Abstract. Estimates of snow and firn density are required for satellite altimetry based retrievals of ice sheet mass balance that rely on volume to mass conversions. Therefore, biases and errors in presently used density models confound assessments of ice sheet mass balance, and by extension, ice sheet contribution to sea level rise. Despite this importance, most contemporary firn densification models rely on simplified semi-empirical methods, which are partially reflected by significant modeled density errors when compared to observations. In this study, we present a new, wind-driven, drifting snow compaction scheme that we have implemented into SNOWPACK, a physics-based land surface snow model. We demonstrate high-quality simulation of near-surface Antarctic snow firn density at 122 observed density profiles across the Antarctic ice sheet, as indicated by reduced model biases throughout most of the near-surface firn column when compared to two semi-empirical firn densification models. Because SNOWPACK is physics-based, its performance does not degrade when applied to sites without observations used in the calibration of semi-empirical models, and could therefore better represent firn properties in locations without extensive observations and under future climate scenarios, in which firn properties are expected to diverge from their present state.

1 Introduction

The Antarctic ice sheet (AIS) is the largest freshwater reservoir on Earth, and if melted entirely would raise globally averaged sea level by 58 m (The IMBIE team, 2018). The AIS is contributing to sea level rise via net mass loss, with an increasing rate from $40 \pm 9 \text{ Gt yr}^{-1}$ in 1979 - 1990 to $252 \pm 26 \text{ Gt yr}^{-1}$ in 2009 - 2017 (Rignot et al., 2019). In order to quantify ice sheet contribution to sea level rise, glaciologists compute the mass balance (MB), defined as the difference between the grounded ice sheet surface mass balance (SMB) and solid ice discharge across the grounding line (Lenaerts et al., 2019). MB can be estimated by combining satellite altimetry estimates of ice sheet volume change with modeled snow and firn density estimates (e.g. Shepherd et al., 2012; Smith et al., 2020). Similar to MB, spatial variations in SMB can be determined from combined density and radar derived annual snow accumulation estimates (e.g. Medley et al., 2013; Dattler et al., 2019; Kausch et al., 2020). However, in all cases, density estimates represent one of the largest sources of uncertainty (Shepherd et al., 2012; Montgomery et al., 2020) due to an uncertain and simplified representation of snow and firn densification (Alexander et al., 2019; Montgomery et al., 2020), particularly over the low-accumulation interior of ice sheets (Weinhardt et al., 2020).

Antarctic new snow density and subsequent densification are known to vary in both space and time and are influenced by, among other factors, local meteorology and drifting snow (Herron and Langway, 1980; Sommer et al., 2018). In particular, surface snow and firn density are known to be strongly impacted by wind driven compaction, a process hereafter referred to as drifting snow compaction. Drifting snow occurs up to 75 % of the time in the AIS escarpment zone (Lenaerts et al., 2012; Palm et al., 2017; van Wessem et al., 2018; Amory and Kittel, 2019), and because of drifting snow redistribution, precipitating snow particles are not always permanently incorporated into the snowpack at the time or location of precipitation. In fact, observations show that in the high-elevation, dry, and windy areas of the AIS, pockets of fresh snow can be found alongside snow that is more than one year old (Picard et al., 2019). Including processes such as drifting snow compaction, snow metamorphism, and compaction due to overburden stress has been shown to improve model representation of polar snow and firn (van Kampenhout et al., 2017). However, despite this finding, as well as the demonstrated complexity of snow and firn densification, many AIS MB studies (e.g. Zwally et al., 2015; Smith et al., 2020) rely on relatively simplified semi-empirical models (e.g. Ligtenberg et al., 2011; Li and Zwally, 2011; Medley et al., 2020). Semi-empirical densification models successfully capture broad regional variability in firn characteristics (van den Broeke, 2008; Ligtenberg et al., 2011). However, due to their limited complexity, as measured by the inclusion of ephemeral processes such as drifting snow compaction, they cannot capture all local and temporal density variability. Additionally, semi-empirical models are tuned to observations representative of the past or present climate (Herron and Langway, 1980; Ligtenberg et al., 2011; Li and Zwally, 2011), which may not be representative under future climate change scenarios (Ligtenberg et al., 2014). Furthermore, because semi-empirical models rely on extensive tuning to observations, rather than physical principles, they may not perform well in climates poorly sampled by observations (e.g. the East Antarctic plateau). Alternatively, physics based models, for example CROCUS (Vionnet et al., 2012) and SNOWPACK (Bartelt and Lehning, 2002; Lehning et al., 2002a, b), do not explicitly tune simulated density to observations. Instead, physics-based models represent densification using a constitutive relationship between stress and strain for snow. However, physics-based approaches are hindered by a variety of factors including computational expense, the requirement to estimate unknown parameters such as surface roughness length and snow activation energy, as well as the need to calculate intermediate prognostic variables including snow grain size and viscosity. Despite these drawbacks, the complex material properties of snow, combined with an acute scarcity of snow and firn density measurements lead us to hypothesize that a physics-based modeling approach is preferred.

