10
11 **Abstract.** Snow is an important climate regulator because it greatly increases the surface
12 albedo of large parts of the Earth. Earth System Models (ESMs) often adopt two-stream
13 approximations with different radiative transfer techniques, the same snow therefore has
14 different solar radiative properties depending whether it is on land or on sea ice. Here we
15 inter-compare three two-stream algorithms widely used in snow models, improve their
16 predictions at large zenith angles, and introduce a hybrid model suitable for all
17 cryospheric surfaces in ESMs. The algorithms are those employed by the SNOW ICE and
18 Aerosol Radiative (SNICAR) module used in land models, and by dEdd-AD used in
19 Icepack, the column physics used in the Los Alamos sea ice model CICE and MPAS-
20 seaice, and a two-stream discrete ordinate (2SD) model. Compared with a 16-stream
21 benchmark model, the errors in snow visible albedo for a direct-incident beam from all
22 three two-stream models are small ($< \pm 0.005$) and increase as snow shallows, especially
23 for aged snow. The errors in direct near-infrared (near-IR) albedo are small ($< \pm 0.005$) for
24 solar zenith angles $\theta < 75^\circ$, and increase as θ increases. For diffuse incidence under
25 cloudy skies, dEdd-AD produces the most accurate snow albedo for both visible and
26 near-IR ($< \pm 0.0002$) with the lowest underestimate (-0.01) for melting thin snow.
27 SNICAR performs similarly to dEdd-AD for visible albedos, with a slightly larger
28 underestimate (-0.02), while it overestimates the near-IR albedo by an order of magnitude
29 more (up to 0.04). 2SD overestimates both visible and near-IR albedo by up to 0.03. We
30 develop a new parameterization that adjusts the underestimated direct near-IR albedo and
31 overestimated direct near-IR heating persistent across all two-stream models for solar
32 zenith angles $> 75^\circ$. These results are incorporated in a hybrid model SNICAR-AD,
33 which can now serve as a unified solar radiative transfer model for snow in ESM land,
34 land ice, and sea-ice components.

35

36 **1. Introduction**

37
38 Snow cover on land, land ice, and sea ice, modulates the surface energy balance of mid
39 and high latitudes of the Earth, principally because even a thin layer of snow can greatly
40 increase the surface albedo. Integrated over the solar spectrum, the broadband albedo of
41 opaque snow ranges from 0.7 – 0.9 (e.g., Wiscombe and Warren 1980; Dang et al.,
42 2015). In contrast, the albedo of other natural surfaces is smaller: 0.2, 0.25, and 0.5-0.7
43 for damp soil, grassland, and bare multi-year sea ice, respectively (Perovich 1996; Liang
44 et al., 2002; Brandt et al., 2005; Bøggild et al., 2010). The accumulation, evolution, and
45 depletion of snow cover modify the seasonal cycle of surface albedo globally. In
46 particular, snow over sea ice absorbs more solar energy and begins to melt in the spring,
47 which forms melt ponds that bring the sea-ice albedo to as low as 0.15 to further
48 accelerate ice melt (Light et al., 2008, 2015). An accurate simulation of the shortwave
49 radiative properties of snowpack is therefore crucial for spectrally partitioning solar
50 energy and representing snow-albedo feedbacks across the Earth system. Unfortunately,
51 computational demands and coupling architectures often constrain representation of
52 snowpack radiative processes in Earth System Models (ESMs, please refer to Table 1 for
53 all acronyms used in this work) to relatively crude approximations such as two-stream
54 methods (Wiscombe and Warren, 1980, Toon et al., 1989). In this work, we inter-
55 compare two-stream methods widely used in snow models and then introduce a new
56 parameterization that significantly reduces their snowpack reflectance and heating biases
57 at large zenith angles, to produce more realistic behavior in polar regions.

58
59 Snow albedo is determined by many factors including the snow grain radius, the solar
60 zenith angle, cloud transmittance, light-absorbing particles, and the albedo of underlying
61 ground if snow is optically thin (Wiscombe and Warren, 1980; Warren and Wiscombe,
62 1980); it also varies strongly with wavelength since the ice absorption coefficient varies
63 by 7 orders of magnitudes across the solar spectrum (Warren and Brandt, 2008). At
64 visible wavelengths (0.2 - 0.7 μm), ice is almost non-absorptive such that the absorption
65 of visible energy by snowpack is mostly due to the light-absorbing particles (e.g. black
66 carbon, organic carbon, mineral dust) that were incorporated during ice nucleation in
67 clouds, scavenged during precipitation, or slowly sedimented from the atmosphere by
68 gravity (Warren and Wiscombe, 1980, 1985; Doherty et al., 2010, 2014, 2016; Wang et
69 al., 2013; Dang and Hegg 2014). As snow becomes shallower, visible photons are more
70 likely to penetrate through snowpack and get absorbed by darker underlying ground. At
71 near-infrared (near-IR) wavelengths (0.7 – 5 μm), ice is much more absorptive than the

72 snow albedo is lower than the visible albedo. Larger ice crystals form a lower albedo
73 surface than smaller ice crystals hence aged snowpacks absorb more solar energy.
74 Photons incident at smaller solar zenith angles are more likely to penetrate deeper
75 vertically and be scattered in the snowpack until being absorbed by the ice/the underlying
76 ground/absorbing impurities, which also leads to a smaller snow albedo. To compute the
77 reflected solar flux, spectrally resolved albedo must be weighted by the incident solar
78 flux, which is mostly determined by solar zenith angle, cloud cover and transmittance,
79 and column water vapor. Modeling the solar properties of snowpacks must consider the
80 spectral signatures of these atmospheric properties.

81
82 Several parameterizations have been developed to compute the snow solar properties
83 without solving the radiative transfer equations and some are incorporated into ESMs or
84 regional models. Marshall and Warren (1987) and Marshall (1989) parameterized snow
85 albedo in both visible and near-IR bands as functions of snow grain size, solar zenith
86 angle, cloud transmittance, snow depth, underlying surface albedo, and black carbon
87 content. Marshall and Oglesby (1994) used this in an ESM. Gardner and Sharp (2010)
88 parameterized the all-wave snow albedo with similar inputs. This was incorporated into
89 the regional climate model RACMO
90 (<https://www.projects.science.uu.nl/iceclimate/models/racmo.php>) to simulate snow
91 albedo in glaciated regions like Antarctica and Greenland (Munneke et al., 2011). Dang
92 et al., (2015) compute snow albedo as functions of snow grain radius, black carbon
93 content, and dust content for visible and near-IR bands and 14 narrower bands used in the
94 rapid radiative transfer model (RRTM, Mlawer and Clough, 1997). Their
95 parameterization can also be expanded to different solar zenith angles using the zenith
96 angle parameterization developed by Marshall and Warren (1987). Aoki et al., (2011)
97 developed a more complex model based on the offline snow albedo and a transmittance
98 look-up table. This can be applied to multilayer snowpack to compute the snow albedo
99 and the solar heating profiles as functions of snow grain size, black carbon and dust
100 content, snow temperature, and snowmelt water equivalent. These parameterizations are
101 often in the form of simplified polynomial equations, which are especially suitable to
102 long-term ESM simulations that require less time-consuming snow representations.

