite the ensemble extension of the IIEE (the SPS paper of Goessling and Jung, 2018) and say that your RMSE is like a deterministic version of that, which is misleading. It would be better to just cite the 2016 paper instead and call your metric “IIEE” instead of “RMSE”: Goessling, H. F., Tietsche, S., Day, J. J., Hawkins, E., and Jung, T.: Predictability of the Arctic sea ice edge, *Geophys. Res. Lett.*, 43, 1642–1650, <https://doi.org/10.1002/2015GL067232>, 2016

Agreed - we have renamed the metric to IIEE to avoid confusion and replaced the reference with your suggested one.

12. *In Figure 3 I note that the neXtSIM concentration evolution is very smooth – more so than the low resolution SSMIS data – which I didn't expect given the resolution of the model. Can you comment on this? Is this caused by the fact that neXtSIM still uses the continuum formulation and so doesn't resolve small scale features?*

For this refer to p10 “For all comparisons we average the model fields in time over an appropriate time window (in practice 1, 2 or 7 days), apply some spatial smoothing (being guided by the size of the satellite footprint), and interpolate onto the observation grid.” When comparing to OSISAF SSMIS we average over 1 day and apply some spatial smoothing, as SSMIS is too coarse to resolve the cracks/leads etc. However, we have applied a bit less smoothing this time around (see fig 11).

13. *I note with interest that MOSAiC forecasting is mentioned as a motivation for improving sea ice forecasts. There is an international project (SIDFEx) currently coordinating operational sea ice drift forecasts specifically to provide guidance to the Polarstern/MOSAiC. Presently the list of models includes TOPAZ but not neXtSIM. Are there any plans to contribute neXtSIM drift forecasts to SIDFEx? This might be an interesting way to show the skill of neXtSIM in this regard.*

This would be interesting if it were still possible, and is worth discussing with the leaders of that project.

14. *Some of the figures (e.g., Figs 10&11) suggest that the data assimilation is having a rather modest impact on the forecasts compared with many of the operational systems that I have seen in the past. Can you comment as to why that might be?*

After 2 quite major updates to our sea ice rheology we had to change the assimilation scheme quite a lot. It is now quite conservative in that we mostly leave the model alone, except where the ice mask is incorrect. There is a noticeable improvement in the IIEE for the first days after doing this, although the improvement is diminishing with lead time.

15. *On page 20 it is mentioned that the “RMSE for drifters placed on the first day. . .” but this is the 1st time in the manuscript that drifters are mentioned. Can you explain this a bit more please?*

Every day at 12:00 we place drifters at the grid points of the OSISAF drift product and advect them for 48h at the ice velocity. The total drift is then compared to the OSISAF drift product.

Figures

As mentioned above I feel that there are too many figures in this manuscript. In particular in Figs 11 & 12 there are 12 panels and each row looks virtually identical. Apart from telling me that the assimilation is having a rather modest impact, I don't understand what I'm supposed to do with all this information.

Additionally the next similar set of figures, Figs 13-14, don't even seem to be discussed in the text at all. So are they necessary?

We have revised the figures substantially now (eg figs 11-12 and figs 13-14 have been replaced.)

Many of the figure captions are too brief and should be improved. I believe that the

Copernicus journal guidelines are that figures should be able to work stand-alone from the text, for which a bit more information is required.

We have now checked the captions contain enough information.

I find that the x-axis date tick-marks provided on the time-series plots (Figs 3, 5, 7, 12 – less so for Fig 9) are not very useful. With such a short run period it would be better to include more dates. At the very least there minor tick marks should be used to show each day (or 5-days or something). It would also be good to specify this in the figure caption perhaps.

We have tried to add enough major and minor tick marks to the time series plots, although the run is a lot longer now.

Figure 1 is a bit confusing because I am left wondering whether different time-scales are involved here. Is this a daily schematic or does it depict the whole run? For example the 2 top boxes (initialization) are surely not done each day are they? If not then it should be made clear what is done each day and what isn't – either in the caption or the figure (or both). Perhaps the initialization boxes could be enclosed in a dotted box or something?

These were snapshots, but they have actually been removed to reduce the number of figures.

I suggest you should also re-think your use of red-blue colour maps for sea ice concentration. I have seen people use red for less ice (as it's hotter) and blue for more ice (colder) in the past as well as the other way around. It might be better to avoid the use of a hot<->cold colour-map therefore.

We tried out some other colormaps but decided to keep this one for lack of a better alternative.

Technical corrections

The 1st instance of “SSMIS” is correct but thereafter it has been changed to “SMMIS”.

Fixed

Also “first day (4th day)” appears in many places, which is not very consistent

P2, L26: CMEMS should be “Copernicus Marine Environment Monitoring Service”

Fixed

P2, L29: “. . .the version 4.1 of the. . .” – suggest to remove the 1st instance of “the”

Here

Fixed

P2, L30: The reference for CICE v4.1 is Hunke and Lipscomb (2010): Hunke, E. C. and Lipscomb, W. H.: CICE: the Los Alamos sea ice model. Documentation and software users manual, Version 4.1 (LA-CC-06-012), T-3 Fluid Dynamics Group, Los Alamos National Laboratory, Los Alamos, 2010

Thanks - added this

P3, L30: “As specified by the validation reports above. . .” should be “As specified by the validation reports cited above. . .”

Changed to this.

P4, L5: “metrics” should be “metric”

Fixed

P4, L6: is extent “above 15%” or “at least 15%”? I thought the latter.

In our evaluation script it was >15% - in practice I would expect either to give the same result
P4, L13: “. . .can be obtained for 48 hours. . .” sounds like only 48 hours of data. Do you mean this or do you mean the data is available 48-hours behind real-time?

In the OSISAF product, the drift is estimated daily from 12:00 on the start date until 48 hours later. In practice this does imply a time lag of at least 48h. “From October to April, however, daily 48-hour ice drift vectors can be obtained at a spatial resolution of 62.5 km.”

P5, L5: calculating volume for each model & obs based on thickness like this will involve different areas of ice won't it?

Yes. In the end we decided to remove the SMOS comparison as errors were greatly affected by errors in extent (which we struggled with).

P5, L26: “Modelling” is spelt incorrectly as “Modeling” in the NEMO acronym

Fixed

P5, L31: “. . .if the temperature is below 0C”. Which temperature – surface skin temperature, or near-surface atmosphere temperature (T2M)? Please be more specific.

It is T2M: we have added a clarification to the paper.

P10, L29: “of these variables” is not adding to this sentence and should be removed

Removed

P11, L6: “. . .predicts the no ice. . .”. Please remove the “the”.

Fixed

P11, L11: “averages values” should be “average values”

Fixed

P11, L19: “underestimation in the Bering Sea”. I presume that you mean the Chukchi Sea here because the Bering Sea is outside your model domain?

P13, L33-4: “land-fast“ should be “land-fast ice”?

Fixed

P13, L35: (as above) I suspect that “Bering Sea” should be “Chukchi Sea” here

That is correct, although with the change of simulation length the figures and discussion relating to the free run are quite changed and this sentence has been removed.

P14, L9: the title “Evaluation of forecasts with assimilation” is confusing because I doubt that you are actually doing assimilation in your forecasts are you? Perhaps this should be changed to something more like “Forecasts performed from analysed ice conditions”?

We are doing a kind of assimilation known as “data insertion” (modifying the initial conditions of the forecast) combined with “nudging” (through the compensating heat flux)

P16, L9: Do you mean “significantly” here in the scientific sense of the word? If so include a p-value, if not I suggest changing to “considerably”.

Changed to ‘considerably’

P18, Fig 9 caption: “(blue)”, “(orange)”, and “(red)” are provided but not “(green)”

This figure has now been removed.

P21, Fig 12 caption: “error bars” should be “shading”

We have removed references to error bars since we use shading.

P26, L7: “limited resources” suggests a deficiency in resource. You should change to “minimal resources” if you wish to suggest that the model is cheap to run.

We decided to remove this discussion.

*P26, L20-21: “. . . forecasts used saved atmospheric and ocean forecasts as forcing. . .”.
What does this mean?*

This is mainly an issue of forecasts vs hindcast winds which we have clarified in a few places (introduction, start of results section, discussion and conclusions)

Presentation and evaluation of the Arctic sea ice forecasting system neXtSIM-F

Correspondence: Timothy Williams (timothy.williams@nersc.no)

Abstract. The neXtSIM-F ~~forecast~~ forecasting system consists of a stand-alone sea ice model, neXtSIM, forced by the TOPAZ ocean forecast and the ECMWF atmospheric forecast, combined with daily data assimilation of sea ice concentration. It uses the novel Brittle Bingham-Maxwell (BBM) sea ice rheology, making it the first forecast based on a continuum model not to use the viscoplastic (VP) rheology. It was tested ~~for the northern winter of in the Arctic for the time period November 2018–~~ 2019 with different data being assimilated June 2020 and was found to perform well, although there are some shortcomings. Despite drift not being assimilated in our system, ~~we obtain quite good agreement between observations, comparing well to more sophisticated coupled ice-ocean forecast systems~~ the sea ice drift is good throughout the year, being relatively unbiased, even for longer lead times like 5 days. The RMSE in ~~drift speed is around 3 km/day~~ speed and the total RMSE are also good for the first ~~three days, climbing to about 4 km/day for the next day or two; computing the RMSE in the total drift adds about~~ 1 km/day to the error in speed. ~~The drift bias remains close to zero over the whole period from Nov 2018–Apr 2019.~~ 3 or so days, although they both increase steadily with lead time. The thickness distribution is relatively good, although there are some regions that experience excessive thickening with negative implications for the summer-time sea ice extent, particularly in the Greenland Sea.

The neXtSIM-F ~~forecast system assimilates OSISAF~~ forecasting system assimilates OSI-SAF sea ice concentration products (both SSMI and AMSR2) ~~and SMOS sea ice thickness~~ by modifying the initial conditions daily and adding a compensating heat flux to prevent removed ice growing back too quickly. ~~This~~ The assimilation greatly improved the ~~agreement of these quantities with observations for the first 3–4 days of the forecast~~ sea ice extent for the forecast duration.

1 Introduction

Arctic sea ice has been in great decline in the last number of years (Meier, 2017). Perovich et al. (2018) report that in 2018, the summer extent was the sixth lowest and the winter extent was the second lowest in the satellite record (1979–2018). Moreover, surface air temperatures in the Arctic continued to warm at twice the rate relative to the rest of the globe, and Arctic air temperatures for the past five years (2014-18) have exceeded all previous records since 1900 (Overland et al., 2018), which will also contribute to future sea ice decline if it continues.

With less sea ice comes an increase in summertime accessibility for shipping. Azzara et al. (2015) considered a range of different scenarios and projected an increase in the number of vessels operating in the Bering Strait and the U.S. Arctic of between 100 and 500%. The International Maritime Organization has also recognized that shipping would increase and adopted an International Code for Ships Operating in Polar Waters (Polar Code)¹ on 1 January 2017. This polar code addresses the increased safety and pollution risks of operating in the Arctic. A recent example of the risks and ~~comeomitant~~ concomitant costs of accidents in the Arctic is the rescue of the fishing vessel Northguider, which ran aground between Spitzbergen and Nordaustlandet (Svalbard) after getting into trouble with sea ice. The crew had to be rescued by the Norwegian Coast Guard icebreaker K.V. Svalbard, who then had to drain ~~300kL~~ 300 kl of diesel from the damaged vessel.²

Thus sea ice forecasting is becoming increasingly important. As well as search and rescue/accident prevention, other applications are optimized ship (icebreaker) routing based on forecasts (Kaleschke et al., 2016) and support of research activities – e.g. Schweiger and Zhang (2015) give an example of scheduling of high-resolution SAR images in order to follow the drift of some ice-mass balance (IMB) buoys by using the PIOMAS/MIZMAS forecast from the University of Washington. The ~~planned~~ year-long drift of the Polarstern from September 2019 (part of the MOSAIC project) ~~will also rely~~ also relied heavily on sea ice and weather forecasts.

~~The sea ice forecast system~~ Tonani et al. (2015) give a good overview of the 2015 status of operational forecasting, while Hunke et al. (2020, Table 1) give a comprehensive list of modelling systems that include sea ice, most of which are used in national forecasting capacities. They vary in resolution, in complexity (with regards to the modelled processes and the coupling between these processes) and in the data assimilation schemes that are used. We note however that they do not vary in their numerical framework (e.g. Eulerian advection schemes in all systems) nor in the rheological framework that they use for sea-ice (e.g., viscous-plastic). In this review, the authors claim that the trend is towards fully-coupled systems at high resolution. For example, the ECMWF forecast coupled ice and ocean models to their atmospheric model in between the two papers (this system went operation in June 2018) at a resolution of 0.1°. neXtSIM-F uses this latest ECMWF product (IFS: integrated forecast system: Owens and Hewson, 2018) to provide forecast atmospheric forcing, along with ocean forcing from TOPAZ Sakov et al. (2012).

Another relevant example is the replacement of RIPS³ (Lemieux et al., 2016a) by RIOPS⁴ in 2016, having NEMO coupled to the system, as well as having other processes like tides added. Like neXtSIM-F, RIPS used a stand-alone sea ice model based on the CICE sea ice model which used 3DVAR assimilation of OSI-SAF SSMI and AMSR2 concentration, as well as ice charts from the Canadian Ice Service.

In this paper, we introduce a new sea ice forecasting system, neXtSIM-F, which is based on a stand-alone version of the sea ice model neXtSIM (Rampal et al., 2016b; ?). The dynamical core of this model is based on the Maxwell-Elasto-Brittle (MEB) rheology as developed for sea ice and originally presented in Dansereau et al. (2016), which showed its capabilities at

³Regional Ice Prediction Service: operated by ECCC (Environment and Climate Change Canada) from 2013 to 2016.

⁴Regional Ice Ocean Prediction Service: operated by ECCC. See https://eccc-msc.github.io/open-data/msc-data/nwp_riops/readme_riops_en/#technical-documentation.

reproducing the main spatial characteristics of sea ice mechanics and deformation: strain localization and scaling (Marsan et al., 2004; Rampal et al., 2016a, 2019). With the implementation of this rheology in neXtSIM (along with accompanying thermodynamics and general model infrastructure: ?), MEB was able to be assessed (Rampal et al., 2016a, 2019). neXtSIM is a Lagrangian finite element model, and we are running it with a nominal triangle side length of 10 km, with a distance from one point of a triangle to the opposite edge being about 7.5 km. The name neXtSIM-F refers to the entire platform, including data input/output and assimilation, model initialisation and simulation, export, visualisation and evaluation of results (see Section 3). Due to the relatively recent arrival of the sea ice model, neXtSIM-F is simpler than most other platforms, both in terms of assimilation scheme (data insertion with nudging) and model components (uncoupled to ocean or atmosphere). (See Section 5 for planned improvements.) However, it is the first forecasting system based on a model with brittle sea ice rheology instead of the traditional viscoplastic (VP) rheology.

