9 **Abstract.** The summer albedo of Arctic sea ice is heavily dependent on the fraction and color of melt
10 ponds that form on the ice surface. This work presents a new dataset of sea ice surface fractions along
11 Operation IceBridge (OIB) flight tracks derived from the Digital Mapping System optical imagery set. This
12 dataset was created by deploying version 2 of the Open Source Sea-ice Processing (OSSP) algorithm to
13 NASA's Advanced Supercomputing Pleiades System. These new surface fraction results are then
14 analyzed to investigate the behavior of meltwater on first-year ice in comparison to multiyear ice.
15 Observations herein show that first-year ice does not ubiquitously have a higher melt pond fraction than
16 multiyear ice under the same forcing conditions, contrary to established knowledge in the sea ice
17 community. We discover and document a larger possible spread of pond fractions on first-year ice
18 leading to both high and low pond coverage, in contrast to the uniform melt evolution that has been
19 previously observed on multiyear ice floes. We also present a selection of optical images that captures
20 both the typical and atypical ice types, as observed from the OIB dataset. We hope to demonstrate the
21 power of this new dataset and to encourage future collaborative efforts to utilize the OIB data to
22 explore the behavior of melt pond formation Arctic sea ice.

23 1 Introduction

24 The extent and age of the Arctic sea ice cover has declined since the beginning of the satellite record in
25 1979 (Stroeve et al., 2012). Ice melt is accelerated through albedo feedback cycles initiated by surface
26 melt decreasing the ice cover's reflectance (Curry et al., 1995; Perovich et al., 2003). Understanding
27 changes in sea ice properties that impact albedo, particularly melt pond coverage, is important to
28 parameterizing sea ice in global climate models (Hunke et al., 2013; Serreze et al., 2009). In-situ
29 observations that could support developing this understanding are sparse, difficult to acquire, and may
30 not be broadly representative (Perovich, 2002a; Wright and Polashenski, 2018). Remote sensing
31 platforms provide a path to understanding sea ice surface change over larger scales. Newly developed
32 computational techniques provide the means to analyze large remotely sensed datasets (Miao et al.,
33 2015; Webster et al., 2015; Wright and Polashenski, 2018). The NASA Operation IceBridge project (OIB)
34 has collected large amounts of high-resolution optical imagery of sea ice with the Digital Mapping
35 System (DMS) (Dominguez, 2010, updated 2017). At ~10cm resolution, these images capture the ice
36 surface in fine detail – but it is challenging to convert them to quantitative measures of ice conditions.

37 A new technique for analyzing high-resolution optical imagery of sea ice has recently been
38 developed and demonstrated (Wright and Polashenski, 2018). This technique, named the Open Source
39 Sea-ice Processing algorithm (OSSP), automatically analyzes input imagery and classifies image area into
40 four primary surface type categories: 1) snow and unponded ice, 2) dark or thin ice, 3) melt ponds and
41 submerged ice, and 4) open ocean. Categories 1 and 2 are often combined to create a unified ice
42 category. Several improvements and new features that define version 2 of OSSP are presented here.
43 This version was used to create a new dataset by deploying the algorithm on a large scale to process the
44 entirety of the NASA OIB optical image dataset. This dataset is now publicly available for community use
45 and for other studies leveraging the IceBridge data suite. This publication is intended partially to serve
46 as supporting documentation for those uses.

47 The summer portion of the new dataset is then used to evaluate existing hypotheses about melt
48 pond formation on Arctic sea ice. One such hypothesis describes the prevalence of ponds on first-year
49 sea ice (FYI) versus multiyear ice (MYI). It has been widely stated that FYI has a higher average fractional
50 pond coverage than MYI over the complete melt season (Eicken et al., 2004; Fetterer and Untersteiner,
51 1998a; Morassutti and Ledrew, 1996; Perovich and Polashenski, 2012). This would contribute to positive
52 ice-albedo feedbacks, since the higher pond fraction would lower albedo of FYI, re-enforcing the
53 transition to a younger ice pack. The reasoning most cited for expecting higher pond coverage on FYI is
54 related to ice and snow topography (Barber and Yackel, 1999; Derksen et al., 1997; Eicken et al., 2004).
55 When ice grows from open Arctic waters, it tends to form in flat, undeformed pans or fairly level
56 pancake fields (Weeks, 2010). Though these pans are subsequently broken and ridged by dynamic
57 forces, in most parts of the Arctic a large fraction of FYI remains level. When surface melt begins on level
58 FYI floes, melt water is unconstrained by topography and spreads to cover a large fraction of the surface.
59 On MYI, however, the ice has survived prior melt seasons that create more complex surface topography
60 even in areas without mechanical deformation. The meltwater is then contained by the prior year's
61 melt-formed topography into well-defined pools. The result *should be* that FYI would tend to experience
62 greater pond coverage than MYI. Indeed, this has been presented by several authors as a likely change
63 in the Arctic (Eicken et al., 2004; Polashenski et al., 2012).

