## Abstract.

The sub-Antarctic is one of the most data sparse regions on earth. A number of glaciated Antarctic and sub-Antarctic islands have the potential to provide unique ice core records of past climate, atmospheric circulation and sea ice. However, very little is known about the glaciology of these remote islands or their vulnerability to warming atmospheric temperature. Here we present melt histories and density profiles from shallow ice cores (14 to 24 m) drilled on three sub-Antarctic islands and two Antarctic coastal domes. Additionally, complementary ground-penetrating radar (GPR) data was collected to further characterise each site and assess the spatial distribution of the observed melt layers. This study includes the first ice cores from Bouvet Island (54°26'0 S, 3°25'0 E) in the South Atlantic, from Peter 1<sup>st</sup> Island (68°50'0 S, 90°35'0 W) in the Bellingshausen Sea and from Young Island (66°17'S, 162°25'E) in the Ross Sea sector's Balleny Islands chain. Despite their sub-Antarctic location, surface melt is low at most sites (melt layers account for ~10% of total core), with undisturbed ice layers in the upper ~40 m, suggesting minimal impact of melt water percolation. The exception is Young Island, where melt layers account for 47% of the ice-core. Surface snow densities range from 0.47 to 0.52 kg m<sup>-3</sup>, with close-off depths ranging from 21 to 51 m. Based on the measured density, we estimate that the bottom ages of a 100 m ice core drilled on Peter 1<sup>st</sup> Island would reach ~1856 AD and ~1874 AD at Young Island.

## 1 Introduction

The sub-Antarctic region sits at the interface of polar and mid-latitude climate regimes, making it highly sensitive to shifting climate over time. However, the sub-Antarctic and the Southern Ocean is one of the most data sparse regions on earth. A recent compilation of climate data spanning the 20<sup>th</sup> century revealed that of the 692 records that exist globally (Emile-Geay et al., 2017), none are available for the Southern Ocean. The vast expanse of open water makes climate and paleoclimate observations difficult, but a number of glaciated sub-

Antarctic island's (SAIs- defined here as island's south of the Southern Ocean polar front) may be suitable for extracting  
40paleoclimate information from ice cores (Figure 1).

Many of these SAIs sit within the westerly wind belt and the transitional sea-ice zone (Figure 1). Westerly  
winds drive ocean upwelling and basal melt of Antarctic ice shelves (Favier et al., 2014; Joughin et al., 2014)  
and the 20<sup>th</sup> century increase in Antarctic snowfall has been attributed to changes in their circulation (Medley  
45and Thomas, 2019). Sea ice modulates the earth's albedo and governs the area available for exchange of heat  
and CO<sub>2</sub> between the ocean and the atmosphere. However, records of both westerly winds and sea ice are short,  
with major uncertainty in the trends prior to the satellite era (i.e. pre 1970's). SAIs on the very margin of  
maximum winter sea-ice extent could potentially identify local-scale changes in sea ice, rather than relying on  
ice core records from the Antarctic continent, which record mostly ocean-sector scale trends (Thomas and  
50Abram, 2016; Thomas et al., 2019). An ice core from Bouvet Island, presented in this study, has already proven  
successful in reconstructing past sea ice variability in the adjacent ocean (King et al., 2019).

Paleoclimate records do exist on some SAIs from lake sediments, peat cores and ice cores. Peat records are  
currently the most prolific of the three, with a number of records retrieved on the New Zealand SAIs up to  
5512,000 years old (McGlone, 2002) and on Crozet and South Georgia up to 6,000 and 11,000 years old  
respectively (Van der Putten et al., 2012). One limitation is that annual layers are not preserved in such records  
and carbon dating carries with it uncertainties in the decadal to centennial range, which complicates the  
identification of annual to decadal-scale climate variations and the precise timing of climate shifts (Van der  
Putten et al., 2012). Peat deposits are also lacking on the more southerly SAIs.

60

Lake sediments are similarly useful for studying vegetation composition on the SAIs. These are related to a  
wide range of environmental parameters within and around the lake used to reconstruct past natural variability  
(Saunders et al., 2008). A novel proxy, based on sea-salt aerosols in lake sediments on Macquarie Island,  
reconstructed past westerly wind strength over the past 12,300 years (Saunders et al., 2018). However, damage  
65from introduced rabbits at this site has compromised the data during the last ~100 years.

Ice core records offer complementary archives to peat and lake archives on glaciated or ice capped island's and  
are in some cases unique records where peat and lake deposits are not available. Shallow ice cores have been  
drilled from low elevation plateaus and glacial terminus on South Georgia, the largest glaciated SAI, revealing  
70ice ages of between 8,000-12,000 years old (Mayewski et al., 2016). However, surface temperatures on South  
Georgia have risen by ~1°C during the 20<sup>th</sup> century (Whitehead et al., 2008) and ninety-seven percent of the 103  
coastal glaciers have retreated since the 1950's (Cook et al., 2010). Thus, the valuable paleoclimate archive  
contained in South Georgia, and potentially the other SAIs glaciers, may be at risk from surface melt.

