11 **Abstract.**

12 Northwestern Alaska has been highly affected by changing climatic patterns with new temperature and precipitation maxima
13 over the recent years. In particular, the Baldwin and northern Seward peninsulas are characterized by an abundance of
14 thermokarst lakes that are highly dynamic and prone to lake drainage, like many other regions at the southern margins of
15 continuous permafrost. We used Sentinel-1 synthetic aperture radar (SAR) and Planet CubeSat optical remote sensing data to
16 analyze recently observed widespread lake drainage. We then used synoptic weather data, climate model outputs and lake-ice
17 growth simulations to analyze potential drivers and future pathways of lake drainage in this region. Following the warmest
18 and wettest winter on record in 2017/2018, 192 lakes were identified to have completely or partially drained in early summer
19 2018, which exceeded the average drainage rate by a factor of ~10 and doubled the rates of the previous extreme lake drainage
20 years of 2005 and 2006. The combination of abundant rain- and snowfall and extremely warm mean annual air temperatures
21 (MAAT), close to 0° C, may have led to the destabilization of permafrost around the lake margins. Rapid snow melt and high
22 amounts of excess meltwater further promoted rapid lateral breaching at lake shores and consequently sudden drainage of
23 some of the largest lakes of the study region that likely persisted for millenia. We hypothesize that permafrost destabilization
24 and lake drainage will accelerate and become the dominant drivers of landscape change in this region. Recent MAAT are
25 already within the range of predictions by UAF SNAP ensemble climate predictions in scenario RCP6.0 for 2100. With MAAT
26 in 2019 exceeding 0° C at the nearby Kotzebue, Alaska climate station for the first time since continuous recording started in
27 1949, permafrost aggradation in drained lake basins will become less likely after drainage, strongly decreasing the potential
28 for freeze-locking carbon sequestered in lake sediments, signifying a prominent regime shift in ice-rich permafrost lowland
29 regions.

31 Keywords: Permafrost, permafrost thaw, thermokarst, lake change, lake drainage, Seward Peninsula, Baldwin Peninsula,
32 Alaska

33 **1 Introduction**

34 Permafrost is widespread (20 to 25 % of the land area) in the northern high latitudes (Brown et al., 1997; Obu et al., 2019) and
35 is primarily a result of past and present cold climatic conditions (Shur and Jorgenson, 2007). The rapidly warming Arctic
36 climate is already reducing the stability and distribution of near-surface permafrost. Warming of permafrost at the global scale
37 has been observed over recent decades from borehole temperature measurements (Romanovsky et al., 2010; Biskaborn et al.,
38 2019), while local to regional permafrost degradation has been observed in many studies of varying scales across the permafrost
39 domain (Nitze et al. 2018a). Widespread near-surface permafrost loss or transition from continuous to discontinuous
40 permafrost has for example been shown with remote sensing-supported permafrost modeling in Alaska (Pastick et al., 2015).
41 Permafrost degradation may lead to long-term surface subsidence (Streletskiy et al., 2017), change in hydrological regimes
42 (Liljedahl et al., 2015), and release of greenhouse gases carbon dioxide (CO₂), methane (CH₄), or nitrous oxide (N₂O)
43 (Elberling et al., 2013; Walter Anthony et al., 2018; Repo et al., 2009). In particular, the release of greenhouse gases from
44 carbon locked away for thousands of years will trigger further warming through the permafrost carbon feedback (Schoor et
45 al., 2015). Furthermore, the stability of permafrost is crucial for local communities which are dependent on ground stability
46 for infrastructure, food security, and water supply (Chambers et al., 2007; White et al., 2007; Melvin et al., 2017; Hjort et al.,
47 2018).

48 Rapid changes in lake area, including expansion and drainage, are strong indicators of permafrost degradation and thaw (Smith
49 et al., 2005; Hinkel et al., 2007; Jones et al., 2011; Grosse et al., 2013; Arp et al., 2018; Nitze et al., 2018a). Natural lake
50 drainage has been associated with near-surface permafrost degradation such as melting of ice wedges, formation of thermo-
51 erosional channels, gully headward erosion, or internal drainage through permafrost-penetrating taliks (Mackay, 1988;
52 Yoshikawa and Hinzman, 2003; Hinkel et al., 2007; Marsh et al., 2009; Jones et al., 2020a). Other natural lake drainage events
53 have been connected to increased precipitation, causing bank overtopping with subsequent drainage channel formation, or
54 snow dams and subsequent outburst floods and drainage channel formation (Mackay, 1988; Jones and Arp, 2015).

55 The southern margin of continuous permafrost in northwestern, western and interior Alaska as well as adjacent northwestern
56 Canada has been identified as a region with a high temporal variability in lake area, and particularly widespread lake drainage
57 (Jones et al., 2011; Chen et al., 2014; Lantz and Turner, 2015; Nitze et al., 2018a). Over the past few decades, lake drainage
58 has outpaced lake growth by 14.9 % on the Seward Peninsula in western Alaska, largely driven by the drainage of several very
59 large individual lakes (Jones et al., 2011; Nitze et al., 2017). Other transitional permafrost regions around the Arctic are broadly
60 affected by the same pattern, with widespread drainage events and net lake area loss (Smith et al., 2005; Nitze et al., 2018a).
61 However, lakes also experience intra-annual (Cooley et al., 2017, 2019) to multi-year (Plug et al., 2008; Karlsson et al., 2014)
62 water level fluctuations linked to precipitation and evaporation dynamics or overall hydrological runoff regimes, which can

63 cause high uncertainty in interpreting temporally sparse observations. In particular, recently shifting weather patterns with
64 warmer air and sea surface temperatures along Arctic coasts driven by reduced sea ice cover (Bhatt et al., 2014) may also have
65 an effect on coastal lowland permafrost (Lawrence and Slater, 2005) and thus potentially lake dynamics (Alexeev et al., 2016;
66 Arp et al., 2019). For example, persistent warm air and sea surface temperatures caused a new sea ice minimum in the Bering
67 Sea west of Alaska resulting in unprecedented largely open seas in the winter 2017/2018 (Stabeno and Bell, 2019) .

68 Other regions with cold continuous permafrost (e.g., Arctic Coastal Plain, Tuktoyaktuk Peninsula, Coastal Lowlands of
69 Siberia) are also affected by lake drainage (Hinkel et al., 2007; Kravtsova and Bystrova, 2009; Karlsson et al., 2012; Lantz
70 and Turner, 2015; Olthof et al., 2015; Nitze et al., 2017, 2018a; Jones et al., 2020a), but to a lesser intensity than the transitional
71 zone towards discontinuous permafrost, particularly in Alaska and western Siberia (Nitze et al., 2017, 2018a).