It is also the first system being based on a Lagrangian (adaptive) deforming grid, as opposed to the other ones being based on the standard Eulerian (fixed) grids.

neXtSIM-F entered into operations as part of the Copernicus Marine and Environmental Monitoring Services (CMEMS) on 7 July 2020. It was equipped with neXtSIM v1.0 based on the Maxwell-Elasto-Brittle (MEB) rheology (Dansereau et al., 2016), which had been shown to reproduce Arctic sea ice drift and deformation particularly well Rampal et al. (2016a, 2019). MEB consisted of an elastic spring in series with a dashpot, together with two main modifications to improve localisation and to prevent excessive convergence: the damage value was only used to modify the stress when it exceeded a threshold of 0.95, and a kind of viscoplastic stress term was added which only played a role when the ice was very damaged (see Appendix A1). This improves the thickness field somewhat over longer simulations, and it was found that it could also reproduce the observed temporal deformation scalings, in addition to the spatial ones. In particular, the results show strong multifractality (1–2 years; Rampal et al. (2019)), but not quite enough for longer than that.

In September 2020 the core of the forecasting platform was replaced with a new model: neXtSIM v2.0 based on a preliminary version of the novel Brittle-Bingham-Maxwell (BBM) sea ice rheology (Ólason et al., in prep.). The new version of neXtSIM-F enters into operations in December 2020.

BBM consists of an elastic spring in series with a composite element that contains a dashpot and a frictional sliding element in parallel (Ólason et al., in prep.). (For a summary of the BBM equations, see Appendix A2.) The BBM's main physical achievement has been to stabilise the thickness for decadal-scale simulations; computationally it is also 5–6 times faster, since it is able to be solved explicitly, unlike our version of the MEB. It also kept the improvements in the model's representation of the main spatial and temporal characteristics of observed deformation that were gained by MEB: strain localization and scaling (Marsan et al., 2004; Rampal et al., 2008; Stern and Lindsay, 2009), multifractality and intermittency in time (Rampal et al., 2019), meaning that higher deformations are more localised in space and more intermittent in time than smaller ones. These properties have strong implications for things like distribution and size of lead openings and how long they will stay open, which will in turn have strong impacts on controls the heat and salt fluxes across the ocean–ice–atmosphere coupled system. Perhaps more More pertinently in a forecast context, they also are are also highly relevant for navigation.

The paper begins by summarising the current status of sea ice forecasting in the Arctic, and then we assess the dynamical and thermodynamical behaviour of The paper is organised as follows: we begin by introducing the data and methods that we

35 use throughout, and then evaluate the neXtSIM modelin-'s general performance for a free run over the winter of 2018–2019.
This is followed by a demonstration of from November 2018 to June 2020 in terms of concentration/extent, thickness and
drift. This free run uses hindcast forcing fields. We then evaluate the neXtSIM-F forecast system-platform for the same winter,
particularly concentrating on the benefits of two different assimilation methods: one assimilating OSISAF and AMSR2 sea
ice concentration, and a second assimilating SMOS ice thickness in regions where sea ice is relatively thin, i.e. lower than
5 0.5 mperiod, when we assimilate concentration but use forecast forcing fields.

2 ~~Sea-ice forecasting status~~Data sources

2.1 ~~Forecast ocean forcing from TOPAZ4~~

The official European forecast for the Arctic is developed and run by the CMEMS (~~Copernicus Marine and Environmental~~
~~Monitoring Service~~) ARC-MFC (Arctic Marine Forecasting Centre)⁵. This uses the TOPAZ system (Simonsen et al., 2018;
10 Sakov et al., 2012), which uses version 2.2.37 of the Hybrid Coordinate Ocean Model (HYCOM) (Bleck, 2002). In the current
version (4) of TOPAZ, HYCOM is coupled to a sea ice model derived from ~~the~~ version 4.1 of the Community Ice Code
~~(CICE)~~(CICE: Hunke et al., 2010); ice thermodynamics are described in Drange and Simonsen (1996), while the dynamics
are based on the visco-plastic (VP) sea ice rheology (implemented with the elastic-viscous-plastic (EVP) solver of Hunke
and Dukowicz, 1997). The model's native grid covers the Arctic and North Atlantic Oceans and has a horizontal resolution
15 of between 11 and 16 km. TOPAZ4 uses the Ensemble Kalman filter method (EnKF; Sakov and Oke, 2008) to assimilate
remotely sensed sea level anomalies, sea surface temperature, sea ice concentration, sea ice thickness and Lagrangian sea ice
velocities (the latter two in winter only), as well as temperature and salinity profiles from Argo floats and ice-tethered profilers.
Data assimilation is performed weekly. ~~The most recent validation report (Melsom et al., 2018), reports a bias in drift of about~~
~~2 km/day, with an RMSE of about 5–8~~

20 To force neXtSIM, we use the following variables from TOPAZ: the near-surface (30 km/day, and a RMSE in concentration
of about 0.18–0.20. The ice edge error ranged from about 30–100km (50m) ocean velocity, the mixed layer depth (MLD), and
the sea surface (3 km on average)-m) temperature and salinity (SST and SSS, respectively). We give more details of how they
are used in Section 3.1 below.

~~The U.S. Naval Research Laboratory runs the Global Ocean Forecast System (Metzger et al., 2017, GOFS 3.1,) which uses~~
25 ~~HYCOM 2.2.99 coupled to CICE (Community Ice Code) on a global grid with 1/12° resolution (about 9 km). The assimilation~~
~~package, NCODA (Navy Coupled Ocean Data Assimilation)~~

2.2 ~~Forecast atmospheric forcing from ECMWF~~

For our forecast demonstration, we use the latest version (Cycle 45r1) of the Integrated Forecast System from ECMWF
(IFS; Owens and Hewson, 2018) to provide atmospheric forcing fields to neXtSIM. It consists of an atmospheric model coupled

⁵Three institutes contribute to the ARC-MFC: the Nansen Environmental and Remote Sensing Center, the Norwegian Meteorological Institute and the
Norwegian Institute for Marine Research.

30 ~~to the NEMO 3.4 ocean model (Nucleus for European Modelling of the Ocean), uses the 3DVar method (Parrish and Derber, 1992) to assimilate available satellite altimeter observations, satellite and in-situ sea surface temperature as well as in-situ vertical temperature and salinity profiles from XBTs, Argo floats and moored buoys. Surface information is projected downward into the water column using Improved Synthetic Ocean Profiles (Helber et al., 2013). In addition, a blend of ice products are assimilated: concentration from AMSR2 (Advanced Microwave Scanning Radiometer 2; Melsheimer, 2019), the LIM2~~
5 ~~(Louvain-la-neuve Sea Ice Model) sea ice model, the ECWAM (ECMWF Wave Model) wave model, and extent from IMS (Interactive Multisensor Snow and Ice Mapping System; Helfrich et al., 2007) and MASIE (Multisensor Analyzed Sea Ice Extent; Fetterer Metzger et al. (2017) report an RMS drift speed error of about 5–8 km/day in the Arctic. This is similar to TOPAZ, although different drift products are used for the validation (IABP buoy trajectories, instead of a land surface model (HTESSEL). Its spatial resolution is 0.1°.~~
10 ~~We use the 10-m wind velocity, the OSISAF high-resolution ice drift) and Melsom et al. (2018) use the vector difference in their RMSE definition (which will be higher than the RMS difference between the speeds). GFS 3.1 also showed an ice edge error of about 20–50 km (growing with forecast lead time) 2-m air and dew point temperatures (the latter is used to determine the specific humidity of air for the latent heat flux calculation), the mean sea level pressure, the long- and short-wave downwelling radiation, and the total precipitation (this becomes snow if the 2-m air temperature is below 0°C).~~

15 3 Data sources

2.1 Sea ice concentration ~~products from OSISAF~~OSI-SAF

~~The Ocean and Sea Ice Satellite Application Facility (OSISAF)~~ OSI-SAF provides estimates of sea ice concentration derived from the Special Sensor Microwave Imager Sounder (SSMIS) radiometer (Tonboe et al., 2016; Tonboe and Lavelle, 2016; Lavelle et al., 2017) and from AMSR2 (Lavelle et al., 2016a, b; Tonboe and Lavelle, 2015). The ~~SMMIS~~ SSMIS algorithm
20 uses the 19 GHz frequency (vertically polarized, footprint size about 56 km) and the 37 GHz frequency (both vertically and horizontally polarized, footprint size about 33 km). The AMSR2 algorithm uses three frequencies: 18.7, 36.5 and 89 GHz (also in vertical and horizontal polarizations) with footprints from 22 to 5 km). The AMSR2 data are presented on a 10-km grid, and we chose this product over the higher resolution (3.25 km) ASI product as we found it less noisy near the ice edge. These products are available daily within 12 hours after acquisition and processing so it is possible to assimilate this data
25 in operational forecasts. ~~However, the file for the day before the bulletin date (the day the model is run) doesn't arrive early enough to be assimilated in our daily run, which is launched at 03:00 (European western time). Therefore, we use the file from two days before the bulletin date.~~

As specified in the validation reports ~~above the SMMIS~~ cited above the SSMIS has lower resolution ice concentration but has the advantage of higher accuracy, while the AMSR2 algorithm has higher resolution but also higher uncertainties. In order
30 to combine the advantages of these products we generated a blended product that was used both for assimilation ~~and evaluation of during~~ the forecasts. Blending was performed with a weighted average of the two products (using the errors in the products

to calculate the weights):

$$C_B = \frac{C_L \sigma_L^{-2} + C_H \sigma_H^{-2}}{\sigma_H^{-2} + \sigma_L^{-2}} \quad (1)$$

where C denotes sea ice concentration, σ denotes the concentration uncertainty, index H denotes high resolution (AMSR2) and L - low resolution ([SMMISSMIS](#)).

Sea ice extent, used as an evaluation ~~metric~~-[metric](#) of the model, was calculated from the concentration product as a sum of areas of all pixels within the model domain with concentration above 15%. Sea ice extent uncertainty was calculated as a difference between the extents calculated from the sum of concentration and uncertainty and concentration alone.

~~We use both SSMI and AMSR2 products for assimilation by the forecasts, but only SSMI for evaluation of the free run and our forecasts. This was because we found the AMSR2 product somewhat inconvenient due to missing sections of data, which made our evaluation statistics quite noisy. (OSI-SAF SSMI is therefore not an independent validation dataset for the forecasts.)~~

10

2.2 Sea ice drift from ~~OSISAF~~[OSI-SAF](#)

~~Low-resolution~~ ~~We use this product for evaluation of both our free run and our forecasts. (It is therefore an independent validation dataset for our forecasts.) To produce it, low-resolution~~ ice drift datasets are computed on a daily basis from aggregated maps of passive microwave (e.g. SSM/I, AMSR-E) or scatterometer (e.g. ASCAT) signals (all channels are used) using the continuous maximum cross-correlation method (~~CMCC, Lavergne et al., 2010; Lavergne and Eastwood, 2010; Lavergne, 2010~~). ~~In summer, surface melting and a denser atmosphere preclude the retrieval of meaningful information. From October to April, however, global~~ (~~CMCC: Lavergne et al., 2010; Lavergne and Eastwood, 2010; Lavergne, 2010~~). Daily 48-hour ice drift vectors can be obtained ~~for 48 hours~~ at a spatial resolution of 62.5 km. ~~To pick the most trustworthy drift vectors, we apply a threshold to the drift uncertainty of 1.25~~ ~~As part of our evaluation we sometimes apply a filter on the uncertainty given in the product to concentrate on the more precise observations, only considering those where the 2-day drift uncertainty is less than 2.5 km. This completely excludes the summer period of May to September (RMS uncertainty is about 12 km/day. Doing this still retains-~~, since surface melting and a denser atmosphere preclude the retrieval of precise information. From October to April, we can still retain about 75% of the observation vectors ~~after using this threshold~~, with the removed ~~ones generally vectors generally being~~ close to the ice edge, coast or the north pole. The error is higher in these ~~region~~-[regions](#) as the sub-images on which the CMCC method is applied must be reduced to limit them to being inside the ice mask (Lavergne and Eastwood, 2010). In the case of the north pole, there are fewer observations there, while the vectors in the MIZ have especially high uncertainties (sometimes up to ~~6~~[12](#) km/day) due to the high velocities in those regions, combined with the relatively long time interval over which the drift is calculated.

20

25

2.3 ~~Thin sea ice thickness from SMOS~~

~~This product from ESA's Soil Moisture and Ocean Salinity (SMOS) mission estimates the average thickness of thin ice from brightness temperatures retrieved from the low microwave frequency of 1.4 GHz (L-band) a~~(~~Kaleschke et al., 2016; Tian-Kunze et al., 2014~~

30

~~It uses an algorithm based on a combined thermodynamic and radiative transfer model which accounts for variations of ice temperature and ice salinity. These latter two variables are estimated using the following auxiliary data from models:~~

~~DOLLARDIF 2-m air temperature and 10-m wind velocity from the Japanese 25-year Reanalysis (JRA-25; Onogi et al., 2007).~~

~~DOLLARDIF Sea surface salinity (which cannot be determined from SMOS under ice) is estimated from an 8-year (2002–2009) climatology of results from the MITgem ice-ocean model (Marshall et al., 1997) run at a resolution of 4km and forced by the Era-Interim atmospheric reanalysis.~~

~~It also assumes the ice thickness distribution follows the one measured in NASA's IceBridge airborne campaign (Kurtz et al., 2013). Although it is distributed on a grid with a resolution of 12.5 km, SMOS has a footprint of about 40 km. It is a daily product with a delay of only 1–2 days so it is possible to assimilate this data in a forecast situation.~~

10 ~~Thin ice volume, used for evaluating the forecasts, was calculated by integration of ice thickness (either from observations or from the simulated fields) in all pixels with thickness below 0.5 m. In order to compare neXtSIM drift to this product, every day at 12:00 we place Lagrangian drifters at the grid points of the OSI-SAF drift product and advect them for 48 hours at the ice velocity. The total drift is then compared to the OSI-SAF drift product.~~

2.3 Sea ice thickness from CS2-SMOS

15 ~~For~~ We use this product (version 2.2: Ricker et al., 2017) for long-term thickness evaluation we use the weekly hybrid CS2-SMOS product (version 2.0: Ricker et al., 2017) evaluation of the free run. This product is a daily hybrid product which combines thickness estimates from the Cryosat-2 (CS2) altimeter (more reliable for thicker ice ($\gtrsim 0.5$ m) and from SMOS (Soil Moisture and Ocean Salinity; better for thin ice). The CS2 altimeter tracks are somewhat sparse so optimal interpolation (OI) is used to fill the gaps between them and the areas of thin ice. ~~(This is also why the product is weekly and not daily.)~~ For this reason each
20 file covers a 7-day period. The OI method requires a background field to be created with full coverage, and that is independent of the target week so it is created from the CS2 values for the two weeks ahead and behind the target week, and from the SMOS values for the day before the target week.