64 It is important to note that pond evolution over the melt season is highly variable and is controlled
65 by the balance of melt water inflow and outflow rates, surface topography, and snow depth. There are
66 four stages that characterize seasonal melt pond formation described in Eicken et al. (2002) and
67 paraphrased as follows: (1) Initial onset of ponds above sea level with a rapid increase in areal coverage,
68 (2) increased outflow allowing drainage to sea level with a decline in areal extent, (3) graduate increase
69 in areal coverage due to ice melting to below ocean freeboard, and (4) refreezing. Despite a common
70 understanding of high pond coverage on FYI, a collection of previous observations (Eicken et al., 2004;
71 Perovich, 2002; Webster et al., 2015) have shown the possibility that FYI has lower pond coverage than
72 MYI under certain circumstances. For example, in stage 2 areal coverage drops significantly more on FYI
73 than it does on MYI (Polashenski et al., 2012). Observations at the SHEBA drifting ice camp found that
74 10-30% of the FYI in the region formed few melt ponds. Measurements there linked this observation to
75 snow cover: Ice with little or no snow cover and with more than 0.5m snow cover had less than 1% pond
76 coverage (Eicken et al., 2004). Webster et al., (2015) found regions where FYI started ponding much
77 later than MYI, though the FYI ultimately developed higher pond coverage later in the summer. A new
78 observational dataset of melt ponds on sea ice from OIB is used here to assess pond coverage
79 differences between ice age at the height of summer melt (July), and to expand previous observations of
80 pond-free FYI to regional scales.

81 A second, related, hypothesis on the behavior of FYI melt ponds suggests two summer melt
82 evolution pathways exist: one which yields high pond fraction, and one that yields near-zero pond
83 fraction (Perovich, 2002a; Polashenski et al., 2017), depending on early season ice permeability and the
84 duration of surface flooding. Our new observations of pond coverage over large areas of FYI provide
85 additional insight. Here, the OSSP-labeled OIB images were used to assess the variation in pond
86 coverage on FYI and the prevalence of pond-free floes within the Chukchi and Beaufort Seas. To
87 accomplish this, a method of post-processing has been developed that determines the size of sea ice
88 areas devoid of pond coverage as a metric to quantitatively address the prevalence of low pond
89 coverage. This new analysis reveals that FYI pond coverage indeed exhibits both pathways, but that
90 there is *not* a strict duality – FYI pond coverage appears to occupy all states across the near-zero to high
91 coverage space. While the OIB image dataset provides large spatial coverage over long flight transects,
92 the lack of temporal coverage makes it impossible to directly link these snapshots of pond coverage to
93 any specific pond evolution process.

94 **2 Methods**

95 **2.1 Data Sources**

96 The datasets described herein are the result of processing NASA Operation IceBridge optical DMS
97 imagery. The DMS images were acquired with a Canon EOS 5D Mark II digital camera which has a 10cm
98 horizontal ground resolution and a spatial footprint of ~600x400m when used at the survey altitude of
99 1500 feet (Dominguez, 2010, updated 2017), and is available for download at the National Snow and Ice
100 Data Center (NSIDC). 87 IceBridge flights were processed, occurring between 2010 and 2018. The OIB
101 flights were categorized into freezing and melting conditions, which map to the spring/fall and summer
102 campaigns respectively. The mean date of melt onset in the Chukchi Sea, Beaufort Sea, and Central
103 Arctic from 1979-2012 was May 17, May 28, and June 10 respectively (Bliss et al., 2014). Spring flights
104 took place before these dates (March to mid-May, typically), and summer flights well after (mid to late

105 July). No flights took place during melt or freeze onset transitional phases, making this a clean
106 categorization: The flights between March and May were categorized as freezing condition flights (no
107 melt ponds expected), and those taken in July were categorized as melting condition flights (melt ponds
108 expected). One flight during fall freeze-up (October 5) was processed and was grouped with the spring
109 set. Using this delineation, there were 9 flights during melting conditions and 78 flights during freezing
110 conditions. Of the 9 melting condition flights, 4 occurred in 2016 originating from Utqiagvik, Alaska, and
111 4 occurred in 2017 originating from Thule AFB, Greenland. There was an additional summer flight
112 departing from Utqiagvik on July 20th, 2016, that was not processed due to constant cloud cover
113 obscuring the images.