72 Several studies suggest that lake drainage might be episodic with drainage events clustered in time and therefore potentially
73 related to specific environmental conditions, such as high precipitation events (Marsh et al., 2009; Swanson, 2019; Jones et
74 al., 2020a). Others, in contrast, find more stable to decreasing, long-term drainage rates, e.g. in northern Alaska and the Western
75 Canadian Arctic (Hinkel et al., 2007; Marsh et al., 2009; Jones et al., 2020a).

76 In western Alaska, a series of major drainage events took place in the mid-2000s, where some of the largest thermokarst lakes
77 on the ground-ice rich northern Seward Peninsula drained within a short period of a few years (Jones et al., 2011; Swanson,
78 2019). The recent drainage of several large lakes on the northern Seward Peninsula and the largest lake on the Baldwin
79 Peninsula provides an interesting test bed for analyzing lake drainage progression in high temporal and spatial detail using
80 remote sensing imagery, meteorological data, and lake ice characteristics. The geographic proximity to the Bering and Chukchi
81 seas that both have experienced rapid sea ice loss and climatic shifts in recent years offers a unique opportunity to study the
82 relationship between changing climate regimes and lake dynamics in permafrost regions on short-time-scales. In this study we
83 therefore use temporally high-resolution remote sensing and meteorological data to quantify:

- 84 1) How much lake area was affected by the recent drainage events in western Alaska in 2018?
- 85 2) How do the drainage events, documented in 2018, compare to other previous events such as in the mid 2000's in
86 terms of area, spatial distribution, and temporal (intra-annual) sequence?
- 87 3) What are the primary drivers of the recent drainage events and how may projected future climate scenarios affect lake
88 trajectories in this region?

89 To answer these questions, we analyzed recent optical and synthetic aperture radar (SAR) satellite imagery (Planet, Sentinel-
90 1) from 2017 and 2018 to map the spatio-temporal lake change dynamics and compared the results to available datasets of past
91 lake dynamics (Nitze et al., 2018a; Nitze et al., 2018b) and climatic conditions. Furthermore, we investigated weather and
92 climate data as well as modeled lake ice conditions as potential drivers of the widespread lake drainage.

93 2 Study area

94 In this study, we focus on the northern Seward Peninsula (NSP) and the Baldwin Peninsula (BP) in western Alaska. The study
95 area covers a total land area (including interior water bodies) of 25,271 km². It is bounded by the Chukchi Sea and Kotzebue
96 Sound to the north and northwest, different hill ranges in the south, and Selawik Lake, Hotham Inlet and the 161°W meridian
97 in the east (Figure 1). It is part of the Bering Land Bridge region, which was largely unglaciated during the last glacial
98 maximum and is now located at the southern margin of the continuous permafrost zone (Jorgenson et al., 2008; Obu et al.,
99 2019). Measured ground temperatures range between -3.5 and -0.8 °C (Biskaborn et al., 2015; GTN-P Ground Temperature
100 Database). Modeled ground temperatures range between -2.8 and +0.5 °C, with the majority between -1.5 and -2.0°C (Obu et
101 al., 2019).

102 The area is characterized by a subarctic continental climate with a mean annual air temperature (MAAT) of -5.1 °C and 279
103 mm precipitation as reported at the Kotzebue climate station (NOAA, 1981-2010). Snowfall accumulation averages 157 cm
104 per year, considerably more than for example in northern Alaska (~95 cm in Utqiagvik/Barrow). Snow typically persists until
105 the mid to end of May (Macander et al., 2015).

106 The study region is composed of a strongly degraded ice-rich permafrost landscape with typical permafrost landforms, such
107 as thermokarst lakes and drained thermokarst lake basins of several generations (Plug and West, 2009; Jones et al., 2011;
108 Jones et al., 2012), pingos, ice wedge polygon networks, and ice-rich yedoma uplands as remnants of the Pleistocene
109 accumulation plain (Hopkins, 1955; Jongejans et al., 2018). The morphology is variable with mostly flat terrain (<20 m) in
110 highly degraded permafrost terrain along the coastal margin of the NSP and undulating terrain with steep slopes in the upland
111 regions of the NSP. The mountainous terrain along the southern margin of the NSP reaches up to ~700 m elevation. The
112 Baldwin Peninsula (BP) is characterized by rolling terrain from sea-level to ~50 m elevation with a mixture of degraded
113 permafrost with partially drained lake basins and uplands in various stages of degradation (see Figure 1).

114 The foothills and mountain ranges of the study area are underlain by bedrock. Furthermore, the NSP is locally affected by Late
115 Quaternary volcanism, with the presence of four known maar lakes (Devil Mountain, White Fish, North Killeak, South
116 Killeak), which are the largest lakes of the study region and the largest maar lakes globally (Beget et al., 1996). Further volcanic
117 landscape features such as degraded volcanic bedrock cores, young basaltic lava flows and young cinder cones are locally
118 present in the southern portion of the NSP (Hopkins, 1955). In part, deposits of the BP are likely of glacial origin, with a buried
119 terminal moraine covered with yedoma-like, ice-rich sediments (Huston et al., 1990; Jongejans et al., 2018).

120 The region is one of the major lake districts in Alaska (Arp and Jones, 2009). Lake presence in the selected study area is
121 concentrated on the coastal plains and thermokarst terrain. The majority of lakes are located in drained thermokarst lake basins,
122 have shallow depths of less than 2 m, and are often later generation thermokarst lakes in locations that experienced several
123 previous lake generations (Jones et al., 2012; Lenz et al., 2016). However, first generation thermokarst lakes up to 15 m in
124 depth, intersecting the remaining yedoma upland surfaces, are still present (Kessler et al., 2012). Yedoma uplands with flat

125 surfaces are speckled with initial thermokarst ponds and small lakes, most notably on the BP (Jongejans et al., 2018). In
126 addition, the four large maar lakes on the NSP that reach depths of up to 100 m (Beget et al., 1996).
127 Vegetation is predominantly composed of shrubby tundra and is located in zones D and E of the Circumpolar Arctic Vegetation
128 Map (CAVM) (Walker et al., 2005). Vegetation is typically abundant in sheltered areas along thermokarst lake margins.
129 Floating vegetation mats may be present on lakes margins and persist above water associated with expanding lake margins
130 (Parsekian et al., 2011).