The errors from this approach can be particularly high in coastal areas of thick ice (for example north of Greenland and Canada), which are too thick to be measured by SMOS, but may be only covered by altimeter tracks every 2–3 weeks. For
25 these gaps in coverage, the product uses the background field.

~~From an operational point of view, the need for the background field requires at least two weeks delay before~~ There is now an operational version of this product, which only uses CS2 data from one week before and after the target week. A delay of one week for thickness would probably be acceptable for assimilation in a real time forecast in the results for a given target
~~week can be obtained, so it would be difficult to use this product operationally.~~

30 2.4 Forecast ocean forcing from TOPAZ4

~~The TOPAZ ice-ocean forecast was discussed in §3. To force neXtSIM, we use the near-surface (30 m) ocean velocity and the mixed-layer depth (MLD) directly in the model, while the temperature and salinity in the model's slab ocean are relaxed~~

towards the TOPAZ sea surface (3-m) temperature (SST) and salinity (SSS) (respectively) over a time scale of about a month. The thickness of the slab ocean is the MLD from TOPAZ.

2.4 Atmospheric forcing from ECMWF

5 For our forecast demonstration, we use Cycle 45r1 of the Integrated Forecast System from ECMWF (IFS: Owens and Hewson, 2018) to force neXtSIM. This is the latest version of the IFS, which came into operation in May 2018. It consists of an atmospheric model coupled to the NEMO 3.4 ocean model (Nucleus for European Modeling of the Ocean), the LIM2 (Louvain-la-neuve Sea Ice Model) sea ice model, the ECWAM (ECMWF Wave Model) wave model, and a land surface model (HTESSEL).

10 We use the 10-m wind velocity, the 2-m air and dew point temperatures (the latter is used to determine the specific humidity of air for the latent heat flux calculation), the mean sea level pressure, the long- and short-wave downwelling radiation, and the total precipitation (this becomes snow if the temperature is below 0°C).

2.4 Atmospheric reanalysis forcing from CFSv2

15 Due to problems with our download of the ECMWF forecast, we had to fill a gap in our atmospheric forcing of just over two weeks, from 15-29 January 2019, with reanalysis forcing. For this we use the Climate Forecast System version 2 (CFSv2, Saha et al., 2014). This is an atmospheric model coupled to the MOM4 ocean model (Modular Ocean Model, Griffies et al., 2004), which itself includes a sea-ice component. It also uses the Noah land-atmosphere model Ek et al. (2003), and the 3DVAR assimilation method (Parrish and Derber, 1992). We use the 10-m wind velocity, the 2-m air and specific humidity of air, the mean sea level pressure, the long- and short-wave downwelling radiation, the total precipitation and the fraction of this that is snowfall [future](#).

20 3 Description of the forecast platform

As shown in Figure 1 the platform consists of pre-processing steps (including generation of the model mesh and initialization of the forecast or assimilation of observations), running of the forecast by the neXtSIM model, and post-processing steps (including forecast evaluation, and visualisation). These steps are explained in [details](#) [detail](#) in the section below.

3.1 The neXtSIM model

25 [Example model fields from 26 February 2018 00:00: sea ice concentration; sea ice thickness; sea ice damage; ridged ice volume ratio.](#)

neXtSIM is a stand-alone sea-ice model which can use winds and currents from a variety of atmospheric and oceanic models (hindcasts or forecasts). This makes it quite flexible and light to run and therefore ideal for a forecasting context. Its dynamical core is the [Maxwell-elasto-brittle \(MEB\) rheology \(Dansereau et al., 2016\). Rampal et al. \(2016b\) new Brittle-Bingham-Maxwell \(BBM\) rheology \(Ólason et al., in prep.\). \(Also see Appendix A2 for a summary.\) Rampal et al. \(2016a\)](#) presented results using a previous version of neXtSIM including an elasto-brittle (EB) rheology as described in Bouillon and Rampal (2015), showing

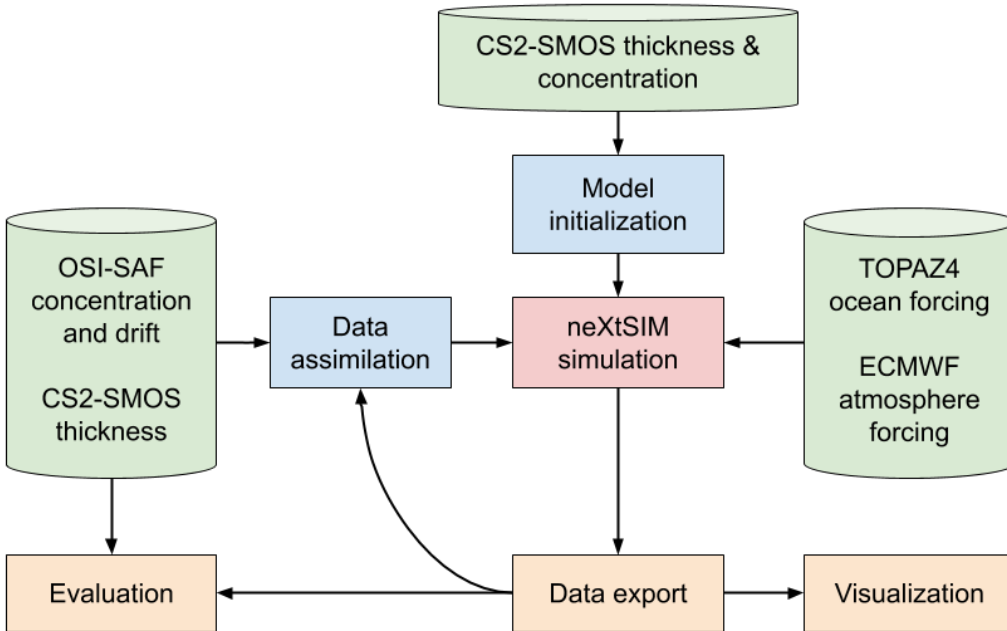

Figure 1. Overall scheme of the [neXtSIM-F](#) forecasting platform. Blue blocks contain pre-processing steps; red block running of the model core; yellow blocks post-processing steps; green blocks input data. Note that we only assimilate OSI-SAF SSMI and AMSR2 concentrations.

good agreement with observed drift and concentration in particular. More recently, [Rampal et al. \(2019\)](#) showed the ability to reproduce the characteristic multi-fractal scalings of deformation when using the ~~current~~ ~~previous~~ version of neXtSIM, which ~~now includes the MEB rheology.~~ ~~update~~ ~~included the Maxwell-elasto-brittle (MEB) rheology (Dansereau et al., 2016).~~ [Rampal et al. \(2019\)](#) ~~updated~~ the paper of [Rampal et al. \(2016b\)](#) [Rampal et al. \(2016a\)](#), evaluating the model's improved performance when using the ~~new~~ MEB rheology. The key addition of the MEB rheology ~~is~~ ~~was~~ ~~the~~ ~~addition~~ of a viscous dissipation of stress in areas where the ice is damaged, ~~which restricts the velocity and particularly convergence in those areas~~ ~~allowing it to move more freely.~~ ~~However, in longer term simulations the MEB showed unrealistic pile-up of ice particularly along the north-east coast of Greenland and the north-west coast of Svalbard. This led to the addition of a frictional element to the rheology (Ólason et al., in prep.), which provides some resistance to compression (up to a threshold). This framework, of a~~ ~~spring in series with a composite element made up a dashpot and friction element in parallel, is called BBM.~~

The dynamical equations are solved with a finite element method on a Lagrangian (moving) triangular mesh. The code has evolved from a serial (non-parallelised) Matlab code (used by eg. Rampal et al. (2016b)), to is currently a parallelised C++ code (used by ?, ?, used by Rampal et al. (2019), and presented by Samaké et al., 2017). We use this parallelised code Samaké et al. (2017). Momentum input comes from the wind and ocean stresses (a turning angle of 25° is applied to the ocean velocity from the ocean forcing), the Coriolis force and sea surface slope, and there is also a basal stress applied at the bottom of the ice when it becomes grounded. For this basal stress we follow the scheme of Lemieux et al. (2016b), using the parameters $k_1 = 10 \text{ m}$, $k_2 = 15 \text{ m}$, $\alpha_b = 20$, $u_0 = 5 \times 10^{-5} \text{ m s}^{-1}$.

There is also a thermodynamic component of the code and beneath the ice is a slab ocean with three variables: temperature, salinity and thickness. The temperature and salinity are modified by the heat and salinity fluxes determined by the thermodynamical model as ice melts and freezes and as the model interacts with the atmosphere. They are relaxed towards the SST and SSS from TOPAZ over a time scale of about one month, while the thickness of the slab ocean is taken directly to be the MLD of TOPAZ. This varies spatially and evolves with time according to the forecast from TOPAZ. The thermodynamical model is a three-category model (detailed in ?, Appendix A) (detailed in Rampal et al., 2019, Appendix A): open water, newly-formed ice (treated as one ice layer and one snow layer; Semtner, 1976) and older ice (treated as two ice layers and a snow layer; Winton, 2000).

The older ice is characterised in the model by concentration, c , and thickness averaged over the entire cell (effective thickness or, in other words, volume per unit area), h . The absolute thickness of ice can be computed as the ratio: $H = h/c$; there is also an effective snow thickness, s . The young ice has concentration c_y , effective and absolute thicknesses, h_y and $H_y = h_y/c_y$, and snow thickness, s_y . H_y is constrained so that $H_{\min} \leq H_y \leq H_{\max}$. If $H_y < H_{\min}$, c_y is reduced to $c'_y = (H_y c_y)/H_{\min}$; if $H_y > H_{\max}$, some ice is moved to the older ice category. During this process H_y is reduced to $H'_y = H_{\max}$, while c_y is also reduced to $c'_y = c_y(H_{\max} - H_{\min})/(H_y - H_{\min})$. This concentration reduction is intended to give some lateral decrease in thin ice volume and not just vertical. The corrected values for h_y and s_y are $h'_y = c'_y H_{\max}$ and $s'_y = c'_y (s_y/c_y)$; the corresponding properties for the older ice h , c and s are then increased in a ice-and-snow-volume-conserving manner. The values that we used for the thresholds on the absolute thin ice thickness are $H_{\min} = 0.05 \text{ m}$ and $H_{\max} = 0.275 \text{ m}$.

The domain we present simulations for is a pan-Arctic one, with a resolution of about 7.5 km. A 7-day forecast for this domain can be run on a laptop with 8 cores at 2 GHz in about 3–4 hours. Figure 2 shows snapshots of some of the more interesting variables from neXtSIM. Figure ??a shows the sea ice concentration — note the many thin cracks and leads — while Figure ??b shows the ice thickness. Figure ??c shows the damage, which is a crucial variable in the MEB rheology. The effective elastic modulus is lower where it is higher, making it more mobile in those places. Figure ??d shows the volume fraction of ridged ice, which is higher in places that have been under convergence. This variable is one that could be particularly useful for icebreakers wishing to travel into the ice runs in about 30 minutes using 16 processors.

3.2 Initialization of the model fields

Before the model can be run it has to be initialized - the triangular mesh for the destination domain should be generated and initial values of sea ice concentration and thickness and the slab ocean surface temperature and salinity have to be set. The

mesh is generated with Unref (a component of Gmsh: Geuzaine and Remacle, 2009) and using the Global Self-consistent, Hierarchical, High-resolution Shoreline Database (GSHHS) (Wessel and Smith, 1996). The model fields are initialized from the observed sea ice concentration and thickness from the CS2SMOS product (sec. 2.3) and simulated sea surface temperature and salinity from TOPAZ4 (sec. 2.1). The ice concentration in the CS2SMOS product ~~is originating from the OSISAF low resolution comes from the low-resolution OSI-SAF~~ product and has to be adjusted in areas with low thickness (Ivanova et al., 2015). Therefore total sea ice concentration (c_t) is calculated by adjusting the observed SIC using the observational operator \mathcal{O} :

$$c_t = c_O / \mathcal{O}(h_{C2S})$$

$$\mathcal{O}(h_{C2S}) = a_0 \sinh\left(\frac{h_{C2S} - a_1 a_2}{2a_1}\right) \quad (2)$$

where c_O is the ~~OSISAF OSI-SAF~~ concentration, h_{C2S} is the CS2SMOS (effective) thickness, and $a_0 = 0.9569$, $a_1 = 0.06787$ and $a_2 = 0.4255$ are parameters fitted from the observations (personal communication with Thomas Lavergne).

As mentioned above the model has two ice categories - young ice and older ice with different rheological behaviour. At the initialization step young ice c_y is set to comprise 20% and the older ice c 80% of the total SIC. If the observed absolute thickness h_{C2S}/c_t is below the young ice upper thickness limit H_{\max} , then thickness is distributed between young and older ice in the same proportion, otherwise young ice thickness is calculated as $h_y = c_y H_{\max}$ and for the older ice: $h = h_{C2S} - h_y$. It was identified that the model has little sensitivity to the fraction of young ice and it may vary within 5 - 30%.

The temperature and salinity of the slab ocean is taken to be equal to the TOPAZ4 surface forecast, ~~while the ice velocity and damage are set to zero.~~

3.3 Assimilation of concentration and thickness

The assimilation is performed before each forecast run using the data insertion method — an updated ~~variable (V_U concentration (c_U))~~ is calculated as a function of the forecast variable ($V_F c_F$) and observations (V_O): ~~$V_U = f(V_F, V_O)$. The c_O): $c_U = f(c_F, c_O)$.~~ ~~Other variables (particularly ice and snow thicknesses and the SST of the slab ocean) are adjusted for consistency, and the simulation is then restarted using the updated ~~variable V_U variables~~ and the model is run for 7-8 days to provide a one day of hindcast and a 7-day forecast.~~ The assimilation is performed on the model mesh — the satellite observations, originally provided on a regular grid, are linearly interpolated onto the centers of the mesh elements so that they can be directly compared with the neXtSIM prognostic variables.

~~Two types of satellite observations are assimilated in neXtSIM-F: The concentration is done as follows. The observed concentration c_O is taken to be the blended concentration from OSI-SAF (c_O , see. ??) and effective thickness from SMOS (h_S , see. ??) see Section 2.1) and is combined with the model concentration using a weighted average approach:~~

$$\underline{V_U c_U'} = \frac{V_F \sigma_F^{-2} + V_O \sigma_O^{-2}}{\sigma_O^{-2} + \sigma_F^{-2}}, \frac{c_F \sigma_F^{-2} + c_O \sigma_O^{-2}}{\sigma_O^{-2} + \sigma_F^{-2}}. \quad (3)$$

~~where V denotes ice concentration or thickness, σ denotes uncertainty of concentration or thickness, index F denotes forecast variable or uncertainty and index O — the observed ones.~~

5 The uncertainties of the observed concentration and thickness (σ_O^c and σ_O^h) are obtained from the input product and uncertainties of the forecast concentration and thickness (σ_F^c, σ_F^h) are set, respectively to 10% and 0.1 m. The values for the uncertainties products, while the value for the uncertainty in the forecast variables are chosen concentration is set to 0.3 to reduce strong discontinuities in the modelled fields. It can also be thought of as introducing a time scale (in days) of $1 + \sigma_O^2 / \sigma_F^2$ for relaxation towards the observations that depends on the relative uncertainties. Assimilation of both concentration and thickness is performed in all elements that have valid observations. Even if h_O exceeds the theoretically retrievable threshold of 0.5 m the value of σ_O^h in such elements is considerably larger than σ_F^h and, thus SMOS observations have almost no impact on the updated thickness.