In order to improve model representation of Antarctic snow and firn properties compared to semi-empirical models, we apply the physics-based snow model, SNOWPACK, to nine automatic weather stations (AWS), 55 borehole 10 m depth temperatures, and 122 observed near-surface density profiles for a total of 186 locations across the AIS. First, we describe model setup and a new drifting snow routine designed to improve representation of near-surface (depth ≤ 10 m) snow and firn density (section 2.1). Next, we evaluate SNOWPACK's ability to simulate the surface energy balance by comparing with available surface temperature proxies (section 3.1). We then explore the sensitivity of SNOWPACK simulated density profiles to uncertainties in atmospheric forcing (section 3.2). Next, we compare SNOWPACK to observed density profiles and compare the relative performance of SNOWPACK to two other firn densification models (sections 3.3 - 3.6). Finally, we conclude with a more

detailed example of how SNOWPACK can facilitate remote sensing retrieval processing and attribution by describing other simulated snow and firn properties (section 3.7).

60 2 Methods

2.1 Physics-based snow model SNOWPACK

Many models assume a high ($> 250 \text{ kg m}^{-3}$) new snow density over Antarctica (Ligtenberg et al., 2011; Groot Zwaaftink et al., 2013) despite observational evidence of occasional relatively low ($< 100 \text{ kg m}^{-3}$) new snow density (Groot Zwaaftink et al., 2013; Sommer et al., 2018). This difference can be explained by accumulation of snowfall without sufficient wind speed
65 required for drifting snow compaction to occur. In order to account for this, we implement a new drifting snow compaction routine into the vertical, one-dimensional physics-based land-surface snow model, SNOWPACK (Bartelt and Lehning, 2002; Lehning et al., 2002a, b). Originally designed as an alpine snow cover model capable of describing snow cover properties, including accumulation, densification, temperature, energy balance, and snow microstructure, SNOWPACK has been applied to both ice sheets (Groot Zwaaftink et al., 2013; Van Tricht et al., 2016; Steger et al., 2017; Izeboud et al., 2020; Dunmire
70 et al., 2020). These studies have shown that SNOWPACK is capable of capturing important processes in the ice sheet firn layer, namely accumulation in windy environments, the surface energy balance (SEB), and liquid water retention. However, these studies have not implemented a polar snow accumulation scheme that allows for initial accumulation of low ($< 250 \text{ kg m}^{-3}$) density snow and subsequent drifting snow compaction. Additionally, no previous study has evaluated SNOWPACK simulated near-surface firn density across the entire AIS.

75 Our new drifting snow compaction routine combines an existing alpine new snow density parameterization with a polar snow compaction routine. In particular, we impose the key physical restraint that drifting snow is required for near-surface compaction in addition to overburden stress compaction. This mechanism has previously been proposed in the literature (Brun et al., 1997) and recently confirmed in both laboratory experiments (Sommer et al., 2017) as well as field observations on the AIS (Sommer et al., 2018). In our scheme, new snowfall is given an initial, typically low (30 - 150 kg m^{-3}), density ρ_{new} , Eq.
80 (1), according to the default SNOWPACK alpine new snow density parameterization (Lehning et al., 2002a), which varies as a function of 2 m air temperature T_{2m} ($^{\circ}\text{C}$), snow surface temperature T_s ($^{\circ}\text{C}$), relative humidity RH (0 - 1), and 10 m wind speed $U_{10 \text{ m}}$ (m s^{-1}).

$$\rho_{\text{new}} = 70 + 6.5T_{2m} + 7.5T_s + 0.26RH + 13U_{10 \text{ m}} - 4.5T_{2m}T_s - 0.65T_{2m}U_{10 \text{ m}} - 0.17RHU_{10 \text{ m}} + 0.06T_{2m}T_sRH \quad (1)$$

Densification then occurs via two distinct processes, a) densification due to overburden stress and b) densification due
85 to drifting snow compaction. Densification due to overburden stress is calculated nearly identically as described in Steger et al. (2017) which adapted SNOWPACK for use in the percolation zone of the Greenland Ice Sheet by tuning the viscosity parameters including the snow activation energy Q_s and critical exponent β . However, because of better agreement with observed density profiles, we revert to original SNOWPACK viscosity parameters by setting Q_s and β to $67,000 \text{ J mol}^{-1}$