103
104 More complex models that explicitly solve the multiple scattering radiative transfer
105 equations have also been developed to compute snow solar properties. Flanner and
106 Zender (2005) developed the SNow Ice and Aerosol Radiation model (SNICAR) that
107 utilizes two-stream approximations (Wiscombe and Warren 1980; Toon et al., 1989) to

108 predict heating and reflectance for multi-layer snowpack. They implemented SNICAR in
109 the Community Land Model (CLM) to predict snow albedo and vertically-resolved solar
110 absorption for snow-covered surfaces. Before SNICAR, CLM prescribed snow albedo
111 and confined all solar absorption to the top snow layer (Flanner and Zender 2005). Over
112 the past decades, updates and new features have been added to SNICAR to consider more
113 processes such as black carbon/ice mixing states (Flanner et al., 2012) and snow grain
114 shape (He et al., 2018b). Concurrent with the development of SNICAR, Briegleb and
115 Light (2007) improved the treatment of sea-ice solar radiative calculations in Community
116 Climate System Model (CCSM). They implemented a different two-stream scheme with
117 delta-Eddington approximation and adding-doubling technique (hereafter, dEdd-AD) that
118 allows CCSM to compute bare/ponded/snow-covered sea ice albedo and solar absorption
119 profiles of multi-layer sea ice. Before these improvements, the sea-ice albedo was
120 computed based on surface temperature, snow thickness, and sea-ice thickness using
121 averaged sea ice and snow albedo. dEdd-AD has been adopted by the sea-ice physics
122 library Icepack (<https://github.com/CICE-Consortium/Icepack/wiki>), which is used by the
123 Los Almos Sea Ice Model CICE (Hunke et al., 2010) and Model for Prediction Across
124 Scales Sea Ice MPAS-seaice (Turner et al., 2018). CICE itself is used in numerous global
125 and regional models.

126

127 SNICAR and dEdd-AD solve the multiple scattering radiative transfer equations and
128 provide much improved solar radiative representations for the cryosphere, though their
129 separate development and implementation created an artificial divide for snow
130 simulation. In ESMs that utilize both SNICAR and dEdd-AD, such as the Community
131 Earth System Model (CESM, <http://www.cesm.ucar.edu/>) and the Energy Exscale Earth
132 System Model (E3SM, previously known as ACME, <https://e3sm.org/>), the solar
133 radiative properties of snow on land and snow on sea ice are computed separately via
134 SNICAR and dEdd-AD. As a result, the same snow in nature has different solar radiative
135 properties such as reflectance depending on which model represents it. These differences
136 are model artifacts that should be eliminated so that snow has consistent properties across
137 the Earth system.

138

139 In this paper, we evaluate the accuracy and biases of three two-stream models listed in
140 Table 2, including the algorithms used in SNICAR and dEdd-AD, at representing
141 reflectance and heating. In Sections 2-4, we describe the radiative transfer algorithms and
142 calculations performed in this work. The results and model inter-comparisons are
143 discussed in Section 5. In Section 6, we introduce a parameterization to reduce the

144 simulated albedo and heating bias for solar zenith angles larger than 75° . In Section 7, we
 145 summarize the major differences of algorithm implementations between SNICAR and
 146 dEdd-AD in ESMs. We use these results to develop and justify a unified surface
 147 shortwave radiative transfer method for all Earth system model components in the
 148 cryosphere, presented in Section 8.

149

150 **2. Radiative Transfer Model**

151

152 In this section, we summarize the three two-stream models and the benchmark DISORT
 153 model with 16-streams. These algorithms are well documented in papers by Toon et al.,
 154 (1989), Briegleb and Light (2007), Jin and Stamnes (1994), and Stamnes et al. (1988).
 155 Readers interested in detailed mathematical derivations should refer to those papers. We
 156 only include their key equations to illustrate the difference among two-stream models for
 157 discussion purposes.

158

159 2.1 SNICAR in land models CLM and ELM

160 SNICAR is implemented as the default snow shortwave radiative transfer scheme in
 161 CLM and E3SM land model (ELM). It adopts the two-stream algorithms and the rapid
 162 solver developed by Toon et al., (1989) to compute the solar properties of multi-layer
 163 snowpacks. These two-stream algorithms are derived from the general equation of
 164 radiative transfer in a plane parallel media:

165

$$166 \mu \frac{\partial I}{\partial \tau}(\tau, \mu, \Phi) = I(\tau, \mu, \Phi) - \frac{\varpi}{4\pi} \int_0^{2\pi} \int_{-1}^1 P(\mu, \mu', \phi, \phi') I(\tau, \mu', \Phi') d\mu' d\phi' - S(\tau, \mu, \Phi)$$

167
168 (1)
169

170

171 where $\arccos(\mu)$ and Φ are zenith angle and azimuth angle, ϖ is single-scattering albedo.
 172 On the right-hand side, the three terms are intensity at optical depth τ , internal source
 173 term due to multiple scattering, and external source term S . For a purely external source
 174 at solar wavelengths S is:

175

$$176 S = \frac{\varpi}{4} F_s P(\mu, -\mu_0, \phi, \phi_0) \exp\left(\frac{-\tau}{\mu_0}\right)$$

177 (2)

178

178 where πF_s is incident solar flux, μ_0 is the incident direction of the solar beam. Integrating
 179 equation (1) over azimuth and zenith angles yields the general solution of two-stream

180 approximations (Meador and Weaver, 1980). The upward and downward fluxes at optical
181 depth τ of layer n can be represented as:

182

183

$$184 \quad F_n^+ = k_{1n} \exp(\Lambda_n \tau) + \Gamma_n k_{2n} \exp(-\Lambda_n \tau) + C_n^+(\tau) \quad (3a)$$

185

$$186 \quad F_n^- = \Gamma_n k_{1n} \exp(\Lambda_n \tau) + k_{2n} \exp(-\Lambda_n \tau) + C_n^-(\tau) \quad (3b)$$

187

188

189 where Λ_n , Γ_n , C_n are known coefficients determined by the two-stream method, incident
190 solar flux, and solar zenith angle; whereas k_{1n} and k_{2n} are unknown coefficients
191 determined by the boundary conditions. For an N-layer snowpack, the solutions for
192 upward and downward fluxes are coupled at layer interfaces to generate 2N equations
193 with 2N unknown coefficients k_{1n} and k_{2n} . Combining these equations linearly generates
194 a new set of equations with terms in tridiagonal form that enables the application of a fast
195 tri-diagonal matrix solver. With the solved coefficients, the upward and downward fluxes
196 are computed at different optical depths (Equations 3a and 3b) and eventually the
197 reflectance, transmittance, and absorption profiles of solar flux for any multilayer
198 snowpack.

199

200 SNICAR itself implements all three two-stream algorithms in Toon et al., (1989):
201 Eddington, Quadrature, and Hemispheric-mean. In practical simulations, it utilizes the
202 Eddington and Hemispheric-mean approximations to compute the visible and near-IR
203 snow properties, respectively (Flanner et al., 2007). In addition to their algorithms,
204 SNICAR implements the Delta-transform of the fundamental input variables asymmetry
205 factor (g), single-scattering albedo (ω), and optical depth (τ) to account for the strong
206 forward scattering in snow (Equations 2 (a)-(c), Wiscombe and Warren, 1980).