15 In the pack, the total (young and old ice) model concentration c_F is generally about 1, while the OSI-SAF concentration can be around 0.9. We found that using c'_U as the actual update c_U produced too much of a drop in concentration there, lowering the internal stress to near zero and allowing too much drift. This quickly led to rapid build up of very thick ice in unusual places. Therefore we had to take a quite conservative approach to our correction and only change the model to make sure it had the correct ice mask (this is a kind of assimilation of extent):

$$c_U = \begin{cases} 0 & c'_U < 0.15, \\ c'_U & c_F < 0.15 \text{ and } c'_U \geq 0.15, \\ c_F & \text{otherwise.} \end{cases} \quad (4)$$

20 After calculating the updated variables as specified in (3) the fractions and thicknesses of young and older ice are calculated in the same way as in the initialisation procedure (see sec. 3.2).

Once all the assimilation steps have been performed the model fields are checked for consistency with each other and corrected if necessary. First, the concentration of young ice is reduced in the elements where the total concentration exceeds 100%. Second, the surface temperature of the slab ocean is set to the freezing point where new ice was added during assimilation. The volume of ridged ice, damage and the snow thickness ice and snow thicknesses are set to zero in the added ice. Lastly, we need to correct the SST of the slab ocean. Where new ice is added during assimilation it is set to the freezing point, but if ice is removed then the situation is more complicated. Then we proceed as in the following section.

3.4 Compensating heat flux

One of the side effects of assimilation is that the heat balance in the model is disturbed: reducing the concentration opens more water and given the temperatures, atmosphere humidity and ocean salinity provided by the forcing, the heat flux out of the ocean increases and the ice freezes up again very fast. A compensating heat flux is added to the total ocean heat flux in order to keep the heat balance and prevent refreezing of ice where it was removed by assimilation, thus prolonging the effect of assimilation. If c_t and c'_t are respectively the total concentrations before and after assimilation, a compensating heat flux (Q_c) is calculated if ice was removed — i.e. if $e_t > 0$ and $c'_t < c_t$ — according to the following formula

$$Q_c = Q_o \left((c'_t / c_t)^n - 1 \right) \quad (5)$$

where Q_o is the total heat flux from the ocean (sum of flux from the ocean to sea ice and to the atmosphere), and n is a parameter controlling the strength of correction. The function was chosen so that Q_c is zero when the concentration update is zero, and $Q_c = -Q_o$ when $c'_t = 0$, i.e. all the ice was removed by assimilation. With $n = 1$ the reduction of Q_c from 0 to $-Q_o$ is linear and with $n > 1$ it becomes steeper for values of c'_t closer to c_t . We use $n = 4$ for the runs presented here, as this gives a suitably strong heat flux for a modest reduction in concentration.

4 Results

We begin with an evaluation of a free run over the 20-month period from 1 Nov 2018 to 30 June 2020. This shows the general strengths and weaknesses of the model. We then evaluate the performance of the forecast system over this period to show the improvements gained by the assimilation of OSI-SAF concentration.

4.1 Evaluation of free model run

In this section we demonstrate that the model is generally able to reproduce the overall drift, concentration, and thickness patterns in observations ~~of these variables~~. For all comparisons we average the model fields in time over an appropriate time window (in practice 1, 2 or 7 days), apply some spatial smoothing (being guided by the size of the satellite footprint), and interpolate onto the observation grid. For scalar variables, we define bias as $\langle V_{\text{mod}} - V_{\text{obs}} \rangle$ (with $\langle \cdot \rangle$ defining the spatial mean over pixels where both model and observation are defined, and where either model or observations have ice.) We also define RMSE as $\langle (V_{\text{mod}} - V_{\text{obs}})^2 \rangle^{1/2}$. For the ice ~~velocity we define the bias and RMSE as the mean and RMS values of the difference in speed respectively — i.e. $\langle |\mathbf{u}_{\text{mod}}| - |\mathbf{u}_{\text{obs}}| \rangle$ and $\langle (|\mathbf{u}_{\text{mod}}| - |\mathbf{u}_{\text{obs}}|)^2 \rangle^{1/2}$. We also define the vector RMSE (VRMSE), as the RMS of the vector difference, $\langle |\mathbf{u}_{\text{mod}} - \mathbf{u}_{\text{obs}}|^2 \rangle^{1/2}$. For the ice extent, we use the terms bias and RMSE a bit loosely: we define bias in extent as $A_{10} - A_{01}$, where A_{10} is the total area of pixels where neXtSIM predicts the presence of ice (total concentration greater than 15 %) but the observation has no ice, while A_{01} is the total area of pixels where neXtSIM predicts ~~the~~ no ice (total concentration greater than 15 %) but the observation does have ice; ~~we define RMSE in extent~~. Analogously to the RMSE for other quantities, we define IIEE (Integrated Ice Edge Error, Goessling et al., 2016) as $A_{10} + A_{01}$. Thus the RMSE-IIEE is always positive, and the bias is positive if neXtSIM is overestimating the total extent and negative if it is underestimating it. ~~This definition of the~~ For the ice velocity we define the bias and RMSE as the mean and RMS values of the difference in speed respectively — i.e. $\langle |\mathbf{u}_{\text{mod}}| - |\mathbf{u}_{\text{obs}}| \rangle$ and $\langle (|\mathbf{u}_{\text{mod}}| - |\mathbf{u}_{\text{obs}}|)^2 \rangle^{1/2}$. We also define the vector RMSE (VRMSE), as the RMS of the vector difference, $\langle |\mathbf{u}_{\text{mod}} - \mathbf{u}_{\text{obs}}|^2 \rangle^{1/2}$. Note that these drift errors can only be calculated where both model and observation have ice.~~

Table 1. Accuracy of the free run. Concentration and extent are evaluated against OSI-SAF SSMI; thickness is evaluated against CS2-SMOS; drift against OSI-SAF drift, where observations with reported error up to 10 km/day are considered. Results are 2-monthly-averaged.

	Bias	Concentration, %
Nov-Dec 2018	4.91	9.97
Jan-Feb 2019	2.73	6.94
Mar-Apr 2019	1.41	5.38
May-Jun 2019	-1.65	17.84
Jul-Aug 2019	-2.47	18.79
Sep-Oct 2019	1.90	14.43
Nov-Dec 2019	3.47	10.86
Jan-Feb 2020	2.76	6.06
Mar-Apr 2020	1.36	4.90
May-Jun 2020	-0.99	16.14

15 Figure 2 compares the mean concentration from neXtSIM and the OSISAF concentration product (see ??). Two-monthly averages values for the errors are plotted as dotted lines and are also shown in Table ?? Table 1 shows 2-monthly summary statistics for observations that are available year round (although they are much less reliable between May and September). Errors which are particularly high are the RMSE in ice concentration and the IIEE for extent between May and August — we will discuss reasons behind this below. The bias is initially oscillating about zero, but this drops around the start of March to about -2.5 in these quantities is quite low, being highest between November and December, reflected an ice advance which is too fast. The drift on the other hand compares quite well throughout the period, with the VRMSE being generally less than 4.5 %. Towards the end of April, however, a significant low bias has developed. However, the bias is mostly well within the level of the observational errors. The RMSE is generally within the error range, but like the bias, it starts to leave it around the end of April km/day and the RMSE in speed less than 3.3 km/day (with the exception of the first two months). The bias is quite low, staying between ± 0.8 km/day. The first two months have a bias of zero, despite their high VRMSE and RMSE, with a too-slow Beaufort Gyre cancelling a too-fast drift in the triangle between the north pole, Svalbard and Franz Josef land.

5 Figure 4 shows the spatial distribution of the concentration bias. There are some prominent regions of Table 2 shows the effect of restricting the drift evaluation to regions where the observational error is less than 1.25 km/day. As discussed in Section 2.2 this removes the entire period from May to September, as well as the MIZ, the area around the north pole and areas close to the coast. Without the less accurate observations, the drop in VRMSE is between 0.3 – 1 km/day, with their values now between 3 and 4.1 km/day. However, the less accurate regions are also regions where the model has difficulties with other variables like thickness and extent, so this could also contribute to the reduction in error. Notwithstanding this, the Nov – Dec 2018 period is now much less of an outlier, now being quite close to Nov – Dec 2019. The RMSE in speed is now less than 2.6 km/day while the bias is between ± 0.3 km/day. There is a clear deterioration going from the first to the second winter.

Table 2. Accuracy of the free run ~~Concentration for the 2018 – 2019~~ and ~~extent are evaluated against OSISAF SSMI; thickness 2019 – 2020~~ winters. Thickness is evaluated against CS2-SMOS; drift against ~~OSISAF-OSI-SAF drift, where only observations with reported error less than 1.25 km/day are considered.~~ Results are ~~averaged over three periods: November – December, January – February and March – April or just March (CS2-SMOS ice thickness is not available in April) 2-monthly-averaged.~~

	Thickness, m		Drift, km/day				
	Bias	RMSE	Bias	RMSE	Bias	RMSE	VRMSE
Nov-Dec 2018	0.14-0.09	5.83-0.26	-0.02-0.13	0.23-2.62			-0.12-4.06
Jan-Feb 2019	0.26-0.09	-0.06-0.36	2.74-0.26	4.05-2.22			3.27
Jan-Feb-Mar-Apr 2019	-0.26-0.07	4.73-0.51	0.04-0.24	0.16-2.21			-0.01-3.03
Nov-Dec 2019	0.35-0.04	0.25-0.40	2.52-0.19	3.58-2.59			4.11
Mar-(Apr)-Jan-Feb 2020	-2.52-0.23	6.05-0.46	-0.10-0.27	0.21-2.41			-0.06-3.69
Mar-Apr 2020	0.53-0.19	0.39-0.56	2.59-0.01	3.49-2.39			3.64

Table 2 also summarises the comparison of model thickness with the CS2-SMOS product. RMSE is lower (0.26 m) in Nov-Dec 2018 since thickness was initialised using CS2-SMOS, and grows to 0.51 m over the first winter. The RMSE grows from 0.4 m to 0.56 m over the second winter. The bias is quite low in the first winter, but about 0.2 m from Jan – Apr 2020.

5 Figures 2 and 3 compare the mean concentration and extent from neXtSIM and the OSI-SAF concentration product (see 2.1). Since we do not have enough information to create an error model for the concentration observations (for example it cannot be Gaussian due to its restriction to being between 0 and 100%) we could not generate confidence intervals for the mean concentration, but instead plot a shaded area corresponding to $\pm(\sigma_{\text{OSISAF}})^{1/2}$ for reference when considering the bias and RMSE in concentration. The seasonal cycle for mean concentration and extent is captured reasonably well, but the bias is clearly positive in winter and clearly negative in summer. As noted from Table 1 the RMSE in concentration and the IIEE are 10 very high between mid-April and August. The RMSE in concentration is generally comparable to the RMS error level outside these periods.

Figure 2. Temporal comparison of model and OSI-SAF SSMI concentrations. The shaded area in the lower plot shows the RMS uncertainty of the concentration for reference when considering the errors. The bias is defined as model – observation.

Figure 3. Temporal comparison of extents from model and OSI-SAF SSMI concentrations. The shaded area in the lower plot shows an estimate for the uncertainty in the extent. The bias is defined as model – observation.

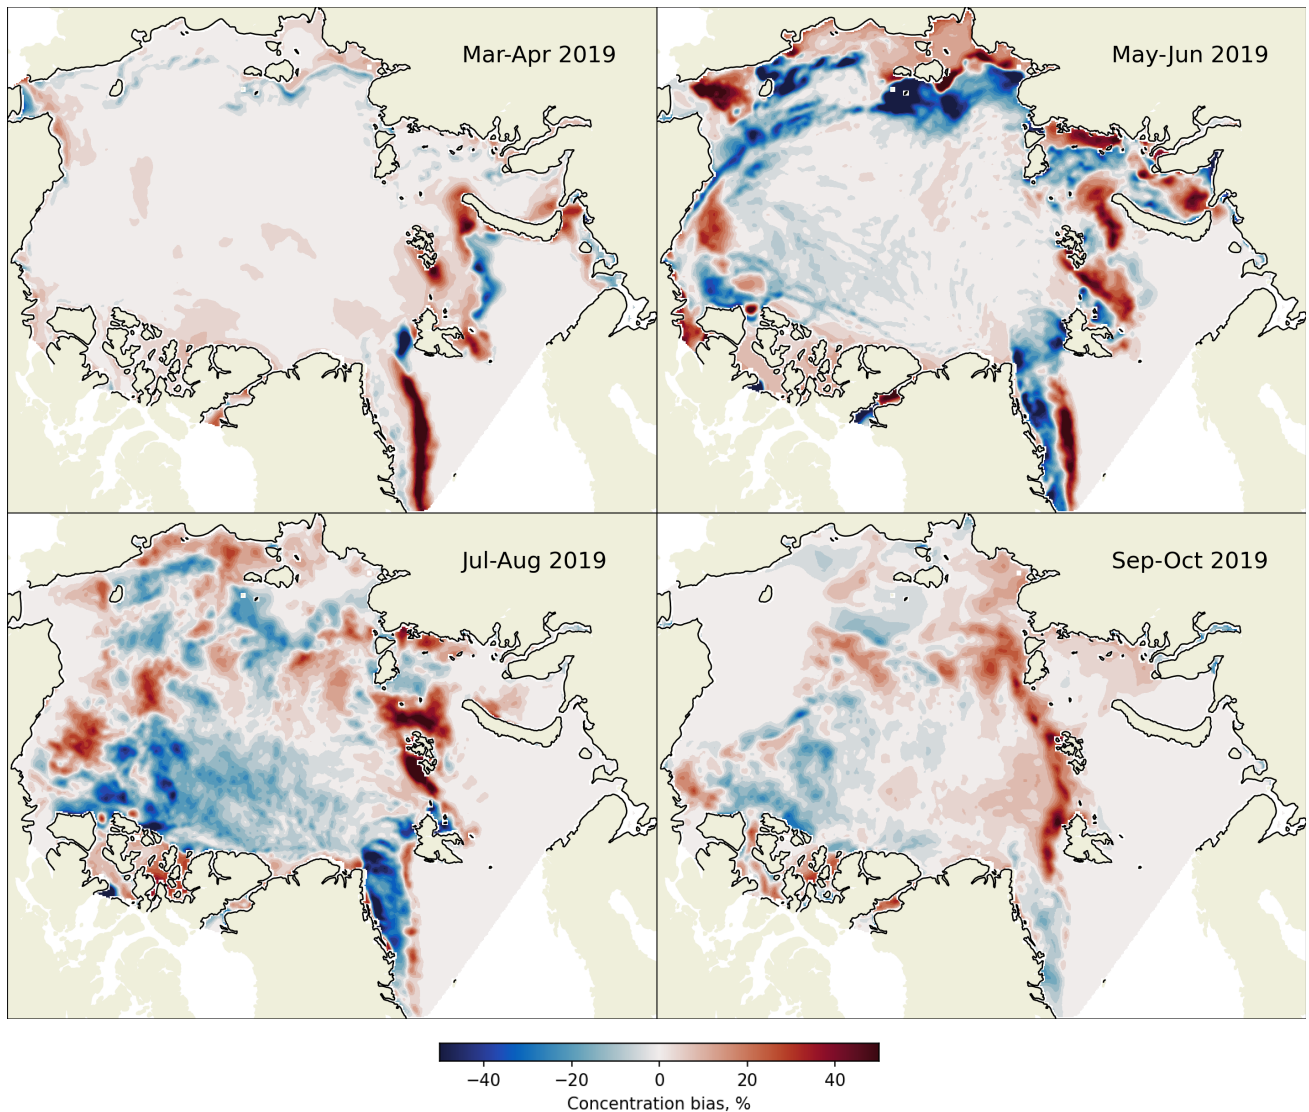

Figure 4. Spatial comparisons of selected 2-monthly-averaged concentrations from the free model run and from OSI-SAF SSMI. The bias is defined as model – observation.