114 A graphic of the flight tracks for all OIB sea ice flights processed, colored by freezing/melting
115 condition status, is presented in Fig. 1. For the majority of this paper, we will focus on the melting
116 season (summer) flights, colored in yellow. Spring data products are posted for use by the community.
117 We anticipate that future analysis of spring flight data will help confirm lead identification in analysis of
118 altimetry data and provide statistics on lead size and spacing and morphology useful to studies of, for
119 example, blowing snow loss to leads or ice dynamics.

120 **2.2 OSSP Algorithm Improvements**

121 A number of improvements have been made to OSSP since the initial version 1 release described in
122 Wright and Polashenski (2018). These changes can be divided into three categories: 1) Those that alter
123 the algorithms used to classify images, 2) those which add new features, and 3) those which improve
124 code efficiency but do not alter the core methodology. Changes that fall into category (3)
125 reimplemented existing functions for improved performance and decreased computational resource
126 usage. These will not be discussed in detail as they do not change the results.

127 **2.2.1 Algorithm Refinements**

128 OSSP is an object-based segmentation and classification image processing algorithm. In version 1, edge
129 detection for segmentation was done by applying a Sobel-Feldman filter to the image, amplifying the
130 resulting values to highlight strong edges, and thresholding low gradient value pixels to remove weak
131 edges. The amplification factor and threshold value were both presented as tuning parameters that
132 could control the number and strength of edges to detect in the image. In version 2, image edges are
133 instead found with a Canny edge detector (van der Walt et al., 2014), which has three built-in tuning
134 parameters: A gaussian filter with chosen radius that removes noise from the image, a high threshold
135 which selects strong edges, and a low threshold which defines weak edges. These three parameters can
136 be selected based on the quality of the input image and the degree of segmentation sought. The change
137 in edge detection method does not significantly shift the behavior of the OSSP method but allows the
138 user to better tune the segmentation to specific images. The remainder of the OSSP code uses
139 methodology as presented in Wright and Polashenski (2018).

140 **2.2.2 New Features**

141 Four new features were added for processing the OIB optical image dataset: 1) An image quality
142 analyzer which flags excessive cloud cover or haze, 2) an automatic white balance correction function, 3)

143 expanded training datasets specific to OIB images, including shadow detection in spring images, and 4)
144 orthorectification to a flat plane WGS84 spheroid.

145 Clouds and semi-opaque haze are common in OIB imagery. These often partly obscure the surface
146 and prevent accurate image classification. An automated algorithm has been added that detects
147 obscured images so that they can be removed from analysis. The quality check is based on applying a
148 Fourier transformation to the image to detect the ratio of high and low frequency features. It is an
149 implementation of the De and Masilamani (2013) method, where the quality score is the percent of
150 image pixels that have a frequency greater than 1/100,000th of the maximum frequency. Poor quality
151 images were empirically found to have a score of less than 0.025, potentially unusable images had a
152 score between 0.025 and 0.035, and images with a score greater than 0.035 were generally acceptable.

153 A large number of OIB images are taken in poor surface lighting conditions. This is often a result of
154 the aircraft flying under cloud cover or high solar zenith angles. Darker than expected and blue-shifted
155 images are observed under these conditions. Unlike the hazy images flagged by the quality check, these
156 can still be accurately classified. An automatic white balance correction function has been added to
157 standardize the hue and exposure of these images and the resulting image classification. We use a
158 single-point white balance algorithm:

$$159 \begin{bmatrix} R_c \\ G_c \\ B_c \end{bmatrix} = \begin{bmatrix} \frac{omax}{R_w} & 0 & 0 \\ 0 & \frac{omax}{G_w} & 0 \\ 0 & 0 & \frac{omax}{B_w} \end{bmatrix} * \begin{bmatrix} R \\ G \\ B \end{bmatrix}$$

160 where

$$161 \quad \quad \quad omax = \max (R_w, G_w, B_w)$$

162 and (R_w, G_w, B_w) is a chosen white reference pixel, (R,G,B) is the original pixel value triplet, and
163 (R_c, G_c, B_c) is the corrected pixel value triplet. The reference point triplet is chosen automatically based
164 on the image histogram of each color band; it is the smallest value that is both larger than the highest
165 intensity peak and has less than 15% of that peak's pixel counts. This method sets the selected reference
166 point to true white (255,255,255). All other pixels in the image are corrected with the same linear
167 scaling which serves to both adjust the image exposure and rebalance the RGB ratios. The white
168 reference pixel is limited to a minimum value of 200 for images with only a single surface. This prevents
169 them from being improperly stretched so that an open water only image will remain black. The effect
170 this color correction has on two poorly illuminated images is shown in Fig. 2.