75The sub-Antarctic Ice Core drilling Expedition (subICE) was part of the international Antarctic  
Circumnavigation Expedition (ACE) 2017-2018 (Walton, 2018), which offered an exceptional opportunity to  
access multiple SAIs. In this study we present the density profiles, melt histories and ground-penetrating radar  
(GPR) data collected during subICE. These include the first ever ice core records from three of the glaciated

Antarctic and SAIs in the Pacific and South Atlantic sector of the Southern Ocean, together with two continental ice cores collected from coastal domes in East and West Antarctica. The aim of this study is to 1) evaluate the ice conditions and internal layering in the upper ice column, 2) determine the extent of surface melt and the potential impact on proxy preservation 3) estimate potential bottom ages for future deep drilling expeditions.

## 2 Methods and Data

### 2.1 Ice Cores

Six ice cores were drilled as part of subICE, between January and March 2017 (Table. 1). The teams were deployed to the ice-core sites via helicopter from the ship (Akademik Tryoshnikov), allowing between three and eight hours of drilling time, dependent on weather conditions and logistical capability. The ice cores were drilled using a Mark III Kovacs hand-auger with sidewinder winch and power-head, retrieving ice-sections of approximately 70 cm in length. The ice was measured, placed inside pre-cut layflat tubing and packed in insulated ice core storage boxes for transportation. During the voyage, the ice was stored in a -25°C freezer and later transported to the ice core laboratories at the British Antarctic Survey (BAS).

#### 2.2.1 Bouvet Island (Bouvetøya)

A 14 m ice core was drilled from the volcanic island of Bouvet in the central South Atlantic (54°26'0 S, 3°25'0 E, 50 km<sup>2</sup>), also known as Bouvetøya (Figure 1a). This was the most northerly site but the island's location within the polar front (Figure 1) classifies it as sub-Antarctic.

Bouvet is almost entirely ice covered (~50 km<sup>2</sup>) except for a few rocky outcrops around the coast. Ice flows down the flanks of the volcano, with no visible crevassing, giving way to shear ice-cliffs and near-vertical icefalls into the sea. The island is the southernmost extension of the mid-Atlantic ridge, located at the triple junction between the African, South American and Antarctic plates. These pronounced sea floor features drive the cold Antarctic Circumpolar Current close to the island, keeping surface temperature cold and allowing sea ice to extend north of the island.

105

The last known volcanic eruption on Bouvet was 50 BC; however, visible ash and dust layers suggest eruptions may be more frequent. At several locations, the ice edge has broken vertically away (Figure S1) revealing horizontal bands of clean and dirty layers in the vertical stratigraphy. The island's remote location, and absence of significant local dust sources, suggests a local volcanic source from either Bouvet or the South Sandwich Islands. The 3.5 km wide Wilhelmplataet caldera appears entirely ice filled. This potentially offers the deepest coring location; however, it is unclear if this is instead an ice bridge formed since the last eruption.

#### 2.1.2 Peter 1st Island

A 12 m ice core was drilled from Peter 1st Island (68°50'0 S, 90°35'0 W), in the Bellingshausen Sea (Figure 1151b). The former shield volcano (154 km<sup>2</sup>) is almost completely covered by a heavily crevassed ice cap and sits within the seasonal sea ice zone. The core was drilled on a ridge (Midtryggen) at 730 m above sea level, in a small saddle on the eastern side of the island overlooking the main glacier Storfallet.

### 2.1.3 Mount Siple

120A 24 m ~~ice~~ core was drilled fr  Mount Siple (73°43'S, 126°66'W) on the Amundsen Sea coast, West Antarctica (Figure 1c). Mount Siple is an active shield-volcano rising to 3,110 m at its peak from Siple Island on the coast of Marie Byrd Land, surrounded by the Getz ice shelf. The core was drilled at 685 m above sea level.

### 2.1.4 Young Island

125A 17 m ice core was drilled on Young Island (66°17'S, 162°25'E), the northernmost island in the Balleny Island chain (245 km<sup>2</sup>), off the coast of Adélie Land (Figure 1d). The Balleny Island's comprise three major dormant volcanic islands, Young, Buckle and Sturge (Hatherton et al., 1965), which sit in the Antarctic seasonal sea ice zone at the boundary of the polar westerlies and Antarctic coastal easterlies. Young Island is characterized by a thick ice cover, marine-terminating piedmont-glacier tongues, steep coastal cliffs, and is therefore described as 130"among the most inaccessible places in the world" (Hatherton et al., 1965). The core was drilled 238 m above sea level.