Figure 4 shows some selected maps of the concentration bias. In Jan-Feb there is a general overestimation in the pack as the model is approximately 100% with some leads, while the SSMI field has large regions of lower concentration that contribute to the errors (85 – 90%). There is also a general overestimation in ice extent, which is also the case in Nov-Dec, primarily located in the Greenland Sea, and the Barents Seas. **Particularly persistent are the** The areas north of Novaya Zemlya (around the Santa Anna Trough), around Franz Josef land, and northwest of Svalbard. ~~However, the area~~ stand out as places where the ice edge

is not being located correctly. This continues into Mar-Apr. The region of underestimation to the northwest of Svalbard starts to become underestimated around mid-February.

20 The map for Nov-Dec shows strong underestimation in the Bering Sea, which was too slow to freeze up in November, and north of the Novo-Sibirski Islands related to the development of an arch between there and the northeast tip of Greenland. (This is also related to relatively large thicknesses in these areas, which increases the capacity of undamaged ice to stay undamaged.) This arching also reduces the ice export through the Fram Strait, the effect of which is seen in the maps for May–Jun and Jul–Aug. In May–Jun we also see that the ice that is in the Greenland Sea is displaced too far to the east, producing a double penalty effect in the RMSE score. This is strongest from about 3–11 Nov. It also returns at the start of 25 April, although the region extends further in this period than at the start of the winter, following the Siberian coast around to the Severny Islands. There are also significant underestimations at the end of the simulation along the coasts of the Beaufort Sea (particularly Mackenzie Bay), and the Bering and East Siberian Seas. In addition, also a result of the ice off Greenland is being driven away from the coast too much, leading to a double penalty in the RMSE score at the end of the simulation. arching in this area — the ice at the corner of Greenland is too thick to be exported, and so the ice that is exported has detached 30 from the arch away from the coast and has then travelled roughly parallel to the coast without being pushed back towards it. In Jul–Aug the thicker ice has mostly melted and there is less of a dipole situation and more of a clear-cut underestimation.

Temporal comparison of model and OSISAF concentrations. Two-monthly average values of the different errors are plotted as dotted lines with colours corresponding to the solid lines; these values can be found in Table ???. Another problem area is around the Novo Sibirski Islands and the Laptev Sea. April sees the model opening slightly too far to the north; in May and 35 June there is a strong underestimation to the north of the islands and too much fast ice. The underestimation is partly from too fast melting and that the fast ice has not detached and flowed into this area.

There is a similar problem to the west of Wrangel Island in the Chukchi Sea — an opening that is too large compared to the observations and too much land-fast ice close to the coast which should be flowing into this region. There is also a large region of overestimation to the east of Wrangel Island, which is actually an artefact of the boundary conditions that we are using at 5 the open Bering Strait boundary. If there is inflow at any open boundaries the value of any tracers is taken to be its value in the nearest mesh element, and in this case we are getting too much ice being imported through the Bering Strait, which leads to a build-up at this location.

The last things to mention about the Jul–Aug map are the strong overestimation around Franz Josef land, and the dipole situation in the Beaufort sea, which is the result of a too-slow Beaufort Gyre.

10 However, by Sep–Oct, the situation has improved substantially. The main disagreement is in the ice edge from Severnaya Zemlya round to the just past Svalbard. This is due to an ice advance that is slightly too fast.

Figure 5 shows time series of mean thicknesses and of thickness errors when compared to CS2-SMOS, while Figure 6 also shows the spatial distribution of the errors. Also refer to Table ??? for the two-monthly averages and the average for March. Since our run was initialised from this product, the RMSE begins well within the observation error levels, but it grows steadily 15 over the winter, leaving the shaded area in mid-December which have already been discussed to some extent in the context of Table 2. The mean observed and modelled thicknesses show a steady increase after November, but the modelled value is

Figure 5. ~~Spatial comparisons~~ Comparison of 2-monthly-averaged-model and OSISAF-concentration ~~CS2-SMOS thickness.~~ The shaded regions show the RMS uncertainty in the CS2-SMOS product for reference. The bias is defined as model – observation.

increasing faster than the observed one. The timing of when the modelled increase starts is close to when the observed increase starts. The lower plots have the RMS uncertainties plotted for reference, and the model bias is generally at a similar level to this uncertainty. The RMSE is about twice this uncertainty in the second winter. We note here that the error levels in the CS2-SMOS product are only the interpolation error, and are thus a lower bound as they don't include uncertainties in the individual CS2 and SMOS products. CS2 in particular is sensitive to the ice and snow densities used or the snow thickness which affect the conversion from freeboard to thickness (Zygmuntowska et al., 2014).

To a large degree, this growth in RMSE is a consequence of misplacement of the ice edge. However there seems to be systematic underestimation in the central Arctic, and overestimation to the north of Greenland. More local differences are seen around Banks Island off Canada. In at least one case (26 Nov-

Figure 6 also shows the spatial distribution of the errors. Throughout the winter there is overestimation off the north coast of Greenland round to Axel Heiberg Island. Further to the west there is a thinning (but not an opening) from Axel Heiberg Island to Ellef Ringnes Island which also seems to be related to the westward drift along this coast being too high. This persists throughout the winter but the affected area reduces with time. In Oct–3 Dec 2018), this is due to opening to the north and east of Banks Island (seen in Sentinel-1 SAR images), which was captured by the model but which occurred in-between CS2 altimeter passes. Since the ice around there was too thick for SMOS to be reliable, this opening was not present in the CS2-SMOS product that week. Therefore it is likely that the RMSE at the start of winter is being overestimated due to cases like this where relatively thick ice in regions of infrequent CS2 coverage is still quite mobile. Dec there is a dipole pattern where the ice is too thin in the Beaufort Sea and too thick in the triangle between the north pole, Svalbard and Franz Josef Land. However, in Jan–Apr, this dipole reverses.

The thickness bias begins slightly negative, but increases to a plateau near zero after about 2 months, remaining around there for the rest of the simulation. While it is encouraging that the mean thickness in the model (roughly total volume in domain divided by total area) is approximately the same as for the observations, modelled thickness is also quite high around the growing underestimation in the central Arctic must be compensating for overestimation elsewhere. We will discuss this further in the context of the drift results below, noting that the interpolation error of north of Svalbard, in contrast with the CS2-SMOS

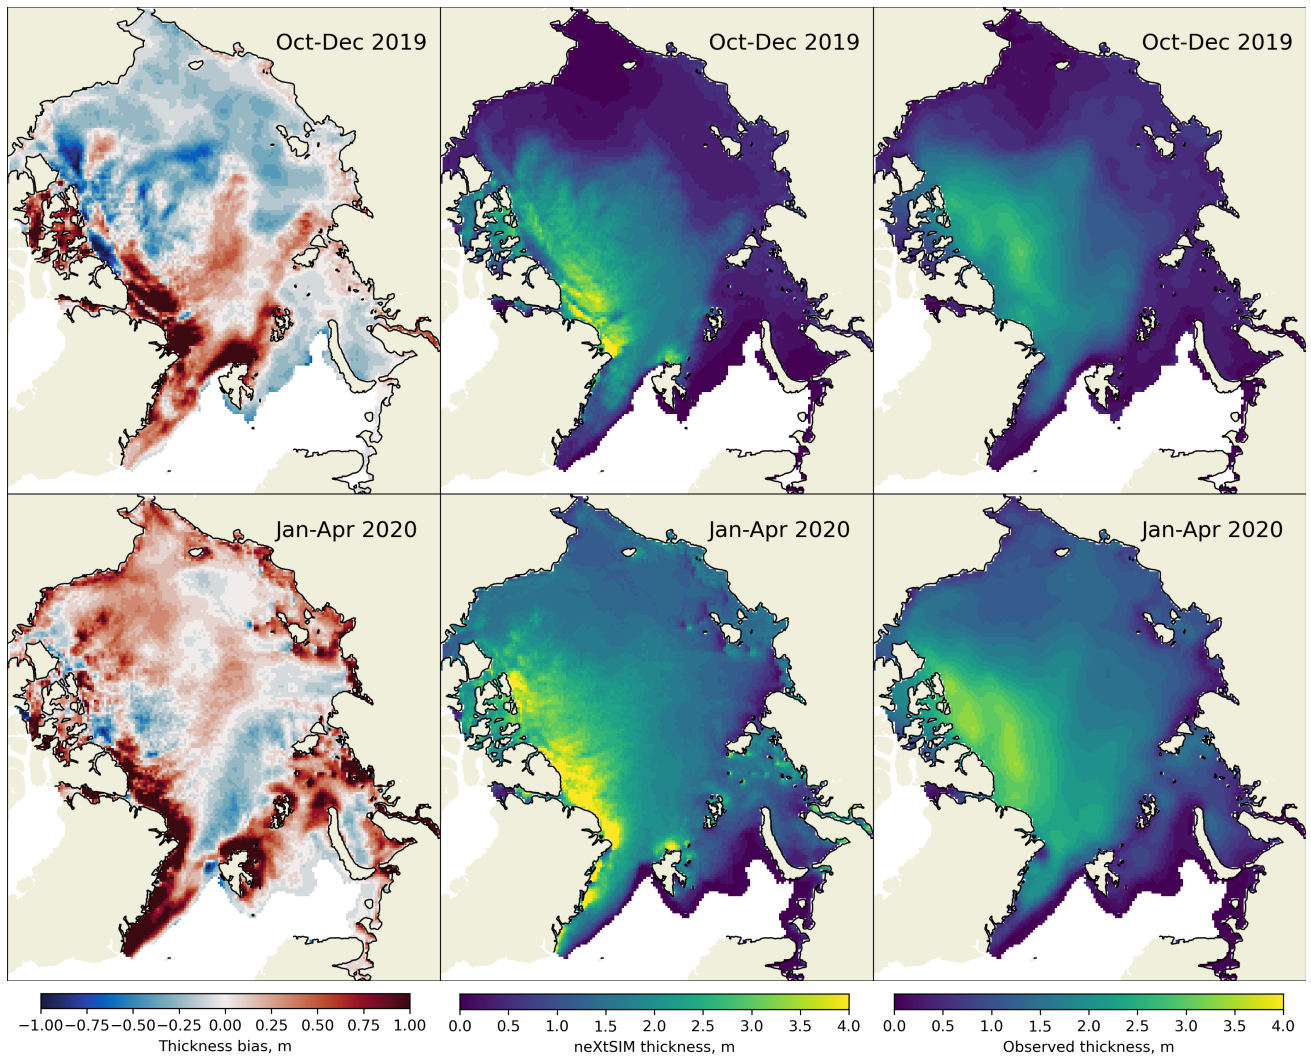

Figure 6. Comparisons of 2-monthly averaged model and CS2-SMOS thickness. Left hand column: bias maps; centre column: neXtSIM thickness; right hand column: CS2-SMOS thickness. The bias is defined as model – observation.

Figure 7. Comparison of model and **CS2-SMOS thickness** **OSI-SAF drift**. The shaded **regions show** **region shows** the RMS uncertainty in the **CS2-SMOS** **OSI-SAF drift** product. **The bias is defined as model – observation.**

is also quite high in the central Arctic **product**, which has quite thin ice. This build-up contributes to the arching discussed in relation to the concentration errors, reducing the ice export through the Fram Strait. This stems from damaged ice not having enough resistance to compression. In the BBM rheology there is a balance between resisting compression enough to stop the build-up of ice at the coasts and resisting it so much that drift becomes too slow.