207

208 2.2. dEdd-AD in sea ice models Icepack, CICE, and MPAS-seaice

209 Icepack, CICE, and MPAS-seaice use the same shortwave radiative scheme dEdd-AD
210 developed and documented by Briegleb and Light (2007). Sea ice is divided into multiple
211 layers to first compute the single-layer reflectance and transmittance using two-stream
212 delta-Eddington solutions to account for the multiple scattering of light within each layer
213 (Equation set 50, Briegleb and Light, 2007), where the name “delta” implies dEdd-AD
214 implements the Delta-transform to account for the strong forward scattering of snow and

215 sea ice (Equations 2 (a)-(c), Wiscombe and Warren, 1980). The single-layer direct albedo
 216 and transmittance are computed by equations:

217

$$218 \quad R(\mu_{0,n}) = A_n \exp\left(\frac{-\tau}{\mu_{0,n}}\right) + B_n(\exp(\varepsilon_n \tau) - \exp(-\varepsilon_n \tau)) - K_n \quad (4a)$$

219

$$220 \quad T(\mu_{0,n}) = E_n + H_n(\exp(\varepsilon_n \tau) - \exp(-\varepsilon_n \tau)) \exp\left(\frac{-\tau}{\mu_{0,n}}\right) \quad (4b)$$

221

222 where coefficients A_n , B_n , K_n , E_n , H_n , and ε_n are determined by the single-scattering
 223 albedo (ϖ), asymmetry factor (g), optical depth (τ), and angle of the incident beam at
 224 layer n ($\mu_{0,n}$). Following the delta-Eddington assumption, simple formulas are available
 225 for the single-layer reflectance and transmittance under both clear sky (direct flux,
 226 equations 4a and 4b) and overcast sky (diffuse flux) conditions, however, the formula
 227 derived by applying diffuse-flux upper boundary conditions sometimes yields negative
 228 albedos (Wiscombe 1977). To avoid the unphysical values, diffuse reflectance \bar{R} and
 229 transmittance \bar{T} of a single layer are computed by integrating the direct reflectance $R(\mu)$
 230 and transmittance $T(\mu)$ over the incident hemisphere assuming isotropic incidence:

231

$$232 \quad \bar{R} = 2 \int_0^1 \mu R(\mu) d\mu \quad (5a)$$

233

$$234 \quad \bar{T} = 2 \int_0^1 \mu T(\mu) d\mu \quad (5b)$$

235

236 This is the same as the method proposed by Wiscombe and Warren (1980, their equation
 237 5). In practice, eight Gaussian angles are implemented to perform the integration for
 238 every layer.

239

240 The computed single-layer reflectance and transmittance of direct and diffuse
 241 components are then combined to account for the inter-layer scattering of light to
 242 compute the reflectance and transmission at every interface (Equation set 51, Briegleb
 243 and Light, 2007), and eventually the upward and downward fluxes (Equation set 52,
 244 Briegleb and Light, 2007). These upward and downward fluxes at each optical depth are
 245 then used to compute the column reflectance and transmittance, and the absorption
 246 profiles for any multilayered media, such as snowpacks on land and sea ice.

247

248 In nature, a large fraction of sea ice is covered by snow during winter. As snow melts
 249 away in late spring and summer, it exposes bare ice, and melt ponds form on the ice

250 surface. Such variation of sea-ice surface types requires the shortwave radiative transfer
 251 model to be flexible and capable of capturing the light refraction and reflection.
 252 Refractive boundaries exist where air (refractive index $m_{re} = 1.0$), snow (assuming snow
 253 as medium of air containing a collection of ice particles, $m_{re} = 1.0$), pond (assuming pure
 254 water, $m_{re} = 1.33$), and ice (assuming pure ice, $m_{re} = 1.31$) are present in the same sea-ice
 255 column. The general solution of delta-Eddington, and the two-stream algorithms used in
 256 SNICAR are not applicable to such non-uniformly refractive layered media. To include
 257 the effects of refraction, Briegleb and Light (2007) modified the adding formula at the
 258 refractive boundaries (i.e. interfaces between air/ice, snow/ice, air/pond). The reflectance
 259 and transmittance of the adjacent layers above and below the refractive boundary are
 260 combined with modifications to include the Fresnel reflection and refraction of direct and
 261 diffuse fluxes (Section 4.1, Briegleb and Light, 2007). dEdd-AD can thus be applied to
 262 any layered media with either uniform (e.g., snow on land) or non-uniform (e.g., snow on
 263 sea ice) refractive indexes.

264

265 In this paper, we apply dEdd-AD to snowpacks that can be treated as uniform refractive
 266 media such as the air/snowpack/land columns assumed in SNICAR for model evaluation.
 267 An ideal radiative treatment for snow should, however, keep the potential to include
 268 refraction for further applications to snow on sea ice or ice sheets. Therefore, besides
 269 these two widely used algorithms in Icepack and SNICAR, we evaluate a third algorithm
 270 (section 2.3) that can be applied to layered media with either uniform or non-uniform
 271 refractive indexes.

272

273 2.3. two-stream discrete-ordinate algorithm (2SD)

274 A refractive boundary also exists between the atmosphere and the ocean, and models
 275 have been developed to solve the radiative transfer problems in the atmosphere-ocean
 276 system using the discrete-ordinate technique (e.g. Jin and Stamnes, 1994; Lee and Liou,
 277 2007). Similar to the two-stream algorithms of Toon et al., (1989) used in SNICAR, Jin
 278 and Stamnes (1994) also developed their algorithm from the general equation:

279

$$280 \mu \frac{\partial I}{\partial \tau}(\tau, \mu) = I(\tau, \mu) - \frac{\overline{\omega}}{4\pi} \int_{-1}^1 P(\tau, \mu, \mu') I(\tau, \mu') d\mu' - S(\tau, \mu) \quad (6)$$

281

282 Equation (6) is the azimuthally integrated version of equation (1). However, for vertically
 283 inhomogeneous media like the atmosphere-ocean or sea ice, the external source term
 284 $S(\tau, \mu)$ is different. Specifically, for the medium of total optical depth τ^a above the

285 refractive interface, one must consider the contribution from the upward beam reflected
 286 at the refractive boundary (second term on the right-hand side):

287

$$288 \quad S^a(\tau, \mu) = \frac{\varpi}{4\pi} F_s P(\tau, -\mu_0, \mu) \exp\left(\frac{-\tau}{\mu_0}\right) + \frac{\varpi}{4\pi} F_s R(-\mu_0, m) P(\tau, +\mu_0, \mu) \exp\left(\frac{-(2\tau^a - \tau)}{\mu_0}\right)$$

289

290

291

(7)

292 where $R(-\mu_0, m)$ is the Fresnel reflectance of radiation and m is the ratio of the
 293 refractive indices of the lower to the upper medium. For the medium below the refractive
 294 interface, one must account for the Fresnel transmittance $T(-\mu_0, m)$ and modify the
 295 angle of beam travel in media b:

296

$$297 \quad S^b(\tau, \mu) = \frac{\varpi}{4\pi} \frac{\mu_0}{\mu_{0n}} F_s T(-\mu_0, m) P(\tau, -\mu_0, \mu) \exp\left(\frac{-\tau^a}{\mu_0}\right) \exp\left(\frac{-(\tau - \tau^a)}{\mu_{0n}}\right)$$

298

(8)

299 where μ_{0n} is the cosine zenith angle of refracted beam incident at angle μ_0 above the
 300 refractive boundary, by Snell's law:

301

$$302 \quad \mu_{0n} = \sqrt{1 - (1 - \mu_0^2)/m^2}$$

303

(9)

304 For uniformly refractive media like snow on land, one can just set the refractive index m_{re}
 305 equal to 1 for every layer. In this case, the Fresnel reflectance $R(-\mu_0, m)$ is 0 in equation
 306 (7), the Fresnel transmittance $T(-\mu_0, m)$ is 1 in equation (8), and μ_{0n} equals to μ_0 : the
 307 two source terms $S^a(\tau, \mu)$ and $S^b(\tau, \mu)$ become the same and equal to the source term of
 308 homogenous media given in equation (2).