171 The OIB dataset has a clear binary division between flights where melt ponds are expected (July),
172 and those where they are not (March–May). This characteristic allows for the utilization of two
173 specialized training datasets—one for each season. The summer training dataset is a new, larger, set than
174 was presented along with OSSP v1.0, including additional points to encompass a wider range of possible
175 ice conditions. The spring training dataset includes a ridge shadow surface classification class and does
176 not include a melt pond category. The shadow detection method was not applied to melting condition
177 images as the typical summer solar zenith angle yields fewer shadows. The algorithm allows melt pond
178 and shadow detection to be used together given the correct training data, but this was not utilized for
179 the creation of the dataset described here. Webster et al., (2015) found that ridge shadows make up less

180 than 0.5% of the ice surface in spring, indicating that any errors due to misclassifying them are small.
181 Removal of the melt pond category from spring images prevented occasional spurious detection of melt
182 ponds and improved the quality of results. The training data creation followed the same technique
183 presented in the OSSP version 1.0 documentation (Wright and Polashenski, 2018). The summer dataset
184 was expanded to a total of 1706 training points, and the spring dataset to a total of 865 points. These
185 training datasets can be found along with the OSSP code at (<https://github.com/wrightni/ossps>).

186 **2.3 Detecting Pond-Free Ice Areas**

187 The labeled image output by the OSSP algorithm was further analyzed to extract metrics about the
188 spatial distribution of water features in summer. A technique was developed to find contiguous regions
189 of pond-free ice. These regions were defined as a circle with diameter greater than 12m that does not
190 overlap any water feature. First, the labeled image was converted into a binary image separating the
191 snow and ice features from water (i.e. melt ponds plus ocean). Next, the distance from every snow/ice
192 pixel to the nearest water feature was calculated, and peaks with a local maximum distance above a
193 threshold of 12 meters were recorded. Pond free areas are the circle centered at these peaks with a
194 radius of the distance to the nearest water feature. Any two overlapping regions were combined by
195 adding the non-overlapping area of the smaller region to that of the larger region. These pond free
196 regions are divided into two categories, small and large, based on a threshold of a 25 m radius. The
197 thresholds of 12m and 25m were selected to be approximately 2x and 4x the mean caliper diameter of
198 melt ponds (Huang et al., 2016). The number of pond free areas per image was multiplied by the ice
199 fraction (sum of all non-ocean categories) of that image to account for differing ice concentrations
200 between images. Figure 3 shows an example of this detection, where the location of both the small and
201 large regions are marked with small dots and the large regions have a translucent circle showing the size
202 of that region.

203 **2.4 Error**

204 There are several sources of error in OSSP ice type classifications when applied to the DMS dataset.
205 The established accuracy of the OSSP method, on a high-quality input image, is 96% (Wright and
206 Polashenski, 2018). The principle source of error novel to this OIB dataset was due to lower quality
207 images, typically from haze obscuring the surface or poor surface illumination. While automated
208 methods standardize the quality of the input and flag bad images (Section 2.2.2), some input errors
209 remain. The impact of uncorrected haze is twofold: First, it causes the algorithm to misclassify open
210 water as melt pond, and second, it obscures surface type boundaries and causes insufficient image
211 segmentation. Both issues can be understood by looking at how haze changes an optical image: It adds
212 noise to the image, tends to brighten the pixel values, and blurs surface features. As the defining feature
213 of open water is its uniform darkness, a layer of haze makes this surface more like a dark melt pond. The
214 blurring impacts the edge detection algorithm used by OSSP and therefore causes a breakdown of the
215 proper delineation of image surfaces. For the analyses of the summer dataset presented herein, images
216 were manually sifted to remove those scenes that were not flagged by the QA analysis, but were still of
217 questionable quality. Due to the heterogenous nature of sea ice, there is a trade-off between accuracy
218 on a specific image and accuracy on the entire dataset – some images flagged as low quality may be
219 usable with a training dataset tailored to those specific images. Users of this dataset should inspect their
220 region of interest to ensure the image quality meets their desired standard.

221 3 Results

222 3.1 Melt pond fraction along OIB flight tracks

223 In this paper we focus on presenting results from summer images only. Images from 87 IceBridge flights
224 were processed with the OSSP algorithm representing over 900,000 individual images using the
225 methods described above – these results are available for other investigations at the NSIDC archive.
226 Figure 4 maps the track of every melt season OIB flight and plots melt pond fraction observed along
227 these tracks. Melt pond fraction was calculated as the number of melt pond pixels divided by the total
228 ice area (ice pixels + pond pixels). Images where more than 70% of the area was classified as open water
229 are colored black in Figure 4 but were processed normally. Images that were automatically removed due
230 to a low quality score (section 2.2.2) are colored orange, and images that were manually removed due
231 to low image quality are colored red. In total, 40,672 summer images were analyzed, of which 14,876
232 (36.6%) were flagged with a low quality score, 5,671 (13.9%) were manually removed, and 20,125
233 (49.5%) were kept for this analysis. The July 20th, 2016 flight was not processed because only about 2%
234 (30 total) of the images were haze free. Note both high variation in pond coverage along track and
235 general regional changes between flights. Some additional variation between flights is due to temporal
236 change, for example it appears a summer snow occurred just prior to the July 19, 2016 flight, lowering
237 the observed pond fraction.