Figure 7 shows the drift bias and RMSE of neXtSIM when compared to the **OSISAF** **OSI-SAF** drift product. The **two-monthly averages are plotted as dotted lines and are also shown in Table ??**. The **bias shaded area** corresponds to $\langle 2\sigma_{\text{OSI-SAF}}^2 \rangle^{1/2}$, where the factor of 2 comes from the fact that drift has two components. We also note that if one cell has components (x_i, y_i) with (not-necessarily-Gaussian) noise $(\varepsilon_i, \delta_i)$ added to it (each with zero mean and variance σ_i^2), the mean-squared drift in the presence of noise,

$$\langle \bar{d}^2 \rangle = \frac{1}{N} \sum_{i=1}^N \langle (x_i + \varepsilon_i)^2 + (y_i + \delta_i)^2 \rangle = \frac{1}{N} \sum_{i=1}^N \langle x_i^2 + y_i^2 + \varepsilon_i^2 + \delta_i^2 \rangle = \frac{1}{N} \sum_{i=1}^N (x_i^2 + y_i^2 + 2\sigma_i^2) = \langle d^2 \rangle + 2\langle \sigma_{\text{OSI-SAF}}^2 \rangle \quad (6)$$

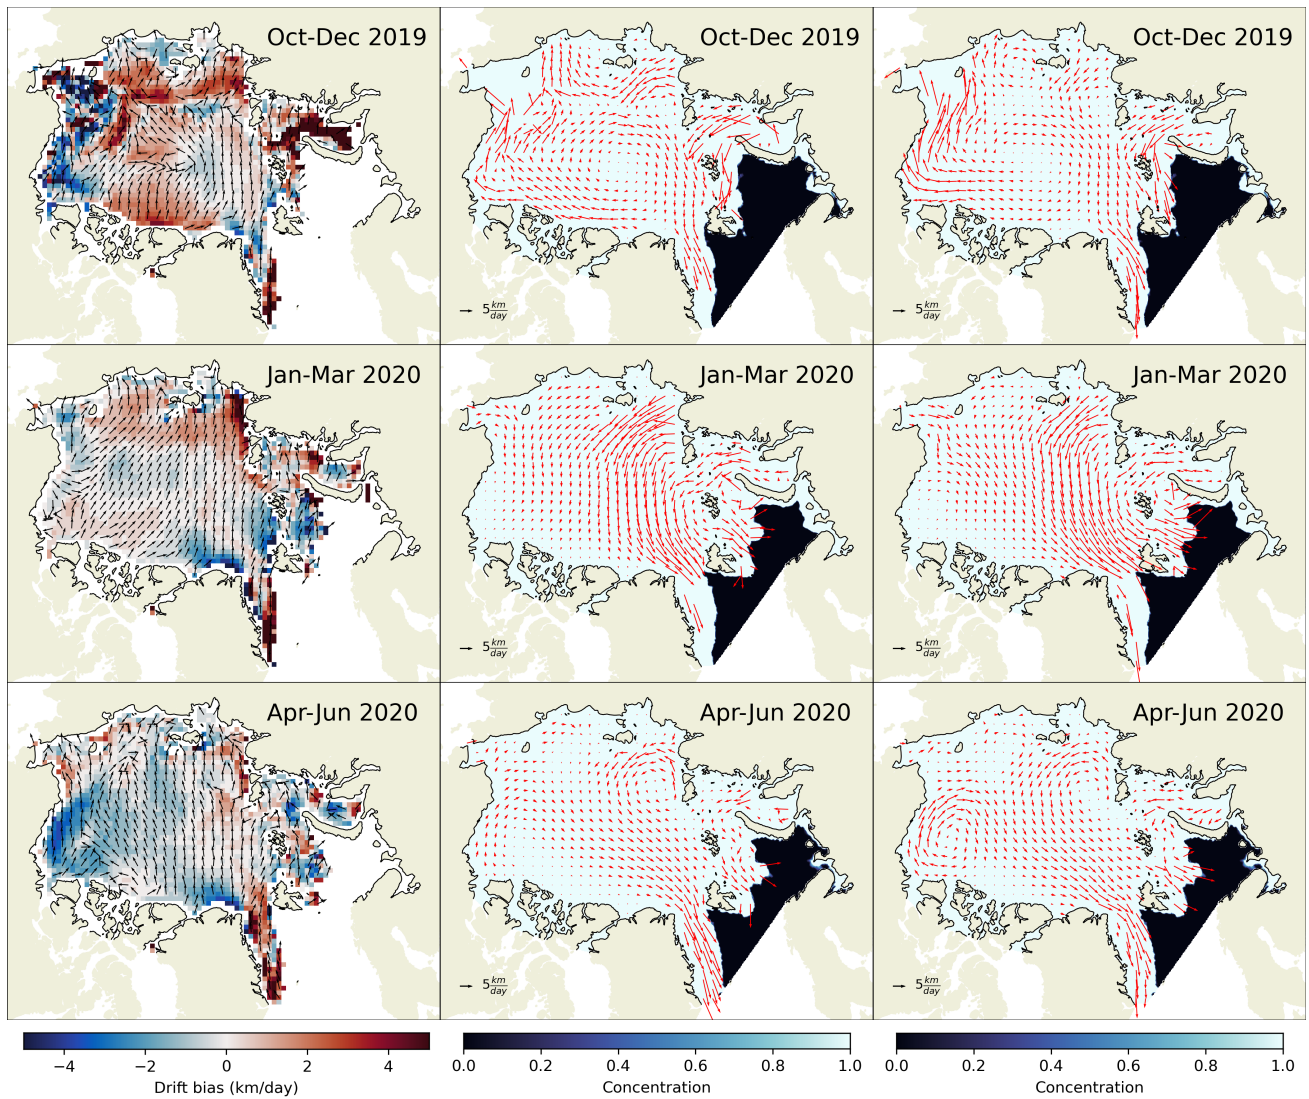

Figure 8. Comparisons of 2-monthly averaged model and [CS2-SMOS-thickness](#) [OSI-SAF drift](#). [Left hand column](#): [The drift bias colour maps](#) [-centre](#) (left column:-) show the bias in speed, while the directions show the difference between the model and observation directions (arrows pointing up indicate the directions are the same). The central column shows ice velocity vectors from [neXtSIM-thickness](#)-, while the right hand column [-CS2-SMOS-thickness](#) shows OSI-SAF vectors. The concentration colour maps show the average [neXtSIM](#) concentration over the analysis period to indicate the approximate ice mask. The bias is defined as model – observation.

is higher than the noise-free ("true") value $\langle d^2 \rangle$ by $2\langle \sigma_{\text{OSI-SAF}}^2 \rangle$. It is tempting to then just subtract this amount from the speed when comparing with the model, but we decided that the uncertainty in the quoted uncertainty could be too influential and also that the model drift has some unknown uncertainty associated with it so we persisted with directly comparing the drift in the OSI-SAF product with the model drift in order to judge when the model is too fast or too slow, and plotted the error level $\langle 2\sigma_{\text{OSI-SAF}}^2 \rangle^{1/2}$ for reference. The difference in speed (model speed - observed speed) fluctuates somewhat, but stays largely within the error limit of just over ± 1 . The RMS error for this product is approximately 1.8 km/day. The RMSE in speed is very good, averaging about 2.7 km/day from October to May, but increases to about 4 km/day for the whole winter with a maximum of about 4.5 km/day from May to September. However, the model is starting to show signs of being too slow in April and May 2020. The RMSE in speed ranges between about 3 - 4.5 km/day, which is outside the estimated error for the more accurate colder months. The VRMSE (vector RMSE) for the drift is higher than the bias, RMSE and the observation error, since it also includes errors in direction, but it is still quite low, ranging from about 3-5.5 km/day. It is highest in November-December, averaging 4.1 km/day, dropping to an average of about 3.6 km/day for January-February, and then to about 3.5 km/day for March-April.

Comparison of model and OSISAF drift. The shaded region shows the RMS uncertainty in the OSISAF drift product.

Figure 8 shows the general spatial pattern in the errors: drift is too slow in Mackenzie Bay and towards the Alaskan coast of the Beaufort Sea, and too fast in the MIZ and where the ice is thinner, especially the Laptev Sea. Note the bias maps are slightly eroded (near the ice edge, coast, and the north pole — see the discussion in §??) compared to the ice mask since we have not used observations with errors higher than 1.25 km/day. In November drift errors. The maps for Oct - December, the averaged drift map for the OSISAF product shows a reasonably strong Beaufort Gyre but which is centred nearly in line with the Bering Strait. There is a strong eastward current in the East Siberian Sea and a quite wide trans-polar drift which extends over to Severnaya Zemlya and the Franz Josef Islands, although it is more connected to the Laptev Sea than the Bering Sea. These latter two features are mostly captured by the model, but it is not quite capturing the full Beaufort Gyre. This may be partly due to too much land-fast off Canada. With the exception of around the Beaufort Gyre and the Canadian Archipelago, the directional bias is quite low. Dec 2019 show that the general circulation of the model and the observations are agreeing well, with the main feature being the gyre in the central Arctic Ocean. However, this gyre is slightly too fast and there is also too much westward drift along the Canadian archipelago. The observations also show a small gyre in the East Siberian sea which is not apparent in the model drift. The strongest positive bias is in the Kara Sea although the errors in the observations are high there, being both close to the coast and the MIZ. The model is also showing strong positive biases in the Laptev and East Siberian seas where the ice is thinner. On the other hand, the drift in the Beaufort and Chukchi Seas is too slow.

In January-Jan - February, the Beaufort Gyre is more concentrated in the Beaufort Sea, while the transpolar drift is extending across the entire Arctic from the Bering Sea. There is also an anticyclonic pattern in Mar 2020, the general pattern in the observations is a strong flow from the Laptev over to the Greenland Sea, with a weaker transpolar drift from the Chukchi Sea joining this outflow. The model also produces the flow from the Laptev Sea, centered close to Severnaya Zemlya. The model is capturing this behaviour quite well, reflecting the drop in VRMSE to a very respectable 3.6 km/day for this period, but it

is again missing the coastal part of the Beaufort Gyre. The model direction has much improved from November–December, with most of the arrows in the bias map pointing up but the flow from the Chukchi Sea is more directed towards the Beaufort Sea than across to the Greenland Sea. This may be contributing to the biases seen in the thicknesses — this probably explains the drop in VRMSE from the first analysis period, too thick in the Beaufort Sea while too thin in the region between the Laptev and Greenland Seas. The drift is also starting to become too slow north of Greenland and Svalbard, and this is most likely due to the ice build-up in those areas.

For the March–April period, the drift pattern is more like that of November–December, although there are fewer valid drift vectors. The VRMSE for this period is now about 3.5 km/day, and in Jun 2020 there is a stronger Beaufort Gyre and a similarly strong cyclonic gyre in the Laptev Sea. These connect to form quite a wide stream from the central Arctic to the model drift pattern is quite close to that of the OSISAF product (including the full Beaufort Gyre this time). The directional bias is again relatively low, but is not quite as good as for the January Greenland Sea. While the model captures the gyre in the Laptev Sea, the Beaufort Gyre is less well-defined in this period, possibly due to the ice being too thick in the Beaufort Sea at this time. As in Jan – February period, Drift is also too slow to the north of Greenland.

4.2 Evaluation of forecasts with assimilation

4.3 Evaluation of forecasts with assimilation

The impact of assimilation on the forecasting skills of the model was tested in two experiments. First, we ran a single, 7-day forecast without assimilation, with assimilation of concentration and thickness. Second, the model was run for 6 months with daily assimilation of concentration and thickness. In this experiment, in was evaluated over the same period as the free run was in Section 4.1 (that is the 20 months from November 2018 to the end of June 2020). In order to reduce computation time, the 7-day forecasts were launched only every three approximately only every seven days with 1-day forecasts being launched in between so that assimilation was still performed daily.

The model performance was evaluated against satellite observations of the blended sea ice concentration and sea ice extent from OSISAF (see sec. ??) and SMOS thickness (see sec. ??) sea ice SSMI concentration and drift from OSI-SAF (see Sections 2.1 and 2.2). The bias and RMSE of the forecast sea ice fields were compared with the metrics we used in our assessment were: bias and RMSE of the field averaged over the first day. In the first experiment only errors from a single 7-day forecast (starting on 7 Nov 2018) were evaluated; in the second one time series of observed and forecast variables were plotted and analyzed.

The evaluation shows that even without assimilation the model predictions of ice extent and thickness (orange lines on fig. ??) are better than the persistence fields (blue lines on fig. ??). Assimilation of concentration only (shown by green lines) reduces RMSE and bias for both concentration and thickness compared to the run without assimilation. Assimilation of thickness (red lines) has a smaller impact on the concentration forecast but significantly reduces the RMSE of the thickness. The bias in the forecast concentration and thickness is greatly reduced by the assimilation and stays closer to zero than the bias in the

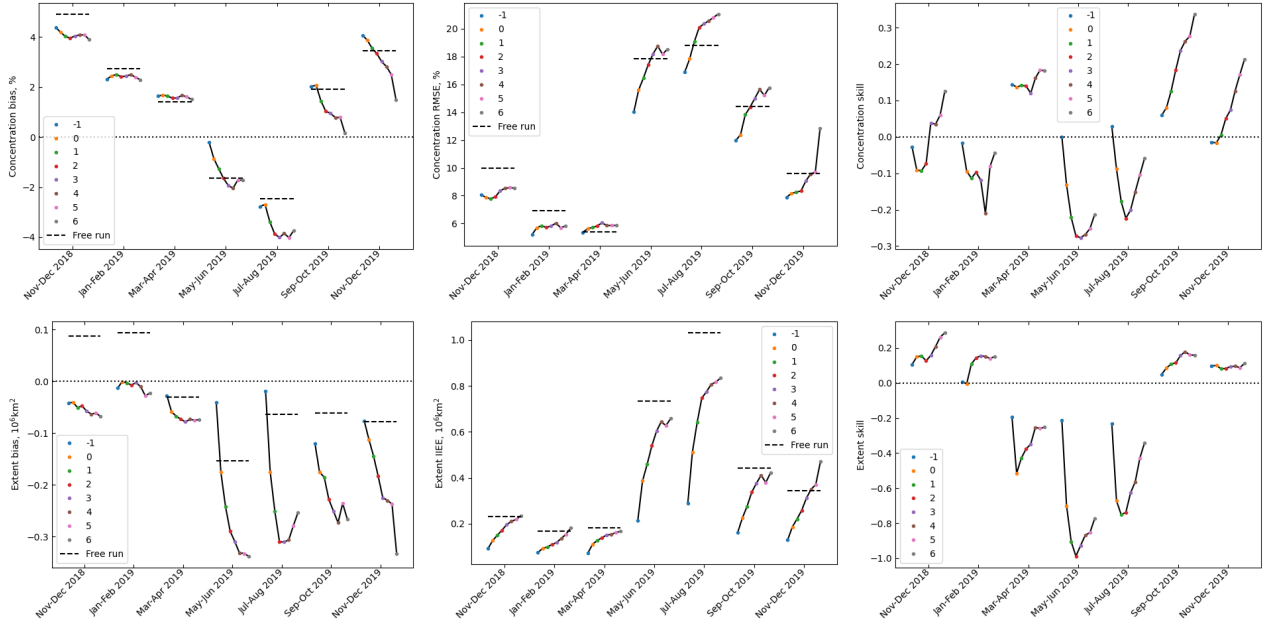

Figure 9. 2-monthly-averaged forecast errors grouped by lead time (lead times are indicated in the figure legends). The free run errors for the corresponding periods are plotted as dotted lines for reference on the bias and RMSE/IIEE plots. Upper row: 2-monthly-averaged bias, RMSE and forecast skill for concentration grouped by lead time. Middle row: 2-monthly-averaged bias, IIEE and forecast skill for extent grouped by lead time. Lower row: 2-monthly-averaged bias, IIEE and forecast skill for extent grouped by lead time.

persistence forecast. The errors in concentration; bias and IIEE in extent; bias, RMSE and VRMSE in drift. A persistence forecast of concentration (the forecast are less than errors in the persistence forecast not only at the day of assimilation (shown by red arrow) but also for the entire 7-day run initial concentration, defined for technical convenience as the average of the first hour) was used as a benchmark for concentration and extent, and forecast skill was defined as:

$$10 \text{ Concentration skill} = 1 - \left(\frac{\text{RMSE}}{\text{RMSE}_{\text{persistence}}} \right)^2, \quad (7a)$$

$$\text{Extent skill} = 1 - \frac{\text{IIEE}}{\text{IIEE}_{\text{persistence}}}. \quad (7b)$$