309

310 For two-stream approximations of this method, analytical solutions of upward and
 311 downward fluxes are coupled at each layer interface to generate 2N equations with 2N
 312 unknown coefficients for any N-layer stratified column. The solutions of two-stream
 313 algorithms and boundary conditions for homogenous media are well documented
 314 (Sections 8.4 and 8.10 of Thomas and Stamnes, 1999). Despite the extra source terms,
 315 these 2N equations can also be organized into a tridiagonal matrix similar to the method
 316 of Toon et al. (1989) used in SNICAR. Flexibility and speed therefore make this two-
 317 stream discrete-ordinate algorithm (hereafter, 2SD) a potentially good candidate for long-

318 term Earth system modeling. In this work, we only apply 2SD to snowpack and note that
319 it can be applied to any uniformly or non-uniformly refractive media like snow on land or
320 sea ice, with the Delta-transform implemented to fundamental optical variables
321 (Equations 2 (a)-(c), Wiscombe and Warren, 1980).

322

323 2.4 16-stream DISORT

324 Besides the mathematical technique, the accuracy and speed of radiative transfer
325 algorithms depend on the number of angles used for flux estimation in the upward and
326 downward hemispheres. SNICAR, dEdd-AD, and 2SD use one angle to represent upward
327 flux and one angle to represent downward flux, hence they are named two-stream
328 algorithm. Lee and Liou (2007) use two upward and two downward streams. Jin and
329 Stamnes (1994) documented the solutions for any even number of streams. The
330 computational efficiency of these models is lower than that of two-stream models while
331 their accuracy is better. To quantify the accuracy of the three two-stream algorithms for
332 snow shortwave simulations, we use the 16-stream DIScrete-Odinate Radiative Transfer
333 model (DISORT) as the benchmark model (<http://lllab.phy.stevens.edu/disort/>) (Stamnes
334 et al., 1988).

335

336 3. Input for radiative transfer models

337 In this work, we focus on the performance of two-stream algorithms for pure snow
338 simulations. The inputs for these three models are the same: single-scattering properties
339 (SSPs, i.e. single-scattering albedo ω , asymmetry factor g , extinction coefficient σ_{ext}) of
340 snow determined by snow grain radius r , snow depth, solar zenith angle θ , solar incident
341 flux, and the albedo of underlying ground (assuming Lambertian reflectance of 0.25 for
342 all wavelengths). A Delta-transform is applied to fundamental input optical variables for
343 all simulations (Equations 2 (a)-(c), Wiscombe and Warren, 1980).

344

345 In snow, photon scattering occurs at the air-ice interface, and the absorption of photons
346 occurs within the ice crystal. The most important factor that determines snow shortwave
347 properties is the ratio of total surface area to total mass of snow grains, aka “the specific
348 surface area” (e.g. Matzl and Schneebeli, 2006, 2010). The specific surface area (β) can
349 be converted to a radiatively effective snow grain radius r :

350

$$351 \beta = 3 / (r \rho_{ice}) \tag{10}$$

352

353 where ρ_{ice} is the density of pure ice, 917 kg m^{-3} . Assuming the grains are spherical, the
354 SSPs of snow can thus be computed using Mie theory (Wiscombe, 1980) and ice optical
355 constants (Warren and Brandt, 2008). In nature, snow grains are not spherical, and many
356 studies have been carried out to quantify the accuracy of such spherical representations
357 (Grenfell and Warren, 1999; Neshyba et al., 2003; Grenfell et al., 2005). In recent years,
358 more research has been done to evaluate the impact of grain shape on snow shortwave
359 properties (Dang et al., 2016; He et al., 2017, 2018ab), and they show that non-spherical
360 snow grain shapes mainly alter the asymmetry factor. Dang et al., (2016) also point out
361 that the solar properties of a snowpack consisting of non-spherical ice grains can be
362 mimicked by a snowpack consisting of spherical grains with a smaller grain size by
363 factors up to 2.4. In this work, we still assume the snow grains are spherical, and this
364 assumption does not qualitatively alter our evaluation of the radiative transfer algorithms.

365

366 The input SSPs of snow grains are computed using Mie theory at a fine spectral
367 resolution for a wide range of ice effective radius r from 10 to $3000 \mu\text{m}$ that covers the
368 possible range of grain radius for snow on Earth (Flanner et al., 2007). The same spectral
369 SSPs were also used to derive the band-averaged SSPs of snow used in SNICAR. Note
370 Briegleb and Light (2007) refer to SSPs as inherent optical properties.

371

372 **4. Solar spectra used for the spectral integrations**

373 In climate modeling, snow albedo computation at a fine spectral resolution is expensive
374 and unnecessary. Instead of computing spectrally resolved snow albedo as shown in
375 Figure 1, wider-band solar properties are more practical. For example, CESM and E3SM
376 aggregate the narrow RRTMG bands used for the atmospheric radiative transfer
377 simulation into visible ($0.2 - 0.7 \mu\text{m}$) and near-IR ($0.7 - 5 \mu\text{m}$) bands. The land model and
378 sea-ice model thus receive visible and near-IR fluxes as the upper boundary condition,
379 and return the corresponding visible and near-IR albedos to atmosphere model. In
380 practice, these bands are also partitioned into direct and diffuse components. Therefore, a
381 practical two-stream algorithm should be able to simulate the direct visible, diffuse
382 visible, direct near-IR and diffuse near-IR albedos and absorptions of snow accurately.

383

384 The band albedo α is an irradiance-weighted average of the spectral albedo $\alpha(\lambda)$:

385

$$386 \quad \alpha = \frac{\int_{\lambda_1}^{\lambda_2} \alpha(\lambda) F(\lambda) d\lambda}{\int_{\lambda_1}^{\lambda_2} F(\lambda) d\lambda} \quad (11)$$

387

388

389 In this work, we use the spectral irradiance $F(\lambda)$ generated by the atmospheric DISORT-
390 based Shortwave Narrowband Model (SWNB2) (Zender et al., 1997; Zender, 1999) for
391 typical clear-sky and cloudy-sky conditions of mid-latitude winter as shown in Figure
392 2(a). The total clear-sky down-welling surface flux at different solar zenith angles are
393 also given in Figure 2(b).

394
395

396 **5. Model Evaluation**

397 5.1 Spectral albedo and reflected solar flux

398 The spectral reflectance of pure deep snow computed using two-stream models and 16-
399 stream DISORT are shown in Figure 1. The snow grain radius is 100 μm - a typical grain
400 size for fresh new snow. For clear sky with direct beam source (left column), all three
401 two-stream models show good accuracy at visible wavelengths (0.3 – 0.7 μm), and within
402 this band, the snow albedo is large and close to 1. As wavelength increases, the albedo
403 diminishes in the near-IR band. two-stream models overestimate snow albedo at these
404 wavelengths, with maximum biases of 0.013 (SNICAR and dEdd-AD) and 0.023 (2SD)
405 within wavelength 1 - 1.7 μm . For cloudy-sky cases with diffuse upper boundary
406 conditions, dEdd-AD reproduces the snow albedo at all wavelengths with the smallest
407 absolute error (< 0.005), SNICAR and 2SD both overestimate the snow albedo with
408 maximum biases > 0.04 between 1.1-1.4 μm .

409

410 In both sky conditions, the errors of snow albedo are larger at near-IR wavelengths
411 ranging from 1.0-1.7 μm , while the solar incident flux peaks at 0.5 μm then decrease as
412 wavelength increases. The largest error in reflected flux is within the 0.7-1.5 μm band for
413 SNICAR and 2SD, as shown in the 3rd row of Figure 1. dEdd-AD overestimate the direct
414 snow albedo mostly at wavelengths larger than 1.5 μm where the error in reflected flux is
415 almost negligible.

416

417 5.2 Broadband albedo and reflected solar flux

418 Integrated over the visible and near-IR wavelengths, the error in band albedos computed
419 using two-stream models for different cases are shown in Figure 3-6.