### 2.1.5 Adélie Land Coast (Mertz)

Two ~~ice~~ cores were drilled on the coast of Adélie Land in East Antarctica (Figure 1e); a 20 m core (Mertz 1) 135 from Cape Hurley, a low elevation ice dome on the eastern side of the Mertz Glacier (67° 33' S, 145° 18' E); and a 9 m ice core (Mertz fast ice) drilled on a triangular wedge of fast ice in Fisher Bay (67° 26' S, 145° 34' E), bounded on the east by the Mertz Glacier and on the west by the AAE (Australian Antarctic Expedition) glacier.

The Mertz Glacier extends into the ocean from coastal King George V land, with a floating ice tongue. The 140 tongue traps pack ice upstream forming the Mertz Glacier Polynya along its western flank during winter, the third most productive polynya in Antarctica, (Lacarra et al., 2014). In 2010, the impact from the B9B iceberg caused this tongue to calve off producing a ~80 km long iceberg. This event had a profound impact on local sea ice conditions and the formation of dense shelf water (Campagne et al., 2015).

### 1452.2 re analysis

Ice-core processing was carried out in the -20°C cold laboratories at BAS. The section length, diameter and weight were measured to provide a density ~~record~~ and the visible melt layers logged and measured (only layers > 1mm).

### 2.3 Ground-Penetrating Radar

150 GPR measurements were performed around each ice core site. We used a SIR3000 unit equipped with a 400 MHz central frequency antennae (GSSI Inc.). The system was pulled on a sledge while walking in parallel and transversal lines of 100 m to 500 m depending on the site surface conditions and available time at each site. The penetration depth of the propagated wave is strongly controlled by the electrical properties of the subsurface combined with the central frequency of the system. The equipment used provides a good compensation between 155 these parameters in polar snow. Vertical resolution is approximately 0.35 m, reaching up to 100 m depth in very dry snow (ideal conditions), such as in the Antarctic plateau (Spikes et al., 2004). However, the resolution and maximum reachable depth are expected to decrease dramatically at lower latitudes. This GPR was intended to

obtain data from the near surface (up to 40 m) to complement the ice-core observations and to better characterise the stratigraphy of each site.

160

The data collected (radargram) represent the number of traces received (x-axis) and the two-way travel time of the wave in nano seconds (ns) (y-axis), which is the time the signal takes from the transmitter to the receiver when reflected from the internal ice discontinuities (melt layers). During data collection the maximum time window was set to a value between 400 – 600 ns, according to the expected maximum depth of signal propagation at the SAI sites. GPR data was monitored in-situ for calibration and stored. Data processing was done using a commercial software (ReflexW) and ~~generally~~ included: removal of repetitive traces (same position), correction of the surface position and distance covered, frequency filters, gain function adjustments, stacking and other visual enhancements to improve the interpretation of the reflecting layers. Each collected file was analysed independently, and layers picked manually in full resolution. ~~Thus,~~ if layers were not sufficiently clear and continuous, they were not picked.

We used the density profile (see section 3.3) of the ice core to obtain ~~the~~ dielectric values through depth, based on the Looyenga model (Looyenga, 1965), and estimated the wave velocity variations and corresponding depth of the layers..

#### 1752.4 Meteorological data

Meteorological data come from the European Centre for Medium-Range Weather Forecasts (ECMWF) ERA-5 analysis (1979–2017) (Copernicus Climate Change Service, 2017), the fifth generation of ECMWF reanalysis. ERA-5 reanalysis currently extends back to 1979, providing hourly data at 0.25° resolution (~ 31 km). Annual average precipitation minus evaporation (P-E) and maximum monthly temperatures (1979-2017) are presented in Table 1. We note that the resolution of ERA-5 is currently unable to capture local climate conditions on the SAIs, however, a recent study from the Antarctic Peninsula confirmed its high accuracy in representing the magnitude and variability of near-surface air temperature and wind regimes (Tetzner et al., 2019).

Limited in-situ meteorological observations are available from the University of Wisconsin-Madison Antarctic Meteorology Program and the Norwegian Polar Institute Automatic weather station (AWS) data is available from Bouvet Island (April 1997-December 2005), Peter 1st Island (September 2006 to January 2007, not complete), Mount Siple (January 1992 to January 2015) and Young Island (January 1991 to December 1997).

The 2 m temperature from ERA-5 (Figure 1) and the AWS sites (typically at low elevations) are expected to be warmer than the ice core drilling locations, as a result of the adiabatic rate of temperature change for vertically moving air. This lapse rate varies with both temperature and mixing ratio from a dry rate of 0.98°/100 m to a saturated rate of 0.44°/100 m at 20°C. As a best guess, we use a lapse rate of 0.68°/100 m to calculate the temperature at the drilling sites. This value is observed on the western Antarctic Peninsula (Martin and Peel, 1978), where the climate and maritime conditions are expected to closely resemble those of the SAIs.