Thus, a model that is agreeing perfectly with the observations has skill equal to 1, while it is negative (with no lower bound) if the persistence error is lower than the forecast error. We decided that given the strong dependence of drift on wind, its rapid variability in time would render a persistence forecast for drift a straw man, so for this variable we just present the forecast errors. We have rough benchmarks from some other models however. Although they use different products for their evaluation so we can't make a direct comparison, we note that the drift from the TOPAZ forecast generally has a bias in speed of about

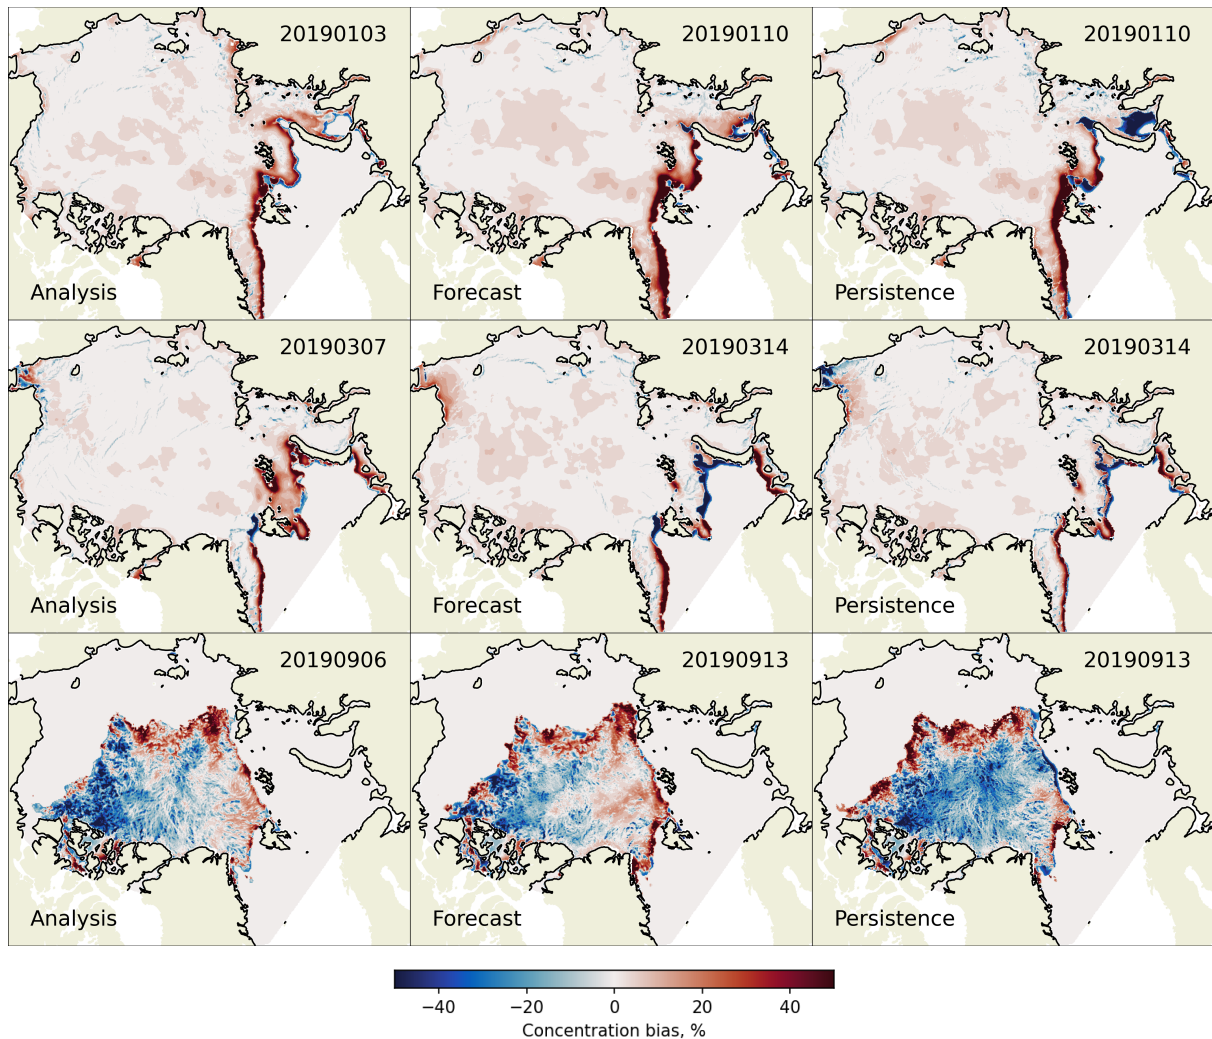

Figure 10. Comparisons Maps of 2-monthly-averaged model-daily-averaged biases in concentration compared to OSI-SAF SSMI for three examples of forecasts, starting on 3 January 2019 (upper row, positive skill) and OSISAF drift the other on 7 March 2019 (middle row, negative skill) and 6 September 2019 (lower row, positive). The drift bias colour maps (left column) hand columns show the bias in speed, evaluation for the first day of simulation (lead time -1: analysis or hindcast) while the directions-right hand columns show the difference between evaluation for the model and observation directions-eighth day of simulation (arrows pointing up indicate the directions are the samelead time 7). The central-column shows ice-velocity-vectors from neXtSIM, while the-right hand column shows OSISAF-vectors. The concentration colour maps-columns show the average neXtSIM-concentration over the analysis period to indicate bias in the approximate ice maskpersistence forecast for lead time 7. The bias is defined as model - observation.

Figure 11. Maps of daily-averaged biases in concentration compared to OSI-SAF SSMI, and modelled and observed concentrations, for an example forecast starting on 6 June 2019. The upper row shows the comparison for the first day of simulation while the lower row shows the comparison for the seventh day of simulation. The bias is defined as model – observation.

2 km/day and a VRMSE of about 5–8 km/day Melsom et al. (2018), while Metzger et al. (2017) report an RMS drift speed error of about 5–8 km/day in the Arctic for the GOFS 3.1 system.

5 ~~Figures ?? and ?? show the maps of bias in concentration and thickness-~~

Figure 9 shows the 2-monthly averages for the different metrics applied to the concentration and extent. We only plot results for the first day (4 Nov. 2018) and the second day (5 Nov. 2018) after the assimilation, respectively. Running the model even without assimilation helps to reduce large negative bias in concentration in the East Siberian and Chukchi seas. Assimilation of concentration helps to reduce this bias. The impact is evidently pronounced during year and two months, since the error statistics from the 2020 results were nearly identical to the previous years. As with the free run, the first day in both correcting average concentrations in the pack ice (e. g. concentration from the forecast is generally higher than OSI-SAF in the winter months. As mentioned earlier, we don't try to correct this as reducing the concentration in the pack causes serious problem with the drift and thickness. The extent, which is adjusted during assimilation is also lower than the observed one for the whole period, by differing amounts. Figure 10 show some example forecasts from winter and autumn, one from January, March and September 2019 respectively. The first and third examples are forecasts with positive skill in extent (model does better than persistence), while the second has negative skill. However, they all have relatively low IIEE and RMSE in concentration. The

Figure 12. Evolution of 2-monthly-averaged bias, RMSE (left column) and bias-VRMSE for drift grouped by lead time (right column lead times are indicated in the figure legends). The lead times refer to the start of persistence (blue line), forecast without assimilation each 2-day drift evaluation period e.g. “0” covers the period from day 0 (orange 12:00) -forecast with assimilation of SIC only to day 2 (red 12:00) and forecast with assimilation of SIC and SIT. Upper row of plots show The free run errors in sea ice extent and for the lower row—in thin ice thickness corresponding periods are plotted as dotted lines for reference. The red arrows show the step at which assimilation was performed bias is defined as model – observation.

Maps of bias in concentration (upper row) and thin ice thickness (lower row) for 3 different cases: persistence, no assimilation, assimilation of SIC and SIT. The biases are averaged over 8 Nov 2019—the first 24 hours after assimilation:
 Maps of biases for 9 Nov 2019—after 48 hours after assimilation (see caption of fig. ?? for details):

January example shows that the rapid advance in the Kara sea) and adjusting the ice edge position (e.g. in the Fram strait and Barents sea). Assimilation of thickness improves thin ice fields (e.g. in the Laptev). After 2 days the impact of assimilation is less pronounced (see Figure ??), however it is obvious that the errors in concentration, thickness and ice edge position are still smaller than those from the persistence field and the fields from Sea is captured relatively well by the model, and while the extent in the Greenland and Barents Seas is too high, the ice edge is quite variable and the model is doing better than the persistence at this time. The March example shows an example where there is quite a persistent negative bias to the northwest of Svalbard and in the Barents Sea. These errors probably originate in the ocean forcing and which we are unable to overcome, even with our flux compensation. The persistence forecast does well in this example since the ice conditions are not changing very much. In the September example, the bias is similar to the free run but it has been reduced by the assimilation. There is still a too-fast ice advance in the European Arctic but it is closer to the observations than the persistence forecast.

Figure ?? shows time series of mean quantities from the second experiment with assimilation, while Figures ??, ??, and ?? present maps of bias averaged over the full period. Tables ?? and ?? summarise the average errors from this experiment. They indicate that concentration, extent, thin ice thickness and drift are consistently well predicted. The 7-day forecasts of concentration (coloured lines on fig. ??, top) are close to In the summer, we are systematically lower in concentration, partly due to differences in the pack, which we don’t correct for, and in the extent. We are not too concerned by differences in the pack, as the differences are still comparable to observation error. Differences in the extent however are more concerning. In the observations (black line, Figure ??, top) and stay well within the observational uncertainty (grey shaded area, Figure ??)

not only during the period of rapid freeze-up (Nov–Dec) but also once ice growth has stabilised (Jan–Mar). The RMSE of concentration predictions on the first day (4th day) is around 4% (6%) with a slight negative bias of around -0.2% (-5%) (see Table ??). In November–February period the areas with negative bias (up to -20%) of the concentration forecasts are predominantly located in the central Arctic. The ice edge in the Barents and Greenland seas is characterised by overestimation of ice concentration by 20–40%. In March–April sea ice concentration in the Barents Sea and Fram Strait are strongly underestimated with average negative bias in concentration of -2%.
summer, we score particularly badly with this metric, largely due to the dynamical problems also seen in the free run: arching above the Fram Strait, and fast ice in the Laptev and East Siberian seas that is too slow to detach. Figure 11 shows a typical example from this time period. Despite the correction in extent during assimilation the ice that is added in the Fram Strait is quite thin and it melts quite quickly.

Sea ice extent predictions also closely follow observations: RMSE on the first day (4th day) does not exceed 10^5 km^2 ($1.8 \times 10^5 \text{ km}^2$) with overall a minor negative bias of $2-10 \times 10^4 \text{ km}^2$ (see Table ??). Note the large improvement in extent from Figure 12 shows the bias, RMSE and VRMSE for the forecast drift. It has similar quality to the free run (also see Table ??).

Thin ice thickness overestimates by the model are consistently higher than observations by 1–2 cm on the first day of forecast and 3–, which is to be expected since we are not modifying fields in the pack, with minor differences that are probably just due to differences in extent determining which observations are included or not. There is a small negative bias in speed in the winter months, and a slight positive bias in the summer. The bias is not showing a large variability with forecast lead time, although there are some exceptions. With the exception of the first two months, which is slightly higher than the others, the RMSE (RMSE in speed) is quite consistent throughout the whole evaluation period with a steady increase with lead time. The RMSE for the final day is still mostly less than 5 cm on the 4th day with RMSE growing from 7 to 10–14 cm. Area of thin ice is considerably larger in November–December than in January km/day. The VRMSE, which evaluates the drift direction as well as its speed, shows a larger dependence on lead time, starting between 4.5–February.

Ice drift is predicted with very high accuracy: RMSE for drifters placed on the first day at midday (recall the OSISAF drift product covers a 2-day period) is between 2.8 and 3.25 km/day on average; the VRMSE is slightly higher, ranging from 3.8 but getting up to between 7–4.58 km/day. These values are about 0.5 by the final day (occasionally being under 7 km/day higher than for the free run (see Table ??), which used best estimates (i.e. the first day of each forecast forcing) for the atmospheric and ocean forcing; this part of the error is presumably largely due to error day or over 8 km/day). This dependence on lead time is almost certainly due to increasing inaccuracy in the forecast winds (our forecasts use the full forecast forcing corresponding to the start day of our forecast). The RMSE and VRMSE do not show significant variations within the studied period from.

5 Discussion and conclusions

neXtSIM-F became operational in July 2020 as part of CMEMS, and this paper presents an upgraded version that will be included in December 2020. Here we have evaluated the neXtSIM model itself in a free run for the period 1 November 2018 to March 2019 and almost doesn't change during the first three days, implying the quality of the forecast drift is reasonably good

for the first four days. There is a minor negative bias of -0.2 km/day for Nov-Dec and slight positive bias of 0.05 30 June 2020, as well as the neXtSIM-F forecast platform which corrects the initial conditions daily by assimilating sea ice concentration.

The free run, which used hindcast winds, had good drift, being relatively unbiased and having a low RMSE in speed of 3 -0.18 4 km/day for Jan-Apr.

The RMSE and VRMSE in drifters placed on the fourth day is higher by about $1-1.5$. The RMSE was closer to 2.5 km/day, but the bias only increases by about 0.4 when less accurate observations (uncertainty less than 2.5 km/day. (For Nov-Dec, this actually makes it closer to zero.)

A map of forecast drift bias (see Figure ??) averaged over the entire period and for the first three days of forecast shows that the model underestimates eastward export of ice north of Greenland by $2-3$ km/day, underestimates anticyclonic drift in the Beaufort Gyre by $1-2$ km/day, overestimates the Transpolar Drift by 2 -day drift) were filtered out, although the observations so removed would also be near the coast and in the MIZ where we do have problems with thickness and extent respectively. Considering the VRMSE, the RMSE in the final position of each trajectory, added about $1-2$ km/day and overestimates westward drift in the Laptev sea by $3-5$ km/day.

Time series of sea ice concentration, extent, thickness and drift averaged over ice covered waters from OSISAF and SMOS observations (black line) and forecasted by neXtSIM (coloured lines). Error bars indicate the averaged uncertainty in the observations:

6 Discussion

The model thickness was biased slightly too thick in general, and there was also a tendency to have a dipole behaviour with one or too areas being too thick, and one or two being too thin. The location of these too-thin regions varied over the winter (the only time when the CS2-SMOS observations were available), but the thickness off northeast Greenland and north Svalbard

was invariably too high. This caused the formation of an arch across the Fram Strait, which limited the export of ice through this strait in the summer, especially close to the coast.