131 **3 Data and Methods**

132 **3.1 Data**

133 **3.1.1 Lake dataset base layer**

134 We used the lake change dataset of Nitze et al. (2018a, 2018b) as the base layer for further analysis and for understanding
135 decadal-scale lake dynamics. This dataset contains polygon vectors of the buffered lake extent of individual lakes larger than
136 1 ha. Water bodies smaller than 1 ha were excluded from the original analysis due to Landsat's spatial resolution of 30m. The
137 dataset includes spatial attributes and statistics such as individual lake area in 1999 and 2014, net change (gain minus loss) and
138 gross changes (gain, loss) from 1999-2014, as well as lake shape parameters, such as orientation, eccentricity, and solidity. All
139 lakes intersecting the study area (n=4605) were selected for analysis. We focussed on this period due to the availability of this
140 already published and available dataset. Further GIS and spatial analyses are based on the geometries of this lake dataset (Lake
141 Change 1999-2014: named Lk hereafter). An overview of the lake change datasets is provided in Table 1.

142 **3.2 Remote sensing analysis**

143 **3.2.1 Water masks for 2017 and 2018: Sentinel-1 imagery**

144 We extracted late-summer water masks for the years 2017 and 2018 using Sentinel-1A/B SAR data in Google Earth Engine
145 (GEE) (Gorelick, et al., 2017) (see Figure 2). We focussed on the difference from 2017 to 2018 as this period was previously
146 identified as strongly affected by lake drainage.

147 We identified all Sentinel-1A/B images available between 1 August and 30 September in both 2017 and 2018 (Watermask
148 2017: WM2017, Watermask 2018: WM2018) and selected VV polarization, which was available for all S1-data within this
149 period. Erroneous low-backscatter values along image margins, which are a common issue for these datasets, were clipped per
150 default with a buffer of 5000 m.

151 We created a median value composite of the entire image stack, to lessen the impact of very high backscatter values caused by
152 windy conditions. After histogram analysis, we determined a backscatter value of -18 dB as the best threshold point between
153 land and water. All backscatter values below -18 dB were added to the surface water masks of 2017 (WM2017) and 2018
154 (WM2018), respectively. We exported the two water masks to raster files with 20x20 m grid spacing in UTM3N projection.

155 The water masks WM2017 and WM2018 were intersected with the lake extent base layer (Lk) using zonal statistics in QGIS
156 version 3.6 (QGIS Development Team, 2019) to retrieve lake area extent and zonal statistics values for 2017 and 2018.
157 Lastly, all lakes with a lake area loss of >25 % and initial size of >1 ha, based on the difference of WM2017 and WM2018,
158 were defined as drained lakes. This follows previous studies defining drainage thresholds by lost water area of >25 % (Hinkel
159 et al., 2007; Olthof et al., 2015; Jones et al., 2020a). The drained lakes dataset is referred to as LkDrain.

160

161 Links to the GEE code used for water masking are provided in the Code and Datasets Section.

162 **3.2.2 Timing of drainage 2017 and 2018: Planet imagery**

163 To determine the drainage patterns and mechanics as well as to compare long-term versus short-term drainage patterns, we
164 automatically analyzed temporally high-resolution Planet CubeSat imagery (Planet Team, 2017) from 2017 and 2018 and
165 visually inspected the largest drained lakes. With over 120 satellites in orbit, the Planet constellation provides a temporal
166 frequency of observations of less than one day at a ground resolution of 3.125 m, which makes Planet data an ideal solution
167 for mapping rapid landscape dynamics at high spatial and temporal resolutions. For mapping individual lake dynamics in 2017
168 and 2018, we used the automated lake tracking workflow presented in Cooley et al. (2017, 2019). A complete description of
169 the method can be found in Cooley et al. (2019). A brief summary is provided here. First, we downloaded all PlanetScope
170 (3.125 m resolution) and RapidEye OrthoTiles (5 m resolution) with <20 % cloud cover available from Planet Labs between
171 May 1 and October 1 for both 2017 and 2018. We then created an initial lake mask which contains the maximum extent of all
172 water bodies in the study area between 2017 and 2018. This initial mask was buffered by 60 m and all rivers were removed to
173 produce a buffered water mask used for both seeding the water classification and tracking changes in lake area.

174 We then classified all of the images into water or land by applying a histogram-derived threshold to each image's NDWI
175 $((\text{NIR} - \text{green}) / (\text{NIR} + \text{green}))$ as described in Cooley et al. (2017; 2019). To track changes in lake area, we used an object-
176 based lake tracking method wherein for every image, we calculated the total amount of water contained within each lake object
177 in the buffered mask. This method allows for direct comparison between RapidEye and PlanetScope imagery with its different
178 spatial resolution and furthermore is robust against potential minor geolocation uncertainty.

179 At the time of analysis, Planet Labs imagery did not provide a reliable cloud mask. Therefore, the third and most critical step
180 of the method was removal of cloudy or poor quality observations using a machine learning-derived filtering algorithm. To do
181 this, we first created a manual training dataset of valid/invalid lake area observations and then used this dataset to build a
182 random forest classifier that automatically removes cloudy/poor quality lake observations. This method is able to accurately
183 classify 97 % of observations as valid or invalid. We then selected the best observation for each day and applied additional
184 outlier and median filters to produce the final time series. While we do not specifically remove ice-covered observations from

185 the analysis, Cooley et al. (2019) demonstrate that most ice-impacted lake area observations are classified as invalid by the
186 random forest classifier.

187 The final lake dynamics dataset, henceforth referred to as LkDyn, includes buffered polygon vectors, seasonal time series of
188 lake area, as well as basic descriptive lake area statistics such as minimum area, maximum area, and seasonal dynamics (max
189 - min) for each individual lake. For the analysis of temporal lake drainage patterns we spatially joined all lakes of LkDyn,
190 which intersected LkDrain.

191 **3.2.3 Identifying past lake drainage for 1999-2014**

192 For lake dynamics from 1999-2014, we used the lake change dataset of Nitze et al. (2018b) (Lk) to compare recent dynamics
193 to the observed drainage events of 2018. We opted for manual image interpretation based on satellite imagery video animations
194 as there is to our best knowledge no reliable automated method available to determine drainage dates in challenging Arctic
195 environments. We tested the automated LandTrendr method, which automatically determines breakpoints in time-series, to
196 retrieve the timing of lake drainage between 1999 and 2018 (Kennedy et al., 2010; Kennedy et al., 2018). Results obtained
197 with this method were highly unstable with insufficient reliability.

198 We created video animations in GEE for each individual drained lake, with time-stamped frames, and determined the drainage
199 year manually through visual interpretation (link to code see below). The drainage year was defined as the point in time of
200 initial clearly visible drainage, which could be a) visible exposure of lake bottom sediments or b) a strong increase in
201 vegetation, e.g. due to sudden lake level drop. The entire calculated area loss was assigned to the determined drainage year.
202 Lake area loss of lakes with a longer drainage process >1 year, e.g. from 2005 until 2009, were counted as full drainage in the
203 initial drainage year (2005). The visual interpretation was aided by plotting the time-series of multi-spectral indices (Tasselled
204 Cap, NDVI, NDWI) for each individual drained lake.