195

### 3 Results

### 3.1 GPR

Given the scope of this paper, one example of a representative profile taken ~~in the area nearby the ice core borehole~~ is shown in the following section. Figures 2-5 show a) a reference map of the track of measurements, 200b) a section of the radargram and c) the estimated depth (up to 20 m) of the picked layers considering the variations of the propagation velocity given the density profile.

#### 3.1.1 Bouvet Island

GPR data obtained at Bouvet island generally show layers of accumulated snow and a consistent reflector 205interpreted as bedrock at about 40 m (average depth). The reference map (Figure 2a) shows the selected profile (grey line) descending from 357 m a.s.l. to 339 m a.s.l towards the south east. Figure 2b shows the interpreted layers observed near the ice core extraction. The estimated depth of the layers show that there is about 2 m of horizontal continuous layering of snow. Below this layer, there is stratified firn that have been eroded by the effect of wind and the surface slope, reaching a layer of solid ice at 15 m from the surface. Another layer is 210detected at 36 m depth, which is interpreted as the bedrock. This depth is consistent with the estimated ice thickness observed from the ice cliffs to the south of the ice core drilling site (Figure S1). Ice thickness from the photograph is estimated relative to the expected size of the observed fur seals on the beach.

#### 3.1.2 Peter 1st Island

Snow surface at Peter 1<sup>st</sup> site was smooth (maximum 5° slope). Internal layers were only (and partially) 215traceable for the upper ~25 m of the snow/firn pack. The maximum time window was set to reach an estimated depth of ~43 m (Table 2) and bedrock was not detected. Figure 3a shows the track of measurements performed at Peter 1<sup>st</sup> island site and the profile shown (Figure 3b) is a section of the line (grey line) taken at increasing elevation from 718 m a.s.l. up to 726 m a.s.l. in a north-westerly direction. Figure 3c shows the estimated depth for the stratified layers of snow in the upper 14 m were these were mostly continuous.

220

#### 3.1.3 Mount Siple

The surface of the studied area at Mount Siple site was relatively smooth (max. 4° slope). Figure 4a shows the length and position of a full profile taken in a south-westerly direction taken in an east-westerly direction rising from 678 m a.s.l. to 685 m a.s.l. and ending at the ice core extraction position. Figure 4b shows the selected 225section where clear layering can be observed for the upper 20 m with smooth depth variation through the profile length. Bedrock was not detected.

#### 3.1.4 Young Island

The Young Island site surface was flat with a compact snow. The maximum estimated depth of detected layers 230was ~36 m (Table 2) and bedrock was not detected. Figure 5b shows a section of a selected profile taken in a north-westerly direction starting at the ice core extraction position, here multiple layers can be identified but they are discontinuous and the small distance between layers resulted in merging, thus they are not traceable through the full profile length.

#### 3.1.5 Adelie Land Coast (Mertz)

235The Mertz 1 site (Cape Hurley) had a flat surface, consistent with observed internal layering. Layers could not be distinguished in the upper ~7 m of snow and only reflected weakly beneath this depth; 11 distinct, but discontinuous, layers were identified down to a depth of 62 m (bedrock was not detected). We estimated this to be the approximate limit of signal propagation of the GPR system at this site. Figure 6 a-c shows a section of a profile taken in north westerly direction and the interpretation of layers depth in the upper 20 m near the ice core  
240extraction.

Data quality for the Mertz fast ice site was very poor (Figure 6 d-e). A single continuous layer at 6.8 m depth was the only one identified.

### 2453.2 Melt records

Given their location, we expect all sites to experience some degree of surface melt. The altitude corrected temperature for each SAI is compared with the 2 m temperature and uncorrected AWS temperature in Table 1. Surprisingly, the site least affected by melt is Bouvet, the warmest and most northerly location. Despite its northerly location the average yearly temperature from ERA-5 (elevation corrected) is -2.9 °C, with a maximum  
250monthly temperature of -0.9°C. The maximum value recorded by the AWS at 42 m above sea level was 6.7 °C (1997-2005, elevation corrected). The average melt layer thickness in the Bouvet core is 0.3 cm, observed at a frequency of five layers per meter; with the largest measured melt layer just 3.95 cm (Table 2).

The coldest site is Mertz Glacier, with an annual average temperature (ERA-5 elevation corrected) of -17.4°C.  
255The percentage of melt at this site is just 6%, with a maximum layer thickness of 8.1 cm. The melt layer thickness at the Mertz fast ice site appears to be lower, however, this only reflects visible melt layers in the top 2.2 m.

Average melt layer thickness at Peter 1<sup>st</sup> Island is comparable to that of Mount Siple, with percentage melt of 11% and 10% respectively. Reflecting the similar summer temperatures, -5.1°C at Peter 1<sup>st</sup> and -5.2°C at Mount  
260Siple.