For our free run, the model is consistently overestimating the ice extent compared to the OSISAF SSMI concentration and this dominates the error statistics of both concentration and thickness. There also seems to be a negative bias in the central Arctic which could have a number of origins: problems in forcing like the heat fluxes/air temperature; snowfall from forcing; problems with dynamics. When we evaluated the concentration and extent we found that the sea ice extent in the summer was greatly affected by the arching mentioned above, in that the total extent was too small and that the ice was also displaced from where it should be — too much export (discussed further below), or too little convergence, or too little opening (which would lead to too little new ice formation); problems with the snow cover. However, the total bias is quite close to zero. The average drift errors are relatively good overall, with the total RMSE 3.5–4.5 km/day (being higher at the start of the winter). The main bias is in the Beaufort Sea where the model is consistently too slow, and the Laptev Sea where it is too fast. The drift in the Greenland Sea is consistently too fast, and the transpolar drift is also slightly too fast. This could be related to the overestimation in extent and also the thickness underestimation in the central Arctic.

Coming to the performance of the forecasts, there are several possible reasons why we observe overestimation of ice concentration and thin ice thickness by the model compared to satellite observations. First, the atmospheric forcing used both for the free run and the forecast may be underestimating air temperatures and, consequently increasing the heat loss from the ocean and concomitant growth of ice. Second, the passive microwave observations may be underestimating ice concentration especially in the vicinity of the ice edge where thin ice is dominating. At the same time SMOS observations of sea ice thickness there was no ice close to the boundary with thick ice thickness can also be quite uncertain and underestimated. Finally, the displacement of ice into open waters due to slightly overestimated drift in the model can lead to mismatch of the ice edge position east coast of Greenland (unlike in the observations) and it extended too far to the east.

Apart from the There were also less severe differences in the ice edge which were probably partly due to errors in the forecast winds, the observed discrepancies in the drift forecasts could be caused by the following. North of Greenland the sea ice may be simulated as too packed and rigid, which prevents sufficient fragmentation and slows down the drift. In the Beaufort Sea it is known that the TOPAZ4 system underestimates the speed of the ocean currents and misplaces the center of the gyre. The Transpolar Drift could be being overestimated due to positive biases in the atmospheric forcing and overly strong winds, and the too-thin ice in the central Arctic could also be playing a role. In the Laptev Sea the extent of fast sea ice is underestimated by neXtSIM. This comes from the fact that in the model polynyas open closer to the shore and therefore sea ice detaches from the fast ice in ocean and/or atmospheric forcings, but the other big issue was the extent of the wrong location and drifts offshore from there landfast ice in May and June in the Laptev and East Siberian Seas — if compared to observations from satellite, this was too slow to detach and also contributed to there being too little ice further away from the coast at this time.

We also presented and assessed a novel method of nudging: we introduced some compensation for excessive heat flux due to reduction of concentration in assimilation, whereby the heat flux in the model out of the ocean (this is primarily to the atmosphere) is reduced according to observations of sea ice concentration. This improves our forecasts of sea ice concentration, thickness and extent, reducing errors which occur due to biased atmosphere or ocean forcing. Our experiments

with the parameter n in (5) found that linear correction ($n=1$) is not sufficient for the improvement due to assimilation to persist longer than 4. Owing to the fairly conservative approach that we had to take to the assimilation the forecasts generally had the same properties as the free run with regards to thickness and drift. The bias in drift remains close to zero for the whole 8-day simulation, although the RMSE in speed and the VRMSE begin to deteriorate after about 4–2 days.

As written in the description section, running of the model requires relatively limited resources. That allows us to run the forecast system at high resolution and to cover the entire Arctic region. We use a workstation based on the AMD Ryzen Threadripper 2990WX CPU, which includes 32 cores being able to run at a base frequency/clock speed of about 3.5 GHz. Our experiments show that running of a 7-day forecast for the entire Arctic ocean at 7.5 km resolution (each mesh triangle is covering approximately 50 km²) takes approximately 22 min on 8 cores. Run time is proportional to the square of resolution (88 min for 3.5 km forecast) and decreases almost linearly with number of cores: 11.5 min for a 7.5 km forecast and 46 min for a 3.5 km forecast on 16 cores.

5 days of simulation (up to a lead time of 4) — this is almost certainly due to less accurate winds at these lead times. The forecasts also had greatly improved IIEE scores compared to the free run. However, the more serious problems with the summer extent — in the Greenland Sea (due to arching) and to a lesser degree the Laptev and East Siberian seas (land fast ice) — were still present in the forecasts. The neXtSIM-F forecast system has been tested for the northern winter of 2018–2019 with different data being assimilated and has been found to perform well.

Despite drift not being assimilated in our system, we obtain fairly good agreement with observations, comparing well to land-fast ice could possibly be improved with further tuning of the basal grounding scheme, while the arching problem is more difficult to solve. However, recent experiments indicate that changing the role of concentration in the more sophisticated coupled ice-ocean forecast systems TOPAZ and GOFS. Notwithstanding different time periods and data used to assess the different forecast systems, rheology could give some improvements here — note that the viscous relaxation time in (A3) and thus the entire left-hand side of (A6) only depend on damage and not on concentration so larger stresses do not drop very quickly if the ice is undamaged and the forecast sea ice drift by neXtSIM-F gives lower RMSE and VRMSE, and concentration drops (this makes the right-hand side of (A6) drop to near zero). There may be additional modifications to the bias remains close to zero over the whole period from Nov 2018–Apr 2019. The forecasts using saved atmospheric and ocean forecasts as forcing have good agreement with observations, with only slightly higher errors than the free run for the first four days which uses best estimates for the ocean and atmospheric forcings. rheology that could be made to help reduce arching in this region.

The neXtSIM-F forecast system assimilates OSISAF sea ice concentration and SMOS sea ice thickness by modifying the initial conditions daily and adding a compensating heat flux to prevent removed ice growing back too quickly. This greatly improved the agreement of these quantities with observations for the first 3–4 days of the forecast. Assimilation of different data might also help:

1. Sea ice thickness: we could use either the hybrid CS2-SMOS product or the CS2 trajectories themselves to limit the build up of ice on either side of the Fram Strait. However, this data stops in mid-April so build-up that occurs later may still be enough to cause the arching.

2. Sea ice deformation: Korosov and Rampal (2017) were able to derive sea ice drift from SAR data using a combination of feature tracking and pattern matching. Deformation can then be calculated to modify the damage variable and thus induce break-up at the right place. Unfortunately, this option is also time-limited as surface melt makes the ice smoother and stops the feature tracking algorithm from working as effectively.

20

~~neXtSIM-F will become operational in November as part of the Copernicus Marine Environment Monitoring Services (CMEMS), and the next steps in the evolution of the system are first to assess the forecast performance for the spring and summer seasons, and to increase the resolution from about 7.5 km to about 3.5 km. The former task is a challenging one as passive microwave data becomes less reliable in summer and the SMOS sea ice thickness product is only available from~~
25 ~~October to April. Thus the data we have used in this study will either be less reliable or else unavailable outside these months. One possible alternative is to use ice charts — e.g. Another possibility could be to take the approach of Ying (2019) and to morph the modelled ice mask onto the observed one so that, for example, ice in the Greenland sea could be moved over towards the coast, instead of removing thicker ice at the ice edge and adding thinner ice towards the coast. Possibly a better source of ice extent than OSI-SAF concentration could also be used in conjunction with such a morphing approach.~~
30 ~~For example,~~ the United States Naval Ice Center⁶ produces daily, pan-Arctic ice charts~~that could be used for correcting the ice extent.~~ Other alternatives for assimilating extent are MASIE ~~and IMS (used by GOFS: see sec. 3) and automatic~~ (Multisensor Analyzed Sea Ice Extent: Fetterer et al., 2010) and IMS (Interactive Multisensor Snow and Ice Mapping System: Helfrich et al., 2010) ~~as done by the GOFS 3.1 system for example. Automatic~~ ice type classification from SAR (~~synthetic aperture radar~~) ~~is also possible now~~ e.g. Zakhvatkina et al. (2017) presented an algorithm for processing Radarsat 2 SAR data, while an algorithm for processing Sentinel-1 SAR data under development at NERSC (Park et al., 2019) will also become operational in November 2019 ~~and be the algorithm developed by Park et al. (2019) and upgraded by Boulze et al. (2020) will become operationally~~
5 ~~distributed by CMEMS in 2021.~~

~~We also plan to test the benefits of assimilation of SAR-derived ice drift (Korosov and Rampal, 2017) on the system. The proposed approach would be to compute sea ice deformation rates from the observed SAR-derived drift and use this information to correct the damage field in the model. The expected outcome is to improve the location and timing of lead and ridge formation, as well as the large-scale drift pattern itself.~~ A framework to produce an ensemble forecast with neXtSIM-F is also
10 being developed (Cheng et al., submitted) (as a follow-up of the work of Rabatel et al., 2018), with the ultimate aim of using the Ensemble Kalman Filter (EnKF) assimilation method. Work on using EnKF with models running on adaptive meshes (like neXtSIM) is being developed in parallel at NERSC (Aydoğdu et al., 2019). This may also be effective at addressing some of the errors in the forecast.

Finally, in order to provide more consistent ocean inputs to the sea ice model (as well as to provide more realistic stresses and fluxes to the ocean model), work is ongoing to couple neXtSIM with the ocean models HYCOM and NEMO, and to add an atmospheric boundary layer model to mediate between the atmospheric model and the ice and/or ocean models. Also, NeXtSIM is already coupled to the WAVEWATCH 3 wave model (Boutin et al., 2020), so there is scope for neXtSIM-F to include more components like wave and ocean models.

Appendix A: Summary of rheological equations

20 For completeness we present the rheological equations for the current operational version of neXtSIM-F (see Appendix A1), and for the version used in this paper, which will become operational in December 2020 (see Appendix A2).

A1 Modified Maxwell-Elasto-Brittle (MEB) rheology

We refer readers to Rampal et al. (2019) for most of the details but give some important modifications below. The momentum balance is

$$\rho_i(h+h_y)\frac{D\mathbf{u}}{Dt} = \nabla \cdot (h(\boldsymbol{\sigma} + \boldsymbol{\sigma}_p)) + \tau - \rho_i(h+h_y)(f\mathbf{k} \times \mathbf{u} + g\nabla\eta), \quad (\text{A1})$$

where $\mathbf{u} = (u, v)$ is the ice velocity, ρ_i is the density of ice, h_y is the mean young ice thickness, h is the mean thickness of older ice, $\boldsymbol{\sigma}$ is the internal stress, $\boldsymbol{\sigma}_p$ is an additional plastic stress that is most active when damaged ice is under convergence, τ is the sum of stresses applied by the wind and ocean currents and by keels grounding on the sea floor, f is the Coriolis parameter, $\mathbf{k} \times \mathbf{u} = (v, -u)$, g is the acceleration due to gravity and η is the sea surface height.

There is an evolution equation for the damage, which is unchanged from (Rampal et al., 2019, see equations A8–A15). The constitutive relations are

$$\dot{\boldsymbol{\sigma}} + \frac{\boldsymbol{\sigma}}{\lambda} = E\mathbf{K} : \dot{\boldsymbol{\varepsilon}}, \quad (\text{A2a})$$

$$\boldsymbol{\sigma}_p = \frac{h^2 e^{-20(1-c)} P_*}{|\nabla \cdot \mathbf{u}| + \delta_p} \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & \frac{1}{2} \end{pmatrix} \begin{pmatrix} \dot{\varepsilon}_{11} \\ \dot{\varepsilon}_{22} \\ \dot{\varepsilon}_{12} \end{pmatrix}, \quad (\text{A2b})$$

where \mathbf{K} is the stiffness tensor (see equation A4 of Rampal et al., 2019), and

$$\lambda = \lambda_0(1-d)^{\alpha-1} \quad (\text{A3})$$

is the viscous relaxation time, λ_0 is its (large) value for undamaged ice, d is damage, and $\alpha > 1$ is an exponent which can be tuned to control how fast λ drops due to damaging. Note we don't consider young ice in the constitutive relations since it is assumed to be weak.

Also, P_* is the resistance to compression and δ_p is a small parameter needed for numerical stability, c is the concentration of older ice and E is the Young's modulus:

$$E = e^{-20(1-c)}(1-d_E)E_0, \quad (\text{A4a})$$

$$d_E = \begin{cases} d & \text{if } d \geq 0.95, \\ 0 & \text{otherwise,} \end{cases} \quad (\text{A4b})$$

20 where E_0 is the undamaged Young's modulus at 100% concentration, and d_E is a kind of "effective damage". Changes to the MEB rheology as presented by Rampal et al. (2019) are the extra stress σ_P in the momentum equation and the use of d_E instead of just d , which helped to improve localisation of deformation.

A2 Brittle-Bingham-Maxwell (BBM) rheology

In this update to the rheology (for full details and further validation, see Ólason et al., in prep.), we could simplify things and make the model much faster (since we could use an explicit solver) by setting $\sigma_P = 0$. Also we no longer needed an "effective damage" d_E , so E is simply

$$E = e^{-20(1-c)}(1-d)E_0. \quad (\text{A5})$$

The new constitutive relation is

$$\dot{\sigma} + \frac{\sigma}{\lambda} \left(\tilde{P} + \frac{\lambda \dot{d}}{1-d} \right) = E \mathbf{K} : \dot{\epsilon}, \quad (\text{A6})$$

where

$$\tilde{P} = \begin{cases} 1 & \text{for } \sigma_n \leq 0 \text{ (diverging),} \\ 0 & \text{for } 0 < \sigma_n < P_{\max} \text{ (elastic),} \\ 1 - \frac{P_{\max}}{\sigma_n} & \text{for } \sigma_n > P_{\max} \text{ (ridging),} \end{cases} \quad (\text{A7})$$

5 where $\sigma_n = \frac{1}{2}(\sigma_{11} + \sigma_{22})$ is the normal stress (defined to be positive under convergent conditions), and

$$P_{\max} = P_* h^2 e^{-20(1-c)} \quad (\text{A8})$$

is the concentration- and thickness-dependent threshold for when the Bingham element starts moving (P_* is a constant tuning parameter).

Author contributions. TW and AK wrote the paper and did the experiments. PR and EO contributed to writing and planning the paper and
10 experiments. EO was also behind many background developments in the model code.

Competing interests. No competing interests.

Acknowledgements. We would like to acknowledge support from the Research Council of Norway (RCN) projects neXtWIM #244001 and Nansen Legacy #276730. The [project-projects](#) ImpSIM 18CP10 funded by the French Navy (SHOM) [and Cryosphere Virtual Laboratory](#)

(CVL AO/1-9465/18/I-NS) funded by the European Space Agency also supported the last phase of this manuscript preparation. We also
15 benefitted from work done during the project SWARP funded by the European Commission FP7 programme (grant number 607476); from
~~the work of interesting discussions with~~ Véronique Dansereau on the MEB ~~rheology which greatly improved the simulations presented in~~
~~this paper~~ and BBM rheology; from the work of Abdoulaye Samaké who parallelised the neXtSIM code; and from the contribution of Mika
Malila to the evaluation scripts. Finally, we would like to thank Sylvain Bouillon and Philip Griewank for their original contribution to
building a forecasting system around the neXtSIM sea ice model.