238 Figure 5 plots 300km of the along-track melt pond fraction for the July 24th, 2017 flight. This figure
239 illustrates the large variability possible in melt pond fraction along track seen in the first half of the flight
240 (top), with a minimum observed fraction of 10% and spikes to greater than 50%. The second half of this
241 flight (bottom) has a more uniform melt pond fraction of ~20%. Four peaks are highlighted in orange
242 where a large blue pond formed on the MYI (See Fig. 11d). Figure 6a zooms in to a 10km subset of this
243 transect, and the surface corresponding to the orange highlighted section is shown in Fig. 6b. The optical
244 image is the result of stitching 23 DMS images together. The highlighted peak in melt pond fraction
245 occurs on a section of FYI between two multiyear floes. This case follows the prevailing hypothesis about
246 the differences between pond formation on MYI and FYI. The relatively flat FYI section allows melt
247 ponds to spread over the surface more evenly, resulting in a higher melt pond coverage, despite
248 encountering the same atmospheric conditions as the MYI on either side. It is also possible that melt
249 water from the MYI drains to the lower elevation FYI (Fetterer and Untersteiner, 1998a).

250 3.2 Influence of Ice Type on Melt Pond Fractions

251 Each summer transect was categorized into first-year ice, multiyear ice, or mixed ice based on manual
252 inspection of those flight's images. The delineation of ice type was based on pond shape, color, and
253 distribution as well as ice surface topography (Johnston and Timco, 2008). The flights classed as a single
254 ice type had at least 90% (estimated from visual inspection) of that type. Melt pond statistics for single
255 ice type flights are shown as box and whisker plots in Fig. 7, where each flight is colored by its ice type
256 categorization; blue for FYI and green for MYI. In these plots the box outline shows the 75th and 25th
257 percentile, the middle line displays the median, the whiskers show 1.5x the interquartile range, and the
258 red points are outliers. Generally, the 2016 flights departing from Utqiagvik, Alaska, observed FYI while
259 the 2017 flights departing from Thule AFB, Greenland, observed MYI. There are three exceptions to this
260 categorization: July 13, 2016 and July 19, 2016 contain both ice types, where small pockets of MYI were
261 included in the northern sections of an otherwise primarily FYI region, and flight A on July 25th, 2017

262 covers FYI. Statistics for the two mixed ice type flights are plotted separately in Fig. 8, where each flight
263 is divided into FY or MY ice categories.

264 Figure 7 reveals two insights into the difference in melt pond fractions between FYI and MYI. First,
265 there is no obvious difference in the median pond fraction between flights, and second, there is more
266 variance in the pond fractions on FYI. The variance is described by the interquartile range, the mean of
267 which is 0.1 for the first-year flights and 0.05 for the multiyear flights. In other words, while FYI exhibited
268 a wider range of possible pond fractions, the average coverage is not observed to be higher than on
269 MYI. The difference in timing and region between OIB flights precludes drawing general conclusions
270 about differences in median melt pond fraction between ice types. However, two flights that contained
271 both FY and MY ice were selected for further analysis to investigate melt pond statistics across ice that
272 experienced similar forcing conditions: July 19, 2016 and July 13, 2016. The portions of these transects
273 that depict each ice type were manually determined. Results, delineated by ice type, for these two
274 flights are shown in Fig. 8. The key observation here is that the two flights show opposite relationships:
275 On July 19 the FYI has a lower median pond fraction, while on July 14, the FYI has a higher median pond
276 fraction. Previous work has shown the possibility for FYI to have lower pond cover than MYI at local
277 scales (i.e. individual floes) (Eicken et al., 2004, Webster et al., 2015). Our results support this
278 observation and show that it can also happen at regional scales. That pond coverage is more variable on
279 FYI than it is on MYI suggests that while ponds evolve differently on each type there is not a simple
280 relationship in mean pond fraction. In other words, one cannot conclude that FYI has either higher or
281 lower pond fractions than MYI.