420

421 Figure 3 shows the error in direct band albedo for fixed snow grain radius of 100 μm with
422 different snow depth and solar zenith angles. As introduced in Section 2, SNICAR and
423 dEdd-AD both use delta-Eddington method to compute the visible albedo. They
424 overestimate the visible albedo for solar zenith angles smaller than 50° by up to 0.005,

425 and underestimate it for solar zenith angles larger than 50° by up to -0.01 . 2SD produces
426 similar results for the visible band but at a larger solar zenith angle threshold of 75° . In
427 the near-IR band, SNICAR and 2SD overestimate the snow albedo for solar zenith angles
428 smaller than 70° , beyond this, the error in albedo increases by up to -0.1 as solar zenith
429 angle increases. dEdd-AD produces a similar error pattern with a smaller solar zenith
430 angle threshold at 60° . As snow ages, its average grain size increases. For typical old
431 melting snow of grain radius $1000\ \mu\text{m}$ (Figure 4), two-stream models produce similar
432 errors of direct albedo in all bands. For snow consisting of smaller grain size, two-stream
433 models produce larger errors for visible albedo. Integrating over the entire solar band, the
434 three two-stream models evaluated show similar error patterns for direct albedo.

435

436 For a fixed solar zenith angle of 60° , the error of direct albedo for different snow depth
437 and snow grain radii are shown in Figure 5. SNICAR and dEdd-AD underestimate the
438 visible albedo in most scenarios, while 2SD overestimates the visible albedo for a larger
439 range of grain radius and snow depth. All three two-stream models tend to overestimate
440 the near-IR albedo except for shallow snow with large grain radius; the error of 2SD is
441 one order of magnitude larger than that of SNICAR and dEdd-AD.

442

443 Figure 6 is similar to Figure 5, but shows the diffuse snow albedo. In the visible band,
444 SNICAR and dEdd-AD generate similar errors in that they both underestimate the albedo
445 as snow grain size increases and snow depth decreases. 2SD overestimates the albedo
446 with a maximum error of around 0.015 . In the near-IR, two-stream models tend to
447 overestimate snow albedo, while the magnitude of biases produced by SNICAR and 2SD
448 are one order larger than that of dEdd-AD with the maximum error of 0.035 generated by
449 SNICAR. As a result, the all-wave diffuse albedos computed using dEdd-AD are more
450 accurate than those computed using SNICAR and 2SD.

451

452 Figures 7, 8 and 9 show the errors in reflected shortwave flux caused by snow albedo
453 errors seen in Figures 3, 4, and 6. In general, two-stream models produce larger errors in
454 reflected direct near-IR flux (Figure 7 and 8), especially with the 2SD model: the
455 maximum overestimate of reflected near-IR flux is $6\text{--}8\ \text{Wm}^{-2}$ for deep melting snow with
456 solar zenith angle $< 30^\circ$. Errors in reflected direct visible flux are smaller (mostly within
457 $\pm 1\ \text{Wm}^{-2}$) for all models in most scenarios, and become larger (mostly within $\pm 3\ \text{Wm}^{-2}$) as
458 snow grain size increases to $1000\ \mu\text{m}$ if computed using 2SD. As shown in Figure 9, for
459 diffuse flux with solar zenith angle of 60° at TOA, SNICAR and dEdd-AD generate

460 small errors in reflected visible flux (mostly within $\pm 1 \text{ Wm}^{-2}$), while 2SD always
461 overestimates reflected visible flux by up to 5 Wm^{-2} . In the near-IR, SNICAR and 2SD
462 overestimate reflected flux by as much as $10\text{-}12 \text{ Wm}^{-2}$; the error in reflected near-IR flux
463 produced by dEdd-AD is much smaller, mostly within $\pm 1 \text{ Wm}^{-2}$.

464

465 In general, dEdd-AD produces the most accurate albedo and thus reflected flux for both
466 direct and diffuse components. SNICAR is similar to dEdd-AD for its accuracy of direct
467 albedo and flux, yet generates large error for the diffuse component. 2SD tends to
468 overestimate snow albedo and reflected flux in both direct and diffuse components and
469 shows the largest errors among three two-stream models. These relatively small
470 differences between algorithms may still yield large impact on snowpack. For example,
471 compared to dEdd-AD, SNICAR and 2SD overestimate the diffuse albedo by ~ 0.015 for
472 melting snow (Figure 6). In Greenland, the daily averaged downward diffuse solar flux
473 from May to September is 200 W/m^2 , and the averaged cloud cover fraction is 80%
474 (Figure 6, Dang et al., 2017). In this case, SNICAR and 2SD overestimate the reflected
475 solar flux by 2.4 W/m^2 per day – the amount of energy otherwise enough to melt 10 cm of
476 snow water equivalent from May to September. dEdd-AD also remediates self-
477 compensating spectral biases (where visible and Near-IR biases are of opposite signs)
478 present in the other schemes. Those spectral biases do not affect the broadband fluxes
479 like the diffuse biases, but they nevertheless degrade proper feedbacks between snow/ice
480 reflectance and heating.”

481

482 5.3 Band absorption of solar flux

483 Figure 10 shows absorption profiles of shortwave flux computed using the 16-stream
484 DISORT model, with errors in absorbed fractional solar flux computed using two-stream
485 models. The snowpack is 10-cm deep and is divided into 5 layers, each 2-cm thick. The
486 snow grain radius is set to $100 \mu\text{m}$. The figure shows fractional absorption for snow
487 layers 1-4 and the underlying ground with an albedo of 0.25.

488

489 As shown in the first column of Figure 10, for new snow with a radius of $100 \mu\text{m}$, most
490 solar absorption occurs in the top 2-cm snow layer, where roughly 10% and 15% of
491 diffuse and direct near-IR flux are absorbed and dominate the solar absorption within the
492 snowpack. In the second layer (2-4 cm), the absorption of solar flux is less than 1% and
493 gradually decreases within the interior layers. The underlying ground absorbs roughly 2%
494 of solar flux, mostly visible flux that penetrates the snowpack more efficiently. As snow

495 ages and snow grain grows, photons penetrate deeper into the snowpack. For typical old
496 melting snow with a radius of 1000 μm , most solar absorption still occurs in the top 2-cm
497 snow layer, where roughly 20% and 14% of diffuse and direct near-IR flux are absorbed.
498 The second snow layer (2-4 cm) absorbs more near-IR solar flux by roughly 2%. More
499 photons can penetrate through the snowpack, and results in a high fractionally absorption
500 by the underlying ground, especially for the visible band. As snow depth increase, the
501 ground absorption will decrease for both snow radii.

502

503 Comparing to 16-stream DISORT, two-stream models underestimate (overestimate) the
504 column solar absorptions for new (old) snow, especially for the surface snow layer and
505 the underground. Overall, dEdd-AD gives the most accurate absorption profiles among
506 the three two-stream models, especially for new snow.

507

508 **6. Correction for direct albedo for large solar zenith angles**

509

510 It has been pointed out in previous studies that the two-stream approximations become
511 poor as solar zenith angle approaches 90° (e.g. Wiscombe 1977, Warren 1982). As shown
512 in Figures 3 and 4, all three two-stream models underestimate the direct snow albedo for
513 large solar zenith angles. In the visible band, when the snow grain size is small, the error
514 in direct albedo is almost negligible (Figure 3); while as snow ages and snow grains
515 become larger, the error increases yet remains low if the snow is deep (Figure 4). In the
516 near-IR, the biases of albedo are also larger for larger snow grain radii. For a given snow
517 size, the magnitudes of such biases are almost independent of snow depth, and mainly
518 determined by the solar zenith angle. In general, the errors of all-wave direct albedo are
519 mostly contributed by the errors of near-IR albedo, especially for optically thick
520 snowpacks (i.e., semi-infinite), because the errors of direct albedo in the visible are
521 negligible compared with those in the near-IR. To improve the performance of two-
522 stream algorithms, we develop a parameterization that corrects the underestimated near-
523 IR snow albedo at large zenith angles.