205 Lakes with data gaps (up to several years) right before the determined drainage year, were flagged in the statistics. This
206 frequently applied to years 2005 and 2008, which had several data gaps in the preceding years (see Supplementary Figure 1).
207 Data gaps were caused by limited data availability, frequent cloud cover and shadows, as well as the Landsat-7 Scan Line
208 Corrector (SLC) error. Lakes where the timing could not be detected manually, e.g. in case of very subtle drainage, were
209 assigned no drainage year (25 of 270 lakes).

210 Links to the GEE video animation processing code and time-series plotting are provided in the Code and Datasets Section.

211 The videos are accessible at:

212 [https://github.com/initze/NW Alaska Drainage Paper/tree/revision01/animations/lake_animations_drainage_1999-2014](https://github.com/initze/NW_Alaska_Drainage_Paper/tree/revision01/animations/lake_animations_drainage_1999-2014)

213

214 3.3 Climate and weather analysis

215 3.3.1 Weather

216 We analyzed synoptic weather data from the nearest weather station in Kotzebue (see Figure 1a) that is provided by the
217 National Oceanic and Atmospheric Administration (NOAA). We acquired the GHCN-Daily datasets (Menne et al., 2012) in
218 CSV format through the web-search on the NOAA website (<https://www.ncdc.noaa.gov/cdo-web/search>). The dataset provides
219 a daily series of minimum (T_{\min}) and maximum (T_{\max}) temperatures (T), precipitation (prcp) and snowfall (sf) since 1897,
220 with continuous observations since 1950. Temperature recordings from 01 May 2019 through 03 September 2019 were
221 affected by erroneous measurements and removed by NOAA from reprocessed datasets (as of 29 July 2020). Precipitation and
222 snowfall measurements were not affected and are available for the entire period.

223 Daily mean temperatures are not available continuously. Therefore, we calculated daily mean temperatures as the mean of
224 daily minimum and daily maximum temperatures. For calculating the influence of winter conditions (T, prcp, sf) we analyzed
225 the weather conditions from July 1 of the preceding year until June 30 on a yearly basis, from here on referred to as “winter
226 year”. Therefore, winter year 2018 for example is defined as the period from July 1 2017 through June 30 2018. In addition to
227 the standard attributes (mentioned above), we calculated Freezing Degree Days (FDD) as the cumulative sum of negative mean
228 daily temperatures per winter year. Snow accumulation is calculated as the cumulative sum of snowfall per winter year. We
229 calculated climatological means for daily observations and yearly aggregated statistics. For daily values we calculated means
230 and standard deviations of mean temperatures (T_{mean}) for each calendar day, excluding 29 February, from 1 January 1981
231 through 31 December 2010. We calculated yearly mean temperature as the mean of daily T_{mean} mean temperatures (T_{mean}).
232 We calculated the mean of yearly values between 1981 and 2010 as the climatic mean temperature. For annual statistics of
233 winter years we calculated values ranging from July 1980 through June 2010, according to the previously stated winter year
234 definition.

235 Code: For climate and weather data preprocessing and time-series plotting, a python package was developed by Ingmar Nitze,
236 which is available at <https://github.com/initze/naaplotter>.

237 3.3.2 Climate prediction

238 We downloaded Decadal SNAP (Scenarios Network for Alaska and Arctic Planning, 2020) Ensemble Climate Model
239 Projections (2 km CMIP/AR5) of Scenarios RCP4.5, RCP6.0, and RCP8.5 for the study region. This dataset contains decadal
240 (2010-2019, 2020-2029, ..., 2090-2099) mean annual, seasonal and monthly air temperature and precipitation. For analysis
241 we used annual predictions of temperature (MAAT) and precipitation (MAP). Gridded data is available at a spatial resolution
242 of 2 km across Alaska and parts of western Canada. We clipped the data to the extent of the study area and calculated the mean
243 and standard deviations for the entire study region for projected MAAT and MAP values for each decade.

244 **3.4 Lake ice simulations**

245 We used the Canadian Lake Ice Model (CLIMo; Duguay et al., 2003) to analyze the impact of weather conditions on lake ice
246 growth and permafrost. CLIMo is a 1-D thermodynamic ice model that has been used in several studies (Ménard et al., 2002;
247 Labrecque et al., 2009; Brown and Duguay, 2011; Surdu et al., 2014; Antonova et al., 2016). CLIMo output includes all energy
248 balance components, on-ice snow depth, the temperature profile at an arbitrary (specified) number of levels within the ice/snow
249 (or the water temperature if there is no ice) and ice thickness (clear ice and snow ice) on a daily basis, as well as freeze-
250 up/break-up dates and end-of-season clear (congelation) ice, snow ice and total ice thickness. Model output of particular
251 interest to lake ice simulations within the context of this study is the evolution of lake ice growth and maximum ice thickness
252 as they are useful proxies for freezing intensity and the influence of weather conditions on potential ground stability.
253 Thicknesses of snow ice and that of congelation ice layers (referred to hereafter as “top-growth” and “bottom-growth”,
254 respectively) were also analyzed to account for snow mass and snow insulation effects.

255 The lake ice model is forced with five meteorological variables consisting of mean daily near-surface air temperature, relative
256 humidity, wind speed, cloud cover, and snowfall (or snow depth from a nearby land site when available). Four of the five
257 meteorological variables (all but snowfall) were taken directly or derived from the ERA5 atmospheric reanalysis product from
258 the European Centre for Medium-Range Weather Forecasts (ECMWF). Since ERA5 did not provide adequate snowfall or
259 snow depth values, we obtained snow depth data from NOAA’s Global Historical Climate Network Daily (from the nearest
260 weather station at Kotzebue Ralph Wien Memorial Airport) for model simulations.

261 We performed simulations over nearly a 40-year period (1980-2018) and with specification of a mixed-layer depth of 2 m.
262 The length of the record was chosen based on the availability of ERA5 data and to be able to place lake ice model output for
263 the 2018 winter year into a broader historical context. Finally, in order to account for redistribution of snow across lake ice
264 surfaces which is a process well documented in several studies (e.g. Duguay et al., 2003; Sturm and Liston, 2003; Brown and
265 Duguay, 2011; Kheyrollah Pour et al., 2012), we ran the model with two sets of snow depth scenarios; one with full snow
266 cover (100 % of the amount measured at the Kotzebue weather station) and the other with no snow cover (0 % snow – i.e.
267 snow free ice surface) to capture the range of snow conditions that one would expect to observe in the field.