The site most affected by melt is Young Island, which has frequent melt layers averaging 6.57 cm and the largest single layer of 58 cm. The annual average temperature from this site is -9.2°C, (ERA-5 1979-2017), with a maximum AWS temperature of 2.8°C (February 1997). Melt layers occur throughout the profile but with greatest density between 5–5.5 m and below 11 m depth. Most melt layers consist of bubbly ice with a minority  
265of thinner layers that are bubble-free or exhibit large crystals. We note that the visual method of determining melt layers is not sufficient to determine if the large layers result from individual melt events or are formed from a sequence of smaller events.

### 3.3 Relationship between GPR horizons and ice core melt layers

270In order to explore the spatial extent of melt surrounding the ice core sites, we compare the ice core melt records with the GPR horizons. However, the melt observations from the ice core has a resolution of 1mm, while the

GPR has an expected range of visibility of ~3m (theoretical resolution). Thus, we first reduce the resolution of the ice core derived melt profiles by summing the total melt in a running 35 cm window. Only sections that would produce a strong enough reflection to be detected by the GPR are included in the comparison. The continuity of the GPR data has been assessed in profile sections of 20 m length near the ice core extraction (plot c in Figures 2-6) and their mean depth have been used. Subsequently, we compared the potentially visible patterns from the ice core to the depth of the handpicked layers in the radargrams (Figure 8).

### 3.3 Density

The change in firn density with depth is dependent on the snow accumulation rate and temperature at the site. Higher temperature and lower accumulation rates result in the greatest change of density with depth. At our sites the depth-density profile exhibits more variability at the island sites (Bouvet, Peter 1<sup>st</sup>, Young) than the continental sites (Mertz and Mount Siple), reflecting the warmer island locations and the influence of surface melt (Figure 7).

285

A fitted density curve is applied based on the assumption that firn densification is linearly related to the weight of overlying snow (Herron and Langway, 1980). The density with depth ( $ph$ ) is calculated following Eq. (1):

$$ph = p_i \cdot \exp(\ln a + b) \quad (1)$$

290

where  $p$  is the density,  $p_i$  is the density of ice ( $0.917 \text{ kg m}^{-3}$ ) and  $h$  is the snow depth. The constants  $a$  and  $b$  are derived from the linear relationship between  $\ln [p/(p_i - p)]$  and depth, where  $\ln(a)$  is the intercept, and  $b$  is the gradient.

The first stage of densification relates to grain settling and packing and occurs below the “critical density” of about  $0.55 \text{ kg m}^{-3}$  (Herron and Langway, 1980). A linear relationship exists between the 2-m temperature from ERA-5 and the critical depth ( $r^2 = 0.57$ ,  $p > 0.05$ ), which is reached first at Bouvet, the most northerly location and the warmest site (Table 1; Table 3).

The second stage of densification ( $0.55\text{--}0.83 \text{ kg m}^{-3}$ ), occurs when the firn air passages become closed off to form individual bubbles. The density at the bottom depth of all cores remains below this value, with the exception of Young Island, which exceeds this limit at 16.6 m. This suggests that pore close-off has been achieved below this depth, when air can no longer be excluded and further densification takes place by compression of the bubbles. However, the presence of a large melt layer at this depth suggests this may be the cause of the density increase. Based on the fitted density profile the actual close-off depth occurs at 21 m. The second fastest close-off depth occurs at Bouvet (28.65 m), considerably shallower than the two coastal Antarctic sites (Mount Siple and Mertz 1).

Surface densities, critical depths and close-off depths at the continental sites (Mount Siple and Mertz 1) are consistent with modelled values (van den Broeke, 2008). A compilation of observed (and modelled) Antarctic snow densities suggest a range of 6- 26 m (modelled 4-29.5 m) for the critical depth and 34-115 m (modelled

45-115 m) for pore close-off. The values for Bouvet, Peter 1<sup>st</sup> and Young Island are close to the modelled values for coastal Antarctica, however, the pore close-off depth at both Bouvet and Young Island is achieved faster than the lowest reported depth for an Antarctic site (34 m at Upstream B, West Antarctica)(van den Broeke, 2008). The presence of melt layers, with a greater density than the surrounding firn, may bias our close-off  
315 estimates to shallower depths. In addition to the influence of temperature, the rapid densification on the SAIs may be caused by layer stretching and compression related to ice flow that is not well understood at these locations.

### 3.4 Estimating the ice core bottom ages

The fitted density curve can provide a first approximation of the age-scale (Table 3), based on the (water-  
320 equivalent) annual average P-E from ERA-5. We note that the resolution of ERA-5 may not be adequate to capture P-E at these sites and that snow accumulation may vary through time. It would have been preferable to use a densification model that accounts for the influence of melt (e.g. Lightenberg et al., 2011), however the current in-situ observations at these sites do not allow for this. Thus, our approach is very simplified with the aim of establishing a preliminary bottom age for each site.