524

525 Figure 11 shows the direct near-IR albedo and fractional absorption of 2-meter thick
526 snowpacks consisting of grains with radius 100 μm and 1000 μm , computed using two-
527 stream algorithms and 16-stream DISORT. For solar zenith angles $> 75^\circ$, two-stream
528 models underestimate snow albedo and overestimate solar absorption within snowpack,
529 mostly in the top 2-cm of snow, and the differences among three two-stream models are
530 small. In Section 5, we have shown that dEdd-AD produces the most accurate snow

531 albedo in general, with anticipated wide application of dEdd-AD, we develop the
 532 following parameterization to adjust its low biases in computed near-IR direct albedo.

533

534 We define and compute R_{75+} as the ratio of direct semi-infinite near-IR albedo computed
 535 using 16-stream DISORT ($\alpha_{16-DISORT}$) to that computed using dEdd-AD ($\alpha_{dEdd-AD}$). This
 536 ratio is shown in Figure 11 (c) and can be parameterized as a function of snow grain
 537 radius (r , unit in meter) and the cosine of incident solar zenith angle (μ_0), as shown in
 538 Figure 11(c):

539

$$540 \quad R_{75+} = \frac{\alpha_{16-DISORT}}{\alpha_{dEdd-AD}} = c_1(\mu_0) \log_{10}(r) + c_0(\mu_0) \quad (12)$$

541

542 where coefficients c_1 and c_0 are polynomial functions of μ_0 , as shown in Figure 11(d):

543

$$544 \quad c_1(\mu_0) = 1.304\mu_0^2 - 0.631\mu_0 + 0.086 \quad (13a)$$

$$545 \quad c_0(\mu_0) = 6.807\mu_0^2 - 3.338\mu_0 + 1.467 \quad (13b)$$

546

547 Since two-stream models always underestimate snow albedo, R_{75+} always exceeds 1
 548 (Figure 11c). We can then adjust the direct near-IR snow albedo ($\alpha_{dEdd-AD}$) and direct
 549 near-IR solar absorption ($Fabs_{dEdd-AD}$) by snow computed using dEdd-AD with ratio
 550 R_{75+} :

551

$$552 \quad \alpha_{dEdd-AD}^{adjust} = R_{75+} \alpha_{dEdd-AD} \quad (14a)$$

553

$$554 \quad Fabs_{dEdd-AD}^{adjust} = Fabs_{dEdd-AD} - (R_{75+} - 1) \alpha_{dEdd-AD} F_{nir} \quad (14b)$$

555

556 where F_{nir} is the direct near-IR flux. This adjustment reduces the error of near-IR albedo
 557 from negative 2-10% to within $\pm 0.5\%$ for solar zenith angles larger than 75° , and for
 558 grain radii ranging from 30-1500 μm (Figure 12). Errors in broadband direct albedo are
 559 therefore also reduced to < 0.01 . The direct near-IR flux absorbed by the snowpack
 560 decreases after applying this adjustment.

561

562 When the solar zenith angle exceeds 75° , our model adjusts the computed direct near-IR
 563 albedo $\alpha_{dEdd-AD}$ by the ratio R_{75+} following equations 12-14a and reduces direct near-

564 IR absorption following equation 14b. If snow is divided into multiple layers, we assume
565 all decreased near-IR absorption (2^{nd} term on the right-hand side, equation 14b) is
566 confined within the top layer. This assumption is fairly accurate for the near-IR band,
567 since most absorption occurs at the surface of snowpack (Figures 10 and 11). As
568 discussed previously, this parameterization is developed based on albedo computed using
569 dEdd-AD. For models that do not use dEdd-AD but SNICAR and 2SD, the same
570 adjustment still applies given the small differences of near-IR direct albedo computed
571 using two-stream models (Figure 11). For models that adopt other radiative transfer
572 algorithms it is best for the developers to examine their model against a benchmark
573 model such as 16-stream DISORT or two-stream models discussed in this work before
574 applying this correction.

575

576 It is important to note that although the errors of direct near-IR albedos are large for large
577 solar zenith angles, the absolute error in reflected shortwave flux is small (Figures 7 and
578 8) as the down-welling solar flux reaches snowpack decreases as solar zenith angle
579 increases (Figures 1(b)). However, such small biases in flux can be important to high
580 latitudes where the solar zenith angle remains large for many days in late winter and early
581 spring.

582

583 **7. Implementation of snow radiative transfer model in Earth system models**

584

585 ESMs often use broader band-averaged SSPs of snow and aerosols for computational
586 efficiency, rather than using brute-force integration of spectral solar properties across
587 narrower bands (per equation 11). Besides using different radiative transfer
588 approximations, SNICAR and dEdd-AD also adopt different methods to derive the band-
589 averaged SSPs of snow for different band schemes.

590

591 In SNICAR, snow solar properties are computed for 5 bands: one visible band (0.3 -
592 $0.7\mu\text{m}$), and four near-IR bands ($0.7 - 1\mu\text{m}$, $1 - 1.2\mu\text{m}$, $1.2 - 1.5\mu\text{m}$, and $1.5 - 5\mu\text{m}$).
593 The solar properties of four subdivided near-IR bands are combined by fixed ratios to
594 compute the direct/diffuse near-IR snow properties. These two sets of ratios are derived
595 offline based on the incident solar spectra of typical of mid-latitude winter for clear and
596 cloudy-sky conditions clear sky and cloudy sky, respectively (Figure 1(a)).

597

598 The band-averaged SSPs of snow grains are computed following the Chandrasekhar
599 Mean approach (Thomas and Stamnes, 1999, their Equation 9.27; Flanner et al., 2007).

600 Specifically, spectral SSPs of snow grains are weighted into bands according to surface
 601 incident solar flux typical of mid-latitude winter for clear and cloudy sky conditions. In
 602 addition, the single-scattering albedo $\varpi(\lambda)$ of ice grains are also weighted by the
 603 hemispheric albedo $\alpha(\lambda)$ of an optically thick snowpack:

$$605 \quad \varpi(\bar{\lambda}) = \frac{\int_{\lambda_1}^{\lambda_2} \varpi(\lambda)F(\lambda)\alpha(\lambda)d\lambda}{\int_{\lambda_1}^{\lambda_2} F(\lambda)\alpha(\lambda)d\lambda} \quad (15a)$$

$$606 \quad g(\bar{\lambda}) = \frac{\int_{\lambda_1}^{\lambda_2} g(\lambda)F(\lambda)d\lambda}{\int_{\lambda_1}^{\lambda_2} F(\lambda)\alpha(\lambda)d\lambda} \quad (15b)$$

$$607 \quad \sigma_{ext}(\bar{\lambda}) = \frac{\int_{\lambda_1}^{\lambda_2} \sigma_{ext}(\lambda)F(\lambda)d\lambda}{\int_{\lambda_1}^{\lambda_2} F(\lambda)\alpha(\lambda)d\lambda} \quad (15c)$$

608
 609 Two sets of snow band-averaged SSPs are generated for all grain radii, suitable for direct
 610 and diffuse light, respectively. For each modeling step and band, SNICAR is called twice
 611 to compute the direct and diffuse snow solar properties.