268 **3.5 Random Forest Feature Importance analysis of annual weather variables**

269 In order to analyze the influence of weather conditions on the annual drained lake area we used the Feature Importance (FI)
270 measure of the Random Forest machine-learning model (Breiman, 2001). The internal FI metric quantifies the importance of
271 individual input variables as a percentage, where all individual FI sum up to 100 %.

272 Random Forest is an ensemble of individual decision trees and is a widely used method for classification and regression tasks
273 (Belgiu and Drăguț, 2016) as well as measuring feature importances (Nitze et al., 2015). We used annual (winter year) weather
274 attributes as input features (mean temperature, cumulative precipitation, cumulative snowfall, freezing days, freezing degrees
275 of the winter year) and annual drained lake area (1999-2014, 2018) as the target variable. As the FI requires a high number of

276 individual decision trees we carried out our analysis with 1000 trees with the scikit-learn package in python. For evaluating
277 the model performance we used the r^2 on the training data and unbiased r^2 based on the internal out-of-bag estimator and leave-
278 one-out cross-validation.

279 **4 Results**

280 **4.1 Lake changes**

281 **4.1.1 Lake drainage 2018**

282 Lake area loss was severe in 2018, where 192 of 4605 lakes larger than 1 ha lost more than 25 % of their initial size (LkDrain).
283 These lakes lost an accumulated water area of 1622.04 ha between late summer 2017 and 2018. Total net lake area loss,
284 including all lakes, was 2062.56 ha (4 % of the total lake area in the study domain).

285 Lake drainage clustered around two types of lake sizes. Five very large lakes (>100 ha) lost 1072.68 or 66.1 % of the total
286 drained lake area (LkDrain), while the remaining 190 lakes accounted for 549.36 ha or 34.9 %, where the largest lake had an
287 initial size of 28.5 ha in 2017 (Table 2). Of the five large drained lakes, four are of thermokarst origin and the largest is a
288 lagoon on the BP, which likely is affected by episodic flooding and drying. The five large lakes that drained were some of the
289 largest thermokarst lakes in the entire study area before drainage (Size rank 6, 12, 32, 39, 51). The only other bigger lakes in
290 the study region were formed or affected by Late Quaternary volcanic activity (four maar lakes and Imuruk Lake) and therefore
291 are less prone to lake drainage caused by permafrost degradation.

292 Spatially, the highest density of lake drainage events is located in the Cape Espenberg region in the northeastern part of the
293 NSP (see Figure 3). On the BP, two spatial clusters of lake drainage prevail. The first cluster is located in the center of the
294 northern part of the BP, which encompasses the now drained formerly largest lake (Lake ID 64656) and its neighboring basins.
295 The second cluster is located in the southern part of the BP, where several partially drained lakes form a nearly linear structure.
296 Smaller clusters or individual lake drainage events are scattered predominantly along coastal and lowland areas of the entire
297 study region and across different landscape units, such as uplands, thermokarst basins, coastal depressions or river floodplains.
298 Lake drainage in the southern more mountainous region of the SP was scarce.

299 **4.1.2 Intra-annual lake drainage dynamics**

300 **Temporal Patterns**

301 The analyzed lakes exhibit various distinct seasonal patterns of lake area loss or drainage. The ice-break-up period in late May
302 and early June 2018 was the most dominant period of lake drainage. Nine of the largest 10 lakes (see Table 3) exhibit a strong
303 decline in lake area before July 2018, and one rapid drainage event in early July (Lake ID 101359). In the majority of these
304 cases (n=8), the first valid observation of 2018 already shows a significant decline compared to the last observation of 2017,
305 which indicates drainage during snow-melt and ice-break-up, when data observations were still masked due to the presence of

306 ice and snow. During June 2018 weather conditions were favorable for optical remote sensing and observations for ice-free
307 persistent lakes are available. From July lake area only decreased slowly and gradually among the analyzed lakes (LkDrain)
308 without further distinct drainage peaks. A detailed example of a representative lake drainage event is presented in Figure 4.
309 Apart from the general regional dynamics, individual lake drainages followed variable patterns of drainage velocity/duration
310 and timing. Drainage patterns included sudden complete lake area loss (e.g. Lake IDs 99230, 64656), multiple recurring
311 drainage events (Lake IDs 72420, 100644, 99583), gradual loss (Lake IDs 99756, 100218) to initial loss followed by partial
312 refilling (Lake IDs 99381, 99465, 99532) (see Supplementary Files).

313 Supplementary figures are available at:

314 https://github.com/initze/NW_Alaska_Drainage_Paper/tree/revision01/figures/lake_drainage/planet_lake_area

315

316 **Quantification**

317 The early season lake drainage affected the largest lakes, and therefore the largest area. The time-series animation of the ten
318 largest lakes can be accessed by video (see Table 2). The third largest drained lake (Lake ID 99230) for example started
319 draining on June 2 and lost the majority of its water within the following two weeks. During the summer months the remaining
320 shallow ponds dried out further, while only few apparently deeper ponds remained. Imagery from spring 2019 showed the
321 development of vegetation, which follows the typical thermokarst lake cycle of this region (lake, lake drainage, drying of
322 exposed lake bottom, vegetation emergence; Jones et al., 2012) (see Table 2 for video). The largest drained lakes follow a
323 similar trajectory of rapid drainage around ice-break-up and further drying of the drained lake basin during peak summer.

324

325 **Spatial patterns**

326 Nine out of the ten largest drained lakes are second generation thermokarst lakes, which are typically located within a complex
327 of previously drained lake basins. The second largest “lake” is actually a lagoon, which is likely influenced by sea water
328 inundation. Each of the lakes had a significant fraction of their shoreline within the former drained lake basin. These are
329 typically covered by wet tundra and underlain by terrestrial peat overlying lacustrine sediments (Jones et al., 2012). Based on
330 visual image interpretation, all lakes drained through previously established drainage pathways, which are located in flat basin
331 terrain and suggest that these likely are “weak spots” for full drainage.

332 During these drainage events new channels formed or existing channels deepened. In several instances (Lake IDs 99368,
333 64656, 99492, 102499), new drainage channels are evident based on new sediment fans that formed downstream. In the case
334 of several lakes, the drainage caused a chain reaction, where hydrologically connected lakes, both up- and/or downstream of
335 the initially drained lake, drained as well. Due to the widespread presence of these surface drainage indicators, talik penetration
336 to a groundwater layer can be excluded for the study area.

337 **4.2 Lake drainage 1999-2014**

338 From 1999 through 2014 we observed 268 lakes larger than 1 ha that lost more than 25 % of their area, resulting in a total
339 water area loss of 3245.74 ha during the observed period within this group of lakes. The net lake loss of the study region,
340 including all lakes was 3677.43 ha or 6.0 % of the overall lake area. The six largest drained lakes accounted for more than half
341 of the lost lake area (50.6 %) and were each among the 33 largest lakes (Size rank 9, 12, 13, 26, 29, 33) of the study area (Table
342 3). Each of these lakes was apparently of thermokarst origin.