282 **3.3 Observations of Pond-Free First-year Ice**

283 The frequency at which FYI develops low pond coverage was investigated using the pond-free region
284 detection algorithm to find large unponded areas. Figure 9 shows the results of applying this algorithm
285 to selected segments of the July 19, 2016 flight. Panel (a) shows the results for a portion of primarily FYI
286 with high pond coverage, (b) shows a region of FYI that has many areas of pond-free ice, and (c) shows
287 results from a section of MYI. The ice analyzed for Fig. 9a is what we understand would be considered as
288 a common state for FYI in an advanced state of melt, where ponds have drained to sea level but a high
289 portion of the ice floe remains below freeboard and yields a uniformly high pond fraction. This state
290 coincides with the third stage of pond evolution. This contrasts with the FYI analyzed for Fig. 9b where,
291 while melt ponds are still present, there are large open areas of pond free ice. The ponds on the MY floe
292 are regularly distributed and the fractional pond coverage shows little variance. This could coincide with
293 stage 2 of pond evolution, where ponds have drained and none remain above freeboard, or to a region
294 where ponds never formed. A timeseries would be required to distinguish these paths. Expanding from
295 these regions of this specific flight, 17% of all summer FYI images processed for this study have 3 or
296 more large pond free regions. This reinforces previous observations by Eicken et al. (2004) that
297 estimated 10 to 30% of FYI surrounding the SHEBA ice camp had “low or zero pond cover”. In contrast,
298 in the MYI portion of this dataset, only 5% of images have 3 or more large pond free regions. While
299 there is a clear difference between the MYI and FYI types, the important observation here is the large
300 percentage of FYI that has lower than expected pond coverage.

301 3.4 Snapshots of a Summer Sea Ice Cover

302 In processing the Operation IceBridge optical imagery dataset, we have had the unique opportunity to
303 review a significant library of images detailing different sea ice states, looking at thousands of square km
304 of sea ice. So few people actually observe the sea ice that notions of what is ‘typical’ or unusual are still
305 not well known. In Figures 10 and 11 we present some examples of what we have observed to be
306 ‘representative’ ice states, and examples of ice conditions that are uncommon. The OSSP analyzed
307 results for each frame in Figure 10 and 11 are in Supplement S1 and S2, respectively. These are intended
308 to serve as a qualitative summary of the extensive OIB observations, against which future campaigns can
309 be quickly compared. For each presented image we label the noted features based on the frequency at
310 which we have observed them. Along an arbitrary 100km transect of ice in a given melt state; *common*
311 describes a feature that can be expected on more than half of the ice, *occasional* describes features that
312 would be expected to show up 5-10 times, and *infrequent* describes a feature that may present once or
313 twice.

314 Sea ice scenes shown in Fig. 10: **(a)** FYI that shows a wide range of the possible melt pond fractions,
315 ranging from pond free to high pond coverage; *occasional*. **(b)** Highly ponded level FYI scene in early
316 melt, where ice appear as islands in a sea of water. Such ice was *common* in large areas in the Chukchi
317 sea. **(c)** FYI with high pond fraction and very interconnected pond structure. *Common*; this represents
318 the generally understood behavior of FYI. Here we also see that ponds preferentially form towards the
319 middle of the floe leaving a pond-free border around the edge. The floe-edge gradients are particularly
320 strong in this image, the pond-free border is an *occasional* feature. **(d)** Example of a floe where ponds
321 preferentially form away from the edges. These small floes with central ponds were common in broken
322 FYI. **(e)** Shorefast level ice in the Lincoln Sea. Ponds have started to drain already, as evidenced by the
323 drainage channels visible throughout the ice. This type of relatively low coverage and consolidated
324 ponds were *infrequent* in the OIB dataset, but may be common of ice in this region. We speculate that
325 deep snow dunes and thick ice are responsible. **(f)** This image shows a region that appears to have had a
326 recent summer snowfall event. The snow serves to fill shallow ponds with slush or to completely cover
327 them and significantly lowers pond fraction – *infrequent* in the OIB dataset as it is dependent on specific
328 weather conditions. **(g)** A *common* example of high pond fraction FYI. **(h)** Flat and thin ice pans that are
329 almost completely covered by melt water, this scene is *common* for late stages of melt on FYI.

330 Sea ice scenes shown in Fig. 11: **(a-c)** *Common* examples of ponded MYI floes with characteristically
331 blue ponds that are well consolidated by surface topography, showing the range of pond fractions that
332 are possible. **(d)** Example of large reservoir-like ponds that were only observed on MYI. These are
333 *occasional* features on large sections of MYI. **(e)** MYI with FYI inclusions from ocean that refroze during
334 the last winter, this is *common* for MYI at lower latitudes, and *occasional* at higher latitudes. In cases of
335 small FYI inclusions in MYI fields like this, the FYI ice is typically darker had has a higher pond coverage.
336 **(f)** An example of low pond coverage MYI – this was *infrequent* in the OIB dataset. **(g+h)** Ponded FYI
337 undergoing drainage, where evidence of previous ponds is still visible. The overall image represents
338 *common* features, but the drainage pattern here is *infrequently* observed, likely due to its short lifespan.