612
 613 In dEdd-AD, the snow-covered sea ice properties are computed for 3 bands: one visible
 614 band (0.3 – 07 μm), and two near-IR bands (0.7 – 1.19 μm and 1.19 – 5 μm). The solar
 615 proprieties of these two near-IR bands are combined using ratios w_{nir1} and w_{nir2} for 0.7-1
 616 .19 μm and 1.19-5 μm , depending on the fraction of direct near-IR flux f_{nidr} :

$$618 \quad w_{nir1} = 0.67 + 0.11 * (1 - f_{nidr}) \quad (16a)$$

$$619 \quad w_{nir2} = 1 - w_{nir1} \quad (16b)$$

620
 621 The band SSPs of snow are derived by integrating the spectral SSPs and the spectral
 622 surface solar irradiance measured in the Arctic under mostly clear sky.

$$624 \quad \varpi(\bar{\lambda}) = \int_{\lambda_1}^{\lambda_2} \varpi(\lambda)F(\lambda)d\lambda \quad (17a)$$

$$625 \quad g(\bar{\lambda}) = \int_{\lambda_1}^{\lambda_2} g(\lambda)F(\lambda)d\lambda \quad (17b)$$

$$626 \quad \sigma_{ext}(\bar{\lambda}) = \int_{\lambda_1}^{\lambda_2} \sigma_{ext}(\lambda)F(\lambda)d\lambda \quad (17c)$$

627

628 In addition, the band-averaged single-scattering albedo $\varpi(\bar{\lambda})$ is also increased to $\varpi(\bar{\lambda})'$
 629 until the band albedo computed using averaged SSPs matches the band albedo $\bar{\alpha}$ within
 630 0.0001, where $\bar{\alpha}$ is:

631

$$632 \quad \bar{\alpha} = \int_{\lambda_1}^{\lambda_2} \alpha(\lambda)F(\lambda)d\lambda \quad (18)$$

633

634 dEdd-AD adopts this single set of band SSPs for both direct and diffuse computations. In
 635 practice, the physical snow grain radius r is adjusted to a radiatively equivalent radius r_{eqv}
 636 based on the fraction of direct flux in the near-IR band (f_{nidr}):

637

$$638 \quad r_{eqv} = (f_{nidr} + 0.8(1 - f_{nidr}))r \quad (19)$$

639

640 This r_{eqv} and the corresponding snow SSPs are then used in the radiative transfer
 641 calculation. The computed direct and diffuse solar properties alone are less accurate,
 642 while the combined all-sky broadband solar properties agree with SNICAR (Briegleb and
 643 Light, 2007). As a result, for each modeling step and band, dEdd-AD radiative transfer
 644 subroutine is called only once to compute both the direct and diffuse snow solar
 645 properties simultaneously.

646

647 SNICAR and dEdd-AD also use different approaches to avoid numerical singularities. In
 648 SNICAR, singularities occur when the denominator of term C_n^\pm in equation (3) equals to
 649 zero (i.e., $\gamma^2 - 1/\mu_0^2 = 0$), where γ is determined by the approximation method and SSPs
 650 of snow, and μ_0 is the cosine of the solar zenith angle (Equations 23 and 24, Toon et al.,
 651 1989). When such a singularity is detected, SNICAR will shift μ_0 by + 0.02 or -0.02 to
 652 obtain physically realistic radiative properties. In the dEdd-AD algorithm, singularities
 653 arise only when $\mu_0 = 0$ (Equation 4). Therefore, in practice, for $\mu_0 < 0.01$, dEdd-AD
 654 computes the sea-ice solar properties for $\mu_0 = 0.01$ to avoid unphysical results.

655

656 **8. Discussion: a unified radiative transfer model for snow, sea ice, and land ice.**

657

658

659 Based on the inter-comparison of three two-stream algorithms and their implementations
 660 in ESMs, we formulated the following surface shortwave radiative transfer

661 recommendations for an accurate, fast, and consistent treatment for snow on land, land
662 ice, and sea ice in ESMs:

663

664 First, the two-stream delta-Eddington adding-doubling algorithm by Briegleb and Light
665 (2007) is unsurpassed as a radiative transfer core. The evaluation in Section 5 shows that
666 this algorithm produces the least error for snow albedo and solar absorption within
667 snowpack, especially under overcast skies. This algorithm applies well to both uniformly
668 refractive media such as snow on land, and to non-uniformly refractive media, such as
669 bare/snow-covered/ponded sea ice and bare/snow-covered land ice. Numerical
670 singularities occur only rarely (when $\mu_0 = 0$) and are easily avoided in model
671 implementations. Among the three two-stream algorithms discussed here, dEdd-AD is
672 also the most efficient one as it takes only $\sim 2/3$ of the time of SNICAR and 2SD to
673 compute solar properties of multi-layer snowpacks.

674

675 Second, any two-stream cryospheric radiative transfer model can incorporate the
676 parameterization described in Section 6 to adjust the low bias of direct near-IR snow
677 albedo and high bias of direct near-IR solar absorption in snow, for solar zenith angles
678 larger than 75° . These biases are persistent across all two-stream algorithms discussed in
679 this work, and should be corrected for snow-covered surfaces. Alternatively, adopting a
680 4-stream approximation would reduce or eliminate such biases, though at considerable
681 expense in computational efficiency.

682

683 Third, a cryospheric radiative transfer model should prefer physically based
684 parameterizations that are extensible and convergent (e.g., with increasing spectral
685 resolution) for the band-averaged SSPs and size distribution of snow. Although the
686 treatments used in SNICAR and dEdd-AD are both practical since they both reproduce
687 the narrowband solar properties with carefully derived band-averaged inputs as discussed
688 in Section 7, the snow treatment used in SNICAR is more physically based and
689 reproducible since it does not rely on subjective adjustment and empirical coefficients as
690 used in dEdd-AD. Specifically, the empirical adjustment to snow grain radius
691 implemented in dEdd-AD may not always produce compensating errors. For example, in
692 snow containing light-absorbing impurities such adjustment may also lead to biases in
693 aerosol absorption since the albedo reduction caused by light-absorbing particles does not
694 linearly depend on snow grain radius (Dang et al., 2015). For further model development
695 incorporating non-spherical snow grain shapes (Dang et al., 2016; He et al., 2018ab),
696 such adjustment on grain radius may fail as well. Moreover, SNICAR computes the snow

697 properties for four near-IR bands, which helps capture the spectral variation of albedo
698 (Figure 1) and therefore better represents near-IR solar properties. It is also worth noting
699 that unlike the radiative core of dEdd-AD, SNICAR is actively maintained with
700 numerous modifications and updates in the past decade (e.g. Flanner et al., 2012; He et
701 al., 2018b). Snow radiative treatments that follow SNICAR conventions for SSPs may
702 take advantage of these updates. Note that any radiative core that follows SNICAR SSP
703 conventions must be called twice to compute diffuse and direct solar properties,
704 respectively.

705

706 Fourth, a surface cryospheric radiative transfer model should flexibly accommodate
707 coupled simulations with distinct atmospheric and surface spectral grids. Both the 5-band
708 scheme used in SNICAR and the 3-band scheme used in dEdd-AD separate the visible
709 from near-IR spectrum at $0.7 \mu\text{m}$. This boundary aligns with the Community
710 Atmospheric Model's original radiation bands (CAM; Neale et al., 2012), though not
711 with the widely used Rapid Radiative Transfer Model (RRTMG; Iacono et al., 2008)
712 which places $0.7 \mu\text{m}$ squarely in the middle of a spectral band. A mismatch in spectral
713 boundaries between atmospheric and surface radiative transfer schemes can require an
714 ESM to unphysically apportion energy from the straddled spectral bin when coupling
715 fluxes between surface and atmosphere. The spectral grids of surface and atmosphere
716 radiation need not be identical so long as the coarser grid shares spectral boundaries with
717 the finer grid. In practice maintaining a portable cryospheric radiative module such as
718 SNICAR requires a complex offline toolchain (Mie solver, spectral refractive indices for
719 air, water, ice, and aerosols, spectral solar insolation for clear and cloudy skies) to
720 compute, integrate, and rebin SSPs. Aligned spectral boundaries between surface and
721 atmospheric would simplify the development of efficient and accurate radiative transfer
722 for the coupled Earth system.