343 These drained and partially drained lakes predominantly occur along the near coastal zone of the NSP and around Shishmaref
344 Inlet (see Figure 3). Within this region, lake drainages are distributed uniformly with no distinct clusters. The BP and southern
345 Kotzebue Sound do not show major drainage activity in this period with only three lakes that fulfill the defined criteria. The
346 vicinity of Imuruk Lake had four drained lakes.

347

348 **Timing of drainage**

349 The analysis of drained lakes revealed a period of widespread lake drainage with up to 21 confirmed events per year from
350 2002 until 2007 and 2009 (see Supplementary Figure 2). The number of detected drained lakes in 2005 was exceptionally high
351 with 56, but the majority (n=33) did not have sufficient observations in the preceding year 2004 or even 2003 to confirm the
352 correct drainage year. This number of drained lakes is therefore associated with a high degree of uncertainty. Years 2003,
353 2007, 2009 and 2012 also have more than 5 lakes, which have an uncertain drainage date.

354 Although the number of drained lakes is relatively stable over time, drained lake area spiked in 2006 and 2007 with 922 ha
355 (uncertain: 6.35 ha) and 631 ha (uncertain: 15.57 ha) net lake area loss, respectively. The significant uptick in 2006 was driven
356 by the drainage of very large lakes, particularly in the Cape Espenberg region of the NSP. The years 2003 and 2004 follow
357 with lake area loss of 323.65 ha (uncertain: 41.58 ha) and 413.06 ha (uncertain: 3.91 ha), respectively. The numbers are
358 conservative and might be even higher (see uncertainty 2005) due to a low data coverage during this period.

359 **4.3 Weather and Climate**

360 **4.3.1 Weather observations**

361 The preceding winter and spring of 2017/2018 (winter year 2018) was the warmest, wettest and second snowiest on record at
362 this time. Compared to the entire weather record this winter was highly exceptional (Figure 5, Table 4). Mean daily air
363 temperatures exceeded the climatological means persistently and frequently with 127 days above one standard deviation from
364 the climatological mean, only interrupted by a short cold snap in January 2018 (Figure 6). On several days air temperatures
365 were close to 0 °C, which is 15 to 20 °C above the climatological mean. Exceptional warmth lasted continuously from October
366 2017 until December 2019. Winter year 2019 even largely surpassed 2018 in temperatures until the temperature measurement
367 failure from 1 May 2019. The mean temperature was 1.11 °C higher than the previous winter year's period from 1 July through

368 30 April, which projects to a MAAT of -0.21 °C. The cumulative precipitation was lower with 279 mm. Cumulative snowfall
369 was 155 cm.

370 During winter year 2018 weather station Kotzebue recorded only 1905 cumulative Freezing Degree Days (FDD; the sum of
371 average daily degrees below 0 °C) and an annual air temperature of -1.3 °C, which exceeded the previous record by 0.53 °C
372 and 238 FDD. The 10 warmest and 5 coldest years are shown in Table 4. Accumulated snowfall was the 2nd highest on record
373 with 274 cm, only exceeded by 2005 (305 cm). Overall precipitation of the winter year 2018 was the highest on record with
374 424.5 mm, exceeding very wet, but much colder winter years 2013 (402 mm, -5.41 °C) and 1995 (393.7, -5.92 °C).
375 Precipitation, mostly as snowfall, was particularly strong from October through February, with the exception of January.
376 All indicators highlight the exceptional conditions of winter 2017/2018 in western Alaska. Weather data from Nome (ca. 300
377 km south of Kotzebue) on the southern SP indicate a similar picture of extreme weather conditions with the second warmest
378 and third-snowiest winter year on record. Climate reanalysis data (GHcnv4) confirm a larger regional pattern of exceptionally
379 warm conditions across the Bering Strait (see Supplementary Figure 2).

380 **4.3.2 Climate model projections**

381 The UAF SNAP Climate model ensemble consistently projects an increase in temperature and precipitation for western Alaska
382 with a plateau after around 2070 for RCP4.5 and continuous increase for the remaining scenarios in the 21st century. They
383 predict an increase to a regional MAAT of -0.39 ± 0.38 °C (RCP4.5), $+0.44 \pm 0.37$ °C (RCP6.0), and $+3.00 \pm 0.38$ °C (RCP8.5)
384 during the 2090s, which marks an increase of 3.7 to 6.6 °C compared to the period from 2010-2019 (Supplementary Figure 3).
385 MAP is projected to increase by around 12 % (RCP4.5), 20 % (RCP6.0), and 32 % (RCP8.5) on average.

386 **4.4 Lake ice simulations**

387 Modeled maximum lake ice thickness of the winter year 2018 was 1.14 (100 % snow) to 1.32 m (no snow). It was below
388 average compared to 1981-2017 ($1.31 \text{ m} \pm 0.14 \text{ m}$ for 100 % snow; $1.68 \text{ m} \pm 0.12 \text{ m}$ for no snow) but thicker than the absolute
389 minimum of 0.99 m (100 % snow) in 2014. Lake ice thickness of 2018 was primarily determined by top ice-growth (snow-ice
390 formation), which is strongly dependent on snow mass on the ice surface. Snow-ice formation correlates well with high
391 snowfall years, such as 2005 or 2011. The bottom (congelation) ice-growth of 2018 reached a new extreme low with only 0.32
392 m (100 % snow) to 1.32 m (no snow) (see Figure 7). This compares to $0.87 \text{ m} \pm 0.23 \text{ m}$ (100 % snow) and $1.68 \text{ m} \pm 0.12 \text{ m}$
393 (no snow) from 1981-2017. Low bottom ice-growth indicates a strongly decreased freezing activity (negative heat flux) into
394 the lake and potentially into the ground of the surrounding terrain. The exceptional combination of high temperatures and high
395 snowfall, as experienced in ice season 2017-2018, are the strongest factors for these patterns.

396 **4.5 Random Forest Feature Importance analysis of annual weather variables**

397 The feature importance analysis based on a Random Forest machine-learning regression and annual weather variables revealed
398 that the number of freezing days are the strongest predictor of drained lake area. It yielded a Feature Importance (FI) 29.7 %.
399 Cumulative freezing degree days, annual winter year temperatures and cumulative precipitation have a similar impact with a
400 FI of 21.8 %, 19.5 % and 18.8 % respectively. Cumulative snowfall yielded an FI score of 10.3 %. The model performance on
401 the training data was very good with an R^2 of 0.85. However, the predictive power of the model on unseen data was poor with
402 an R^2 of -0.18. The model prediction of extreme drainage events (2006, 2018) was particularly poor with the independent
403 validation.