339 **4 Discussion**

340 A common hypothesis in the sea ice community states that FYI has, on average, higher melt pond
341 coverage than MYI. While there is considerable nuance to this statement due to the variability of pond
342 coverage over the temporal domain, it represents a testable hypothesis which our results above did not
343 support. It should be noted that our dataset represents single snapshots in time, and while many melt
344 states were observed, it is impossible to assess complete seasonal averages of melt pond coverage here.
345 There are many factors contributing to areal melt pond coverage differences between FYI and MYI. In
346 the early season, when meltwater sits on impermeable ice above sea level, limited topography causes a
347 similar volume of meltwater to flood larger areas of FYI than it would on rougher MYI. This is supported
348 by observations in early melt stages, which show FYI melt pond coverage in excess of 60%. Such
349 coverage exceeds that seen on MYI at any time (Landy et al., 2014; Polashenski et al., 2012). However, in
350 Stage 2, MPF on FYI tends to decline faster than on MYI because the meltwater can drain to sea level at a
351 faster rate (Polashenski et al., 2012). In the late season, after ponds have drained to sea level, it has
352 been argued that thinner FYI will have less buoyancy and less ice area above freeboard than MYI. In
353 contrast, on thicker FYI the level surface would have fewer depressions and more buoyancy, and
354 therefore more ice area above freeboard (e.g. Figure 10d). The relative pond fraction between FYI and
355 MYI depends on the time along the melt evolution and the ice physical properties. Over many melt
356 states observed in the complete summer dataset (Figures 7 and 8), we did not find a statistically
357 significant difference in average pond fraction between FYI and MYI.

358 An alternate hypothesis about the behavior of FYI ponds emerging in some recent papers is that FYI
359 pond coverage is extremely variable and may have bimodal evolution driven by snow topography and
360 permeability (Perovich, 2002b; Polashenski et al., 2017; Popović et al., 2018). FYI ponds may not form at
361 all under certain circumstances if the ice is highly permeable or lacks snow cover (Polashenski et al.,
362 (2017) and references therein). Other observations show very high melt pond coverage that persists
363 even after ponds drain to sea level (Polashenski et al., 2015). This divergence of pond behavior raises the
364 possibility of bimodal behavior wherein some FYI would flood extensively and experience more ponding
365 than MYI while other FYI might not pond at all. The image dataset analyzed in this study does *not*
366 support the bimodal hypothesis, but rather supports the idea that FYI pond coverage is much more
367 variable than MYI, and existing in all states from low to high pond cover. Several factors could be the
368 cause of the high variability seen in our dataset. For example, diurnal effects can play a large role in the
369 melt pond fraction on FYI by significantly changing surface melt rates on short time scales (Eicken et al.,
370 2004; Hanesiak et al., 1999). Alternatively, if ice and snow topography controls pond fraction after
371 ponds drain (Polashenski et al., 2012), FYI where snow dunes or differential melt create surface
372 roughness will have higher pond fraction while ice that is level will be pond-free. As the sea ice
373 topography is highly variable, we would expect corresponding variability in the pond fraction.

374 Examining the pond coverage in more detail provides evidence that the range of possible melt states
375 is larger on FYI than it is on MYI. In other words, FYI exhibits all possible states between low and high
376 coverage, while MYI pond fraction typically exists within a small window. Returning to the boxplots in
377 Fig. 7, note the larger interquartile range (IQR) of the first-year flights versus the multiyear flights. If we
378 were to accept the traditional hypothesis that all FYI had high pond cover, we would expect the FYI to
379 have a higher median but a similar IQR. However, this is not the case. These observations suggest pond
380 cover on FYI is highly variable, and only in a subset of circumstances does the ice exhibit the expected