325

In the Herron and Langway densification model the dominant densification process in the upper part ( $\rho \leq 550 \text{ kg m}^{-3}$ ) are grain settling and packing of snow grains (Herron and Langway, 1980). Undoubtedly, refreezing of melt water and/or liquid precipitation also cause firn to densify. This is observed in figure 7, as jumps in the measured density corresponding to large melt events. However, if we assume that heat is released upon  
330 refreezing, the local firn temperature will also increase, further accelerating the densification. At the same time, ice layers lead to a higher average density, thereby reducing the potential densification rate. Although not ideal, the measured density value used in the equation will reflect the presence of melt. As such, the values of surface snow (or zero-intersection depth) are considerably higher than those modelled or observed for coastal Antarctica.

335

We apply an error estimate to the bottom ages to account for the potential influence of melt, changing snow accumulation with time and uncertainties in the ERA-5 P-E value. This is based on the difference between the age determined using the mean annual P-E value and the age determined when using an upper (annual P-E plus one standard deviation) or lower (annual P-E minus one standard deviation) P-E value. The error variability  
340 reflects the variability in precipitation at each site and increases with depth and age.

## 4 Discussion

Based on the results we aim to establish which of the sites would be suitable for future deep drilling expeditions,  
345 based on 1) the ice conditions and internal layering in the upper ice column, 2) the extent of surface melt and the potential impact on proxy preservation, and 3) potential bottom ages.

### 4.1 Ice conditions and internal layering in the upper ice column

The aim of the GPR data was to give a preliminary characterisation of each site, particularly the distribution, continuity and clearness of the horizons observed in this data. Bouvet was the only site where bedrock was detected, suggesting that the maximum depth of an ice core from this site is ~40m. Evidence of wind scouring in the reflections may impact the proxy preservation at this site. The profiles at Peter 1<sup>st</sup>, Mount Siple and Mertz indicate more uniform internal structure, with traceable layers in the top 20 m. The largest number of layers was identified at Young Island, but many were discontinuous or difficult to trace. The deepest layer detected was at Mertz, the coldest site, where layers were traceable to a depth of 62 m.

#### 4.1.1 Case study Mertz fast ice

This Mertz fast ice site is fundamentally different in character from the others presented in this study. While we believe the surface snow to be meteoric, it does not sit atop grounded ice, but rather a large wedge of multiyear sea ice, held fast between the AAE and Mertz Glacier tongues (Figure 1d). The top-most layers of snow and firn appeared typical of surface snow. However, at a drill depth of 6.23 meters the recovered ice was saturated with liquid seawater (a strong attenuator of the radar signal). Ice recovered below this depth was different in character from the surface, being solid ice containing bubbles and interstitially saturated with saltwater. There was a standing water table in the borehole at this same depth. These observations, together with the clear radar reflector at just over 6.8 m (Figure 6), the absence of reflectors below this, and the sites elevation of ~6 m above sea level, lead to the conclusion that the fast ice is saturated with seawater below sea level.

If the fast ice is floating (i.e. supported buoyantly), our measurement of the dry freeboard thickness allows us to estimate the total thickness of the fast ice wedge. The average density of the top 6 m is  $0.55 \pm 0.05 \text{ kg m}^{-3}$ , increasing to  $0.85 \pm 0.05 \text{ kg m}^{-3}$  below this. Assuming a seawater density of  $1.0275 \pm 0.004 \text{ kg m}^{-3}$ , freeboard thickness of 6.2 m and a mean density of the ice below the water-table of  $0.85 \pm 0.05 \text{ kg m}^{-3}$ , the total ice-equivalent thickness of the ice at this site is ~30 m. However, there are large uncertainties in this calculation. The radargram indicates that the fast ice increases in thickness away from the drill site, by several meters. While this site is not likely to provide typical geochemical proxy records, it may be of interest to future studies of multiyear sea ice.

#### 4.2 Extent of surface melt and the potential impact on proxy preservation

##### 4.2.1 Melt recorded in the ice core

Surface melting occurs in response to a positive energy balance at the snow surface and is strongly correlated with surface air temperature. The Antarctic ice sheet experiences little melt, due to consistently low temperature, however the coastal margins and areas of the Antarctic Peninsula are subject to surface melting (van Wessem et al., 2016). The relationship between surface melt and surface temperature has been exploited to reconstruct past climate in Antarctic ice cores (Abram et al., 2013). However, the presence of too much surface melt can damage the climate proxies they contain.