723

724 Last, it is important to note that, although we only examine the performance of the dEdd-
725 AD for pure snow in this work, this algorithm can be applied to the surface solar
726 calculation of all cryospheric components with or without light-absorbing particles
727 present. First, Briegleb and Light (2007) proved its accuracy for simulating ponded/bare
728 sea-ice solar properties against observations and a Monte Carlo radiation model. Second,
729 In CESM and E3SM, the radiative transfer simulation of snow on land ice is carried out
730 by SNICAR with prescribed land ice albedo. Adopting dEdd-AD radiative core in
731 SNICAR will permit these ESMs to couple the snow and land ice as a non-uniformly
732 refractive column for more accurate solar computations since bare/snow-covered/ponded

733 land ice is physically similar to bare/snow-covered/ponded sea ice, and the latter is
734 already treated well by dEdd-AD radiative transfer core. Third, adding light-absorbing
735 particles in snow will not change our results qualitatively. Both dEdd-AD and SNICAR
736 simulate the impact of light-absorbing particles (black carbon and dust) on snow and/or
737 sea ice using self-consistent particle SSPs that follow the SNICAR convention (e.g.,
738 Flanner et al., 2007; Holland et al. 2012). These particles are assumed to be either
739 internally or externally mixed with snow crystals; the combined SSPs of mixtures (e.g.
740 Appendix A of Dang et al., 2015) are then used as the inputs for radiative transfer
741 calculation. The adoption of dEdd-AD radiative transfer algorithm in SNICAR, and the
742 implementation of SNICAR snow SSPs in dEdd-AD enables a consistent simulation of
743 the radiative effects of light-absorbing particles in the cryosphere across ESM
744 components.

745

746 In summary, this inter-comparison and evaluation has shown multiple ways that the solar
747 properties of cryospheric surfaces can be improved in the current generation of ESMs.
748 We have merged these findings into a hybrid model SNICAR-AD, which is primarily
749 composed of the radiative transfer scheme of dEdd-AD, 5-band snow/aerosol SSPs of
750 SNICAR, and the parameterization to correct for snow albedo biases when solar zenith
751 angle exceeds 75° . This hybrid model can be applied to snow on land, land ice, and sea
752 ice to produce consistent shortwave radiative properties for snow-covered surfaces across
753 the Earth system. With the evolving and further understanding of snow and aerosol
754 physics and chemistry, the adoption of this hybrid model will obviate the effort to modify
755 and maintain separate optical variable input files used for different model components.

756

757 SNICAR-AD is now implemented in both the sea-ice (MPAS-seaice) and land (ELM)
758 components of E3SM. More simulations and analyses are underway to examine its
759 impact on E3SM model performance and simulated climate. The results are however
760 beyond the scope of this work and will be thoroughly discussed in a future paper.

761 **9. Conclusions**

762 In this work, we aim to improve and unify the solar radiative transfer calculations for
763 snow on land and snow on sea ice in ESMs by evaluating the following two-stream
764 radiative transfer algorithms: the two-stream delta-Eddington adding-doubling algorithm
765 dEdd-AD implemented in sea-ice model Icepack/CICE/MPAS-seaice, the two-stream
766 delta-Eddington and two-stream delta-Hemispheric-Mean algorithms implemented in
767 snow model SNICAR, and a two-stream delta-Discrete-Ordinate algorithm. Among these
768 three models, the dEdd-AD produces the most accurate snow albedo and solar absorption

769 (Section 5). All two-stream models underestimate near-IR snow albedo and overestimate
770 near-IR absorption when solar zenith angles are larger than 75° , which can be adjusted by
771 a parameterization we developed (Section 6). We compared the implementations of
772 radiative transfer cores in SNICAR and dEdd-AD (Section 7) and recommended a
773 consistent and hybrid shortwave radiative model SNICAR-AD for snow-covered surfaces
774 across ESMs (Section 8). Improved treatment of surface cryospheric radiative properties
775 in the thermal infrared has recently been shown to remediate significant climate
776 simulation biases in Polar Regions (Huang et al., 2018). It is hoped that adoption of
777 improved and consistent treatments of solar radiative properties for snow-covered
778 surfaces as described in this study will further remediate simulation biases in snow-
779 covered regions.
780

781 **Data availability.** The data and models are available upon request to Cheng Dang
782 (cdang5@uci.edu). SNICAR and dEdd-AD radiative transfer core can be found at
783 <https://github.com/E3SM-Project/E3SM>.
784

785 **Competing interests.** The authors declare that they have no conflict of interest.
786

787 **Acknowledgments.** The authors thank Prof. Stephen G. Warren and Prof. Qiang Fu for
788 insightful discussions on radiative transfer algorithms. The authors thank Dr. Adrian
789 Turner for instructions on installing and running MPAS-seaice. The authors thank Dr.
790 David Bailey and one anonymous reviewer for their careful reading and insightful
791 suggestions. This research is supported as part of the Energy Exascale Earth System
792 Model (E3SM) project, funded by the U.S. Department of Energy, Office of Science,
793 Office of Biological and Environmental Research, with funding number DE-SC0012998.

971

972 Figure 1. The spectral albedo of pure snow computed using 16-stream DISORT,
 973 SNICAR, dEdd-AD, and 2SD models, for clear-sky (direct beam at solar zenith angle
 974 60°) and cloudy-sky conditions in the left and right panels, respectively. The top panels
 975 show spectral albedo. The middle panels show the difference ($\delta\alpha = \alpha_2 - \alpha_{16}$) in spectral
 976 albedos computed using the two-stream model (α_2) and 16-stream DISORT (α_{16}). The
 977 bottom panels show the difference of reflected spectral flux given $\delta\alpha$. The snowpack is
 978 set to semi-infinite deep with grain radius of $100 \mu\text{m}$.

993 Figure 3. The difference in direct snow albedo ($\delta\alpha = \alpha_2 - \alpha_{16}$) computed using two-stream
 994 models (α_2) and using 16-stream DISORT model (α_{16}), for various snow depths and solar
 995 zenith angles, with snow grain radius of 100 μm . From the top to the bottom rows are
 996 results of two-stream models SNICAR, dEdd-AD, and 2SD. From the left to the right
 997 columns are albedo differences of all-wave, visible, near-IR bands.

1030 Figure 10. Comparison of light-absorption profiles derived from two-stream models and
 1031 16-stream DISORT. The left-most column shows fractional band absorptions computed
 1032 using 16-stream DISORT. The right three panels show the errors of all-wave, visible, and
 1033 near-IR fractional absorptions calculated using two-stream models. The top and bottom
 1034 panels are for clear-sky and cloudy-sky conditions (solar zenith angle of 60°),
 1035 respectively. The snowpack is 10 cm deep and is divided evenly into five 2-cm thick
 1036 layers, for new snow ($r = 100 \mu\text{m}$) and old snow ($r = 1000 \mu\text{m}$). The layers 1-4 represent
 1037 the top four snow layers (top 8 cm), and layer 5 represents underlying ground with albedo
 1038 of 0.25.

Figure 11. (a) Direct near-IR snow albedo and (b) near-IR fractional absorption by top 2-cm snow of a 2-m thick snowpack, for solar zenith angles larger than 70° and snow grain radii of $100 \mu\text{m}$ and $1000 \mu\text{m}$. (c) The ratios of near-IR albedo computed using CICE to that computed using 16-stream DISORT for different solar zenith angles. These ratios are parameterized as linear functions of the logarithmic of snow grain radius. The slopes and y-intercepts are shown in (d). The black dashed curves in figures (c) and (d) are fitting values computed using parameterization discussed in Section 5.