404 **5 Discussion**

405 **Lake drainage in western Alaska in historical context**

406 The massive drainage of many lakes in early summer 2018 in western Alaska was an extreme event, which dwarfs previous
407 lake drainage events within this region since the availability of remote sensing data. Although the study area experienced
408 widespread lake drainage during the mid 2000's (Jones et al., 2011, Nitze et al., 2018a; Swanson, 2019), the year 2018
409 exceeded average annual lake drainage rates of 1999-2014 by a factor of 7.5 in area and 10.9 in numbers of lakes, clearly
410 indicating a response of the system to extreme weather conditions. Recent lake drainage in 2018 even doubled the previous
411 record year of 2006 in drained area and 10-fold in number of drained lakes. From 1950 until 2006/2007 lake drainage and lake
412 expansion rates on the northern SP were fairly stable. The strong influence of large lakes on drainage rates in 2018 confirmed
413 previous findings (Jones et al., 2011). A recent study by Swanson (2019) identified the same exceptional event for the National
414 Parks of northwestern Alaska, which partially overlaps with our study area.

415 The high level of permafrost degradation, apparent by a large fraction of drained basins of several generations (Jones et al.,
416 2012; Regmi et al., 2012), shows the general susceptibility of the landscape to rapid thermokarst lake dynamics, including
417 drainage, within the study region. This landscape underwent intense thermokarst development over the past millennia, with
418 the onset of thermokarst development during the early Holocene (Wetterich et al., 2012; Farquharson et al., 2016; Lenz et al.,
419 2016).

420 Available data of historic lake drainage is sparse. Therefore, a comparison of recent drainage rates with long-term development
421 is difficult due to a lack of consistent observations, in particular for the pre-remote-sensing period.

422

423 **Local context**

424 The BP stands out in particular with a strong increase in lake drainage events in 2018, including its largest lake, relative to the
425 period of 1999 to 2014. However, as evidenced by newly forming and expanding ponds, which are widely dotting the
426 landscape, active thermokarst lake expansion prevailed during the preceding decades, but rarely triggered drainage events. A

427 recent study by Jones et al. (2020b) found a significant expansion of beaver dam building activities on the Baldwin Peninsula
428 during the period 2019 to 2019. Beavers strongly influence local hydrological regimes by damming up thermo-erosional
429 valleys, outlet streams, or drained lake basins, which leads to water level increase as well as pond and lake formation and could
430 potentially factor into lake drainage dynamics.

431 On the SP, lake drainage was concentrated on the coastal lowland region, particularly the Cape Espenberg lowlands, which
432 have also been hot-spots of lake drainage events during the past decades. The location of recently drained lakes follows patterns
433 of strong Holocone thermokarst and lake drainage activity (Jones et al., 2012; Lenz et al, 2016) in the same area. The highly
434 degraded surface morphology in this region indicates active and pervasive thermokarst processes.

436 **Influencing factors**

437 The exceptional weather conditions in western Alaska are likely the main cause of the significant lake drainage events of
438 summer 2018. Abundant snowfall with the second highest cumulative snowfall on record created a thicker-than-usual
439 insulation layer for the ground, which kept cold winter temperatures from penetrating the ground. This situation in combination
440 with record high winter temperatures, often just below freezing, likely led to an unfavorable energy balance for the stability of
441 near-surface permafrost that is already rather warm in the study region. Both snow cover and winter temperatures are known
442 important factors for near surface permafrost conditions (Stieglitz et al., 2003, Ling and Zhang, 2003; Osterkamp, 2007). The
443 abundant early winter snowfall in October and November in our study area further increased the already strong snow insulation
444 effect (Ling and Zhang, 2003). The severe combination of both negative influencing factors very likely restricted the refreezing
445 of the active layer and thus potentially caused a landscape-wide talik development between the active layer and permafrost in
446 2018. A multiple regression analysis of annual weather conditions of the past decades revealed a relatively strong importance
447 (negative correlation) of freezing days on the lake area drained. However, this approach was not able to accurately predict
448 drained lake area using annual weather conditions alone. We conclude that the variability of individual lake area, surrounding
449 landscape morphology and permafrost properties are additional important influence factors.

450 Thinning of lake ice during the ice growth season, also due to increased snow depth and warmer winter temperatures, has been
451 identified as a responsible factor for the shift from bedfast ice to floating ice on shallow lakes in several regions and has been
452 linked to formation of new taliks underneath lakes that previously were underlain by permafrost on the Alaska North Slope
453 (Surdu et al., 2014; Arp et al., 2016; Engram et al., 2018). The observed amounts of snowfall in our study region and our
454 results from lake ice modeling clearly indicate that lake ice must have been much thinner in the 2017/2018 winter compared
455 to previous years. Particularly the bottom-growth of ice, which is driven by negative heat flux, was affected by warm
456 temperatures and snow cover. A similar effect likely affected the terrestrial area. Thin ice, caused by warm temperatures and
457 thick snow cover, enhances lake talik growth and stronger lateral seepage following higher runoff by melt of thicker than usual
458 snow may have initiated many drainage events by thermal-erosion. In addition, a later freeze-up in the fall period leads to a
459 longer exposure of the shore and near-shore lake-bed to liquid water, which likely increases permafrost destabilization and
460 talik growth along shores. Initial research from the Fairbanks region in interior Alaska, which had a similar pattern of mild

461 and snow-rich winter weather conditions, suggests that at various sites the active layer did not refreeze completely during
462 winter 2017/2018 (Farquharson et al., 2019b). This type of landscape-wide talik formation would alter hydrological dynamics
463 in lake-rich permafrost lowlands substantially. Another, so far rarely considered factor for lake dynamics in permafrost regions
464 could be a change in biological agents. The recent movement of beavers from the treeline to tundra regions in northwestern
465 Alaska may also be contributing to lake dynamics in the eastern and southern portions of the study region that requires further
466 attention (Tape et al., 2018; Jones et al., 2020b).

467

468 **Temporal sequence and causes**

469 The occurrence of lake drainage around (during or shortly after) ice break-up indicates drainage driven by bank overtopping
470 or breaching in combination with rapid thermo-erosion during outflow. High water levels due to high precipitation in fall and
471 winter, rapid melt of abundant snow, in combination with destabilized lake margins, and possible talik formation have very
472 likely led to bank overflow or breaching of lake shores, and subsequent thermo-erosion and deepening of outflow channels.
473 The location of lakes within older drained lake basins enhanced the susceptibility of lakes to erosion and drainage in addition
474 to the weather induced driver. These basins are characterized by comparably unstable peaty and fine-grained substrates with
475 high intra-sedimentary ground ice contents, and well developed ice wedge networks.