The influence of melt-water on ice core proxy preservation has been explored for arctic ice cores (Koerner, 1997). Here, melt-water percolation can allow insoluble micro particles to migrate to the melting surface, causing a spike in concentrations, and influence the stable water isotope record, a commonly used proxy for past

surface temperature. Seasonal melting can cause run-off of near-surface snow and melt and refreezing at the base of the annual snowpack. This can redistribute the stable water isotope profile, resulting in a warm or cold-biased record. The influence on both stable water isotopes and chemistry can have a major impact on the ability  
390to date ice cores using annual layer counting.

The site most affected by melt is Young Island, with 47% of the ice core characterised as melt. Given the islands location south of the Polar Front and the seasonal sea ice zone (Figure 1) the evidence of extensive surface melting is unexpected. Especially when considering that the average temperature at Young Island is 6.4° colder than Bouvet, the site least affected by melt. It is likely that the resolution of ERA-5 is not sufficient to capture  
395local surface temperature, however, the 3-hourly data from the AWS (1993-1997) reveals considerable variability.

The maximum temperature recorded by the Young AWS (elevation corrected) is 2.8°C (February 1997), with temperatures in 20 of the 67 months of AWS data exceeding 0°C. The annual average temperature at Young  
400Island is comparable with Peter 1<sup>st</sup>, with a lower maximum AWS temperature. However, the largest melt layer at Young is almost twice that of Peter 1<sup>st</sup> and the percentage melt over four times higher. Solar radiation is the dominant driver of surface melting although atmospheric thermodynamics and cloud radiative properties also play a role. Thus, our study demonstrates that for the SAI's surface temperature alone is not a reliable indicator of potential melt damage.

405The average melt layer thickness at all sites (except Young Island) is considerably lower than the mean melt layer width of 3.2 cm observed at the James Ross Island ice core, from the northern Antarctic Peninsula (Abram et al., 2013). The percentage of melt per year is dependent on the measured snow accumulation. The estimated snow accumulation at Bouvet is 0.59 m water equivalent, based on annual layer counting of chemical and isotopic species (King et al., 2019b). The annual layer counting of the other subICE cores has not yet been  
410completed, however based on our estimates (section 3.4), it is a reasonable assumption that the snow accumulation at these maritime island's will be equal to or more than the snow accumulation at James Ross Island (0.62 +/- 0.14 m water equivalent). Thus, the potential for proxy preservation and climate reconstructions is promising at these sites.

Given the degree of melt at Young Island, it seems likely that the proxy preservation may be compromised.  
415However, an evaluation of the ice microstructure may help determine the extent to which melt water has percolated through the layers.

#### 4.2.2 Comparison of ice core melt with GPR layers

There appears to be little correlation between the melt observed in the ~~ice~~-core and the layers traced in the GPR.  
420The relationship is particularly poor for Young Island, where the ~~ice~~-core shows a high amount of thin melt layers seen in the radar data as very dense non-continuous layering. Although it is not possible to determine the spatial extent of melting based on the GPR profiles, the findings suggest that density variations alone cannot explain the internal layering.

The presented comparison method is subject to several sources of uncertainty. 1) The manual picking of the 425GPR layer, 2) the distance between the ice core extraction point and the section of the radar data, and 3) the use of average depth in sections of 20 m distance, especially for the sites that exhibit an incline (e.g. Bouvet and Mount Siple).

### 4.3 Potential bottom ages of deeper ice cores

430One of the aims of this study was to establish the SAI's suitability for future deep ice core drilling projects. A useful indicator is the potential bottom age at each site. The estimated ice core bottom ages range from 2004 (+/- 3 years), at both the Peter 1<sup>st</sup> and Bouvet ice cores, to 1994 (+/- 8 years) at Mertz 1 (Table 3).

To date, only the Bouvet ice core has been independently dated. Annual layer counting, using a suite of 435chemical and isotopic species, yielded a bottom age of 2001 AD (King et al., 2019). Although older than the bottom age estimate using the density profile it is within error (2004 +/- 3 years) adding confidence to this approach but suggesting our ages may be too conservative. The offset may be explained by an over-estimate in the P-E derived from ERA-5 or suggest the influence of post-depositional processes such as wind scouring or ablation.

440

It is difficult to estimate a potential age limit for a core drilled to bedrock at the Young, Peter 1<sup>st</sup> and Mertz 1 sites since the ice thickness was beyond the penetration depth of the GPR. For example, at Mertz 1 a bottom age of 1926 AD (+/- 34 years) is estimated based on a GPR bottom depth of 63 m (Table 2), although the ice could feasibly be much deeper than this. At the Bouvet site, where we interpret the layer at ~40 m as bedrock, the 445maximum potential age is 1971 AD (+/- 11 years). However, considerably deeper (and therefore older) ice may be present at higher elevations. These results suggest that the subICE ice-core records will be suitable for obtaining sub-annual resolution climate records with the potential to capture climate variability over multi-decadal timescales.