381 higher pond fraction. Examples of each behavior are included in Fig. 8. The traditional understanding of
382 melt pond evolution on FYI, where flat undeformed ice allows melt water to spread horizontally and
383 create large areas of pond covered ice is often observed on landfast ice or ice attached to a multiyear
384 floe (e.g. Barber and Yackel, 1999; Derksen et al., 1997; Fetterer and Untersteiner, 1998b; Uttal et al.,
385 2002). For example, Fig. 6b shows a refrozen lead between two MYI floes, where the pond fraction is
386 significantly higher on the flat FYI than on either of the adjoining MYI floes. Along the July 19, 2016
387 transect many of the smaller (less than 200m diameter) freely floating floes of flat FYI exhibited little to
388 no pond cover late in the melt season (as seen in Fig. 10d). We also note many examples of floes that
389 are pond free along their edges, such as in Fig. 10c, and floes that exhibit nearly complete pond
390 coverage (such as 10b,g,h). This dataset, therefore, helps establish that no simple relationship between
391 FYI and MYI ponding exists, and presents the possibility that the transition to FYI is not causing uniformly
392 higher melt pond fraction, as has been expected. Due to the temporal variability in pond evolution,
393 complete timeseries datasets are needed to fully analyze the relationship between MPF and ice age.
394 Understanding the distribution of MPF on basin wide scales would be key to understanding whether the
395 transition from MY to FYI has a net increase on pond prevalence. No large scale, comprehensive
396 observations have been available to resolve the prevalence of such behaviors.

397 **5 Conclusion**

398 A new dataset quantifying sea ice surface fractions observed in Operation IceBridge DMS imagery has
399 been created using the recently developed OSSP algorithm. This dataset classifies the surface coverage
400 into four categories. During the melt season these categories are: 1) snow or thick ice, 2) dark or thin
401 ice, 3) melt ponds and submerged ice, and 4) open water. In freezing conditions, the categories become
402 1) snow or thick ice, 2) dark or thin ice, 3) open water, and 4) ridge shadows. The dataset allows for the
403 investigation of sea ice surface type distributions along OIB transects and opens the door for new
404 studies, both by analysing this dataset in isolation (as demonstrated here), and by combining it with
405 coincident OIB datasets such as ice thickness or ice roughness. This dataset is available at the NSDIC for
406 community use. Future improvements to this dataset should include work towards a more sophisticated
407 haze removal algorithm to apply to the OIB optical images. This will increase accuracy and increase the
408 fraction of images that can be successfully processed.

409 We have investigated snapshots of melt pond coverage differences between FYI and MYI in the
410 Beaufort/Chukchi Sea region for 2016 and the Lincoln Sea for 2017. Our results support previous
411 findings that FYI can have lower pond fraction than MYI under similar forcing conditions. While the
412 results presented herein cannot definitively confirm or refute the hypothesis that FYI has higher mean
413 pond fraction than MYI, the high variability in FYI pond fraction over large regions suggests that the
414 general rule of thumb that FYI should have higher ponding than MYI is too simplistic. Furthermore, the
415 finding that FYI exhibits much larger variance over its temporal evolution indicates that there is not one
416 path that defines the typical pond coverage changes. We did not find sufficient evidence that there is a
417 strict duality in FYI pond evolution either, and we suggest future process studies investigate the
418 mechanisms that drive FYI towards high or low pond fraction and specifically note that time-series
419 image observations and/or field studies may be necessary to unravel this question. The different
420 trajectories that pond development can apparently take on FYI may have large impacts on sea ice
421 modelling efforts, through albedo feedbacks. Furthermore, we suggest combining this new melt pond

422 dataset with data available from the IceBridge Airborne Topographical Mapper to determine the
423 relationship between sea ice topography and melt pond formation.

424

425 *Data and Code Availability.* The OSSP algorithm code is available on github
426 (<https://github.com/wrightni/ossps>) and the release for this manuscript is archived at zenodo (DOI:
427 10.5281/zenodo.3551033). The pond free detection algorithm is archived at zenodo (DOI:
428 [10.5281/zenodo.3971014](https://doi.org/10.5281/zenodo.3971014)) and is available at github (https://github.com/wrightni/pondfree_detection).
429 Raw Operation IceBridge DMS imagery is available from the National Snow and Ice Data Center
430 (<https://doi.org/10.5067/OZ6VNOPMPRJ0>). OSSP generated results are also archived at the NSDIC
431 (<https://doi.org/10.5067/1LI57H56EB7G>).

432

433 *Author Contributions.* NW was responsible for writing the original draft, creating the data visualizations,
434 review and editing of the manuscript, designing and testing the OSSP software, conceptualization and
435 programming of the pond-free detection algorithm, and formal analysis of the OSSP generated results.
436 CP was responsible for initiating the study, contributing to writing and editing the manuscript, and
437 contributing to methodology and result analysis. SM was responsible for implementing the OSSP
438 software on NASA's Pleiades system, monitoring data processing, and data archiving. RB was responsible
439 for funding acquisition and supervision for the Ames Research Center team and for review and editing of
440 the manuscript draft.

441

442 *Conflicts of Interest.* The authors declare that they have no conflicts of interest.

443

444 *Acknowledgements.* The authors would like to thank NASA's AIST Program whose funding enabled this
445 research. The image processing for this work was carried out on NASA's Advanced Supercomputing
446 Pleiades system.