476 Under current weather/climatic conditions with a MAAT around 0 °C, 5 °C above normal (1981-2010), permafrost aggradation
477 in the freshly exposed lake-beds might be slowed or even prevented, with consequences for basin hydrology and
478 biogeochemical cycling. After lake drainage, the lake-bed typically refreezes and permafrost soils can redevelop, which locks
479 in carbon stored in lacustrine sediments and terrestrial peat (Walter Anthony et al., 2014). *In-situ* measurements and continued
480 observations are necessary to test this hypothesis and determine whether this is happening already now on the SP and BP.

481

482 **Spatial comparison and considerations**

483 Western Alaska has been previously identified as one of the regions with the most intensive lake dynamics on a decadal-scale
484 (Nitze et al., 2017; Nitze et al., 2018a; Jones, et al.; 2011; Swanson, 2019; Jones et al., 2020b). Other regions along the
485 boundary of continuous permafrost in interior Alaska (Chen et al., 2014; Roach et al., 2013; Cooley et al., 2019) or the southern
486 Yamal Peninsula or western Siberia (Nitze et al., 2018a; Smith et al., 2005) are also highly affected by strong lake dynamics,
487 most notably lake drainage. Lake drainage is a common process in continuous permafrost of colder climates such as the Arctic
488 coastal plain of Alaska (Hinkel et al., 2007; Nitze et al., 2017; Jones et al., 2020a), Tuktoyaktuk Peninsula (Plug et al., 2008;
489 Olthof et al., 2015), Old Crow Flats (Labrecque et al., 2009; Lantz and Turner, 2015) or the Kolyma lowlands (Nitze et al.,
490 2017). However, lake dynamics tend to be of higher magnitude in warmer permafrost regions (Nitze et al., 2018a). In this
491 context, the drainage event of summer 2018 in our study region in western Alaska exceeded the average extent of lake area
492 loss by a factor of 7.5 and the previously most extreme year by 2.

493

494 **Data quality discussion**

495 The application of different methods and sensors, different temporal scales and varying spatial resolutions (long-term Landsat
496 datasets vs. Sentinel-1 water masks vs. Planet multi-temporal water masks) may introduce minor differences in masking water
497 and the delineation of water bodies. In a long-tailed distribution, as observed here, the widely used threshold of >25 % lake
498 area loss, strongly influences the number of drained lakes. For example, a threshold of >20 % lake area loss leads to an increase
499 from 192 to 279 drained lakes. However, the influence of total lake area loss remains low.

500 Due to the presence of lake-ice, the automated intra-annual lake tracking algorithm did not detect the early drainage events
501 reliably, however, the integration of multi-annual data into one analysis will highly benefit the automated lake tracking. With
502 the exponential growth of available data due to new satellite constellations (Sentinel-1, Sentinel-2, Planet), processing
503 platforms, and techniques, more reliable, better comparable, and spatially more extensive lake extent datasets will likely
504 become available in the near future.

505

506 **Outlook**

507 Extreme weather conditions of the winter year 2018 in western Alaska were driven by massively reduced sea ice cover in the
508 Bering and Chukchi seas, resulting in much warmer and moister weather conditions than usual, which may have caused an
509 unprecedented spatial and temporal clustering of lake drainage event in our study region. As climate models all predict a
510 significant increase in both mean annual air temperature and precipitation for northern and western Alaska, the dramatic lake
511 dynamics described here provide an early glimpse of the potentially massive changes in hydrology, permafrost, and topography
512 to be expected in a warmer Arctic in similarly ice-rich permafrost landscapes. With MAAT around 0 °C, the years 2017 to
513 2019 already matched the MAAT projected for this region in ~2060 (RCP8.5) to beyond 2100 (RCP4.5) and precipitation
514 projections for ~2080 (RCP8.5). This mismatch indicates that local to regional permafrost landscapes may experience much
515 more severe and earlier impacts in a warming Arctic than what climate models are capable of predicting at fine scales.
516 Permafrost degradation in northern Canada shows that drastic changes in the Arctic climate system can lead to processes which
517 were projected to happen several decades later (Farquharson et al., 2019a).

518 The recent events potentially show the fate of lake-rich landscapes in continuous permafrost along its current southern margins,
519 where near-surface permafrost degradation accelerates and permafrost will become discontinuous in the next decades. The
520 colder less dynamic lake-rich coastal plain of northern Alaska may become more dynamic once climatic patterns will have
521 moved towards the middle-to-end of the century. Temperatures are predicted to rapidly approach 0°C at the beginning of the
522 next century (MAAT 2090-2099: -2.6°C) on the southern Arctic Coastal Plain in a RCP8.5 climate scenario.

523 **6 Conclusion**

524 The lake-rich northern Seward and Baldwin peninsulas in northwestern Alaska were affected by unprecedented lake drainage
525 in 2018, which dwarfed previous lake changes of this historically dynamic permafrost landscape. As mean annual air

526 temperatures reached values close to 0 °C in combination with exceptional precipitation in recent years near-surface permafrost
527 is likely already in a phase of degradation and destabilization around the lake margins. These weather conditions matched
528 average model projections for the years 2060 (RCP8.5) to 2100 (RCP4.5), suggesting that on these local to regional scales our
529 climate forecast capabilities are not sufficient to project the full consequences of warming scenarios. These extreme weather
530 conditions in combination with rapid availability of excess surface water likely caused the rapid drainage of nearly 200 lakes
531 during or shortly after ice-break up in 2018. The drainage event included some of the largest lakes of the region that likely
532 persisted for several millennia. Under a rapidly warming and wetting climate, in conjunction with ongoing sea ice loss in the
533 Bering Strait, we expect a further intensification of permafrost degradation, reshaping of the landscape, a transition from
534 continuous to discontinuous permafrost, and significant changes in hydrology and ecology. The impact on habitat and
535 landscape characteristics will be drastic in these formerly lake-rich regions. The recent processes observed in northwestern
536 Alaska potentially will be a precedent for lake dynamics of rapidly warming lake-rich permafrost landscapes approaching the
537 MAAT threshold of 0 °C.

538 **Competing Interests**

539 The authors declare that there are no competing interests.

Figure 5: Scatterplot of mean air temperature and cumulative snowfall per winter year (July to June) from 1950 through 2019. Winter year 2017/2018 is highlighted with a circled red cross. Extreme years indicated by number. Blue lines indicate climatic means of MAAT and cumulative snowfall (1981-2010). Dot colors indicate the decade.. *Mean air temperature of 2019 interpolated to entire winter year due to missing data from 1 May through 3 September 2019.