450For the sites where bedrock was not detected, we estimate the bottom age of an ice core drilled to 100 m depth (Table 3). This suggests that the oldest ice would be reached at Mertz 1 (1849 +/- 64 years) and the youngest ice at Mount Siple (1912 +/- 35 years).

The estimated ice core bottom age at Bouvet Island, together with the observed visible ash layers (Figure S1), 455offer a glimpse at the volcanic history of this remote island. The last known eruption was 50 BCE; however, visible layers in the upper ~20 m suggest the island has been volcanically active as recently as ~ 1998. The regularity of the layers in the ice cliffs, visible all around the island, indicate frequent volcanic activity has occurred during the 20<sup>th</sup> century. This is consistent with the persistent volcanic activity observed on the near-by South Sandwich Island's, with visible ash clouds identified in the satellite records and even visible from the ship 460during the ACE (March 2017). We note that the visible ash layers at Bouvet (Figure S1) may have been deposited from the South Sandwich Island's but further analysis will help establish the source.

## 5 Conclusions

Initial results from five shallow ice cores drilled in the sub-Antarctic islands and coastal Antarctica suggest that these locations may be suitable for short-term climate reconstructions and up to centennial-scale reconstructions at some sites if deeper cores could be retrieved. Evidence that these ice cores span the 20<sup>th</sup> century, a period of significant global climate change, is exciting. The GPR surveys suggest relatively uniform layering at most sites, at least to the depth of the ice cores, suitable for ice core proxy reconstructions. However, evidence of crevassing at some locations (Young and Peter 1<sup>st</sup>) demonstrates the importance of a thorough geophysical survey before contemplating deeper drilling at these sites. At Bouvet Island, regular volcanic ash deposits during the 20<sup>th</sup> century suggest the island is still volcanically active.

The impact of melt is less severe than expected at some locations, especially Bouvet Island, but more severe at others. Young Island, part of the Balleny Island chain off the coast of Adèle Land, is the most susceptible to melt. However, the observed melt layer thickness at the other sites is less than that observed from the James Ross Island ice core, which yielded paleoclimate reconstructions (Abram et al., 2013). Proxy preservation was not a concern in this ice core, suggesting that melt will also not adversely influence the climate record contained in the sub-Antarctic ice cores. The observed increase in melt intensity at James Ross Island since the mid-20<sup>th</sup> century was linked to warming surface temperature. Thus, the comparable melt intensity observed at some of the SAIs may be evidence that the 20<sup>th</sup> century warming at these locations was analogous to that on the Antarctic Peninsula.

Based on the measured density profile and the P-E from ERA-5, the estimated bottom ages of the subICE cores range from 2004 (Peter 1<sup>st</sup> and Bouvet) to 1994 (Mertz 1), suggesting that these records should contain a multi-decadal record of climate variability in this data sparse region. We were unable to obtain ice thickness estimates for all sites, with the exception of Bouvet, however visible layers were identified in the GPR records to depths of 60 m. Even with a conservative estimate, it is possible that deeper ice cores drilled on these SAIs would have the potential to capture climate variability during the 20<sup>th</sup> century, but most likely considerably longer.

### Data availability

All data will be stored at the UK Polar Data Centre (<https://www.bas.ac.uk/data/uk-pdc/>) or by directly contacting Liz Thomas ([lith@bas.ac.uk](mailto:lith@bas.ac.uk)). DOI to be provided following paper acceptance.

### Author contributions

ERT lead the project; ERT, GG, JP, ACFK, BM, and MP collected the data in the field; ERT, JP, ACFK and DEM processed the ice core data; GG and MP processed the GPR data; all authors contributed to writing and editing the paper.

### Competing interests

All authors declare no competing interests.

**Table 2: Wave velocity and maximum depth detected from the GPR. Frequency (number of layers per meter), percentage (% of whole core), average and maximum layer thickness measured in the ice cores. \* Melt layers in the 705Mertz fast ice core were only measured in the top three bags (0-2.4 m).**

Site name	Ice core density		Age estimate	
	Zero-depth intersection (m)	Close-off depth (m)	Ice core bottom age (AD)	Age at 100 m depth (AD)
Bouvet	0.5	28.7	2004 (+/- 3)	N/A
Peter 1st	0.5	34.5	2004 (+/- 2)	1856 (+/- 23)
Mt Siple	0.5	51.9	1998 (+/- 6)	1912 (+/- 35)
Young	0.5	21.1	2002 (+/- 4)	1874 (+/- 37)
Mertz 1	0.4	50.5	1994 (+/- 8)	1849 (+/- 64)
Mertz fast ice	0.0	7.2	2008 (+/- 3)	N/A

**Table 3: Ice core derived zero-depth intersection and close-off depth. Estimated age (years AD) at the bottom of the 710core and at 100 m, based on the measured ice core density.**