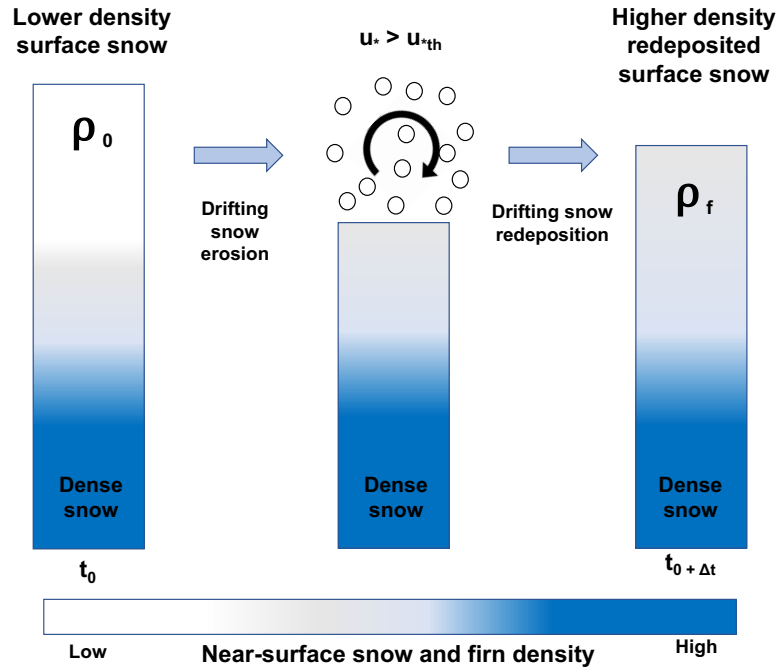

Figure 1. Schematic of SNOWPACK drifting snow compaction. When the friction velocity exceeds the snow threshold friction velocity ($u_* > u_{*th}$), initial lower density surface snow (left) is eroded by the wind, suspended above the snow surface (middle), and then redeposited with a higher density (right).

and 0.7 respectively. The second mechanism driving densification, i.e. drifting snow compaction, occurs when the friction velocity u_* (m s^{-1}) exceeds the snow threshold friction velocity u_{*th} (m s^{-1}) (Fig. 1). In our implementation of SNOWPACK, u_* is estimated by scaling hourly averaged 10 m wind speeds from MERRA-2 atmospheric reanalysis (section 2.2) using a logarithmic wind profile (Lehning et al., 2002a) with a roughness length, z_0 , of 2 mm. Meanwhile, u_{*th} , Eq. (2), is calculated as a function of snow microstructural properties internally determined by SNOWPACK, including snow grain sphericity SP (0 - 1), radius r_g (m), bond radius r_b (m), and coordination number N_3 (Lehning and Fierz, 2008).

$$95 \quad u_{*th} = \sqrt{\frac{A\rho_i g r_g (SP + 1) + B\sigma N_3 \frac{r_b^2}{r_g^2}}{\rho_a}} \quad (2)$$

In Eq. (2), ρ_i is the density of ice (917 kg m^{-3}), ρ_a is the density of air (1.1 kg m^{-3}), g is the gravitational acceleration (9.8 m s^{-2}), σ is a reference shear strength set to 300 Pa , while constants A and B are set to 0.02 and 0.0015 respectively. When u_* exceeds u_{*th} , a saltation mass transport rate Q ($\text{kg m}^{-1} \text{ s}^{-1}$) is calculated following Lehning and Fierz (2008) and

then scaled to a drifting snow mass flux Φ ($\text{kg m}^{-2} \text{s}^{-1}$), Eq. (3), by dividing Q by a characteristic horizontal length scale L .

$$100 \quad \Phi = \frac{Q}{L} = \frac{0.0014 \rho_a u_* (u_* - u_{*th})(u_* + 7.6u_{*th} + 205)}{L} \quad (3)$$

L can be interpreted as a fetch length and characteristic horizontal length scale over which the originally upwind and now mobilized snow particles, accounted for in the drifting snow mass flux Φ , are distributed before erosion. We choose a magnitude for L of 10 m, as this is a typical horizontal length scale of wind erosion features including sastrugi and barchan dunes (Filhol and Sturm, 2015). Given a lack of direct observations, L can effectively be considered a tuning parameter, whose magnitude is
105 inversely proportional to Φ . Note that as suspension of drifting snow cannot be properly resolved by a one-dimensional snow model (Lehning and Fierz, 2008), the saltation mass transport rate Q and subsequent drifting snow mass flux Φ are intended to account for all wind driven snow transport processes (i.e. saltation and suspension).

Following drifting snow erosion, the drifting snow mass flux is redeposited at the snow surface with an updated density $\rho_{\text{redeposit}}$ (kg m^{-3}), Eq. (4), parameterized according to field measurements of fresh surface snow deposited during drifting
110 snow events (Groot Zwaaftink et al., 2013, equation 1). Note that, in contrast to Groot Zwaaftink et al. (2013), which uses 100-hour average wind speeds, we calculate $\rho_{\text{redeposit}}$ using hourly mean MERRA-2 10 m wind speeds. We implement this distinction in order to better resolve the temporal evolution of redeposited snow density during ephemeral (i.e. shorter than 100 hours) drifting snow events.

$$\rho_{\text{redeposit}} = \begin{cases} 361 \log_{10}(U_{10 \text{ m}}) + 33 & U_{10 \text{ m}} > 1 \text{ m s}^{-1} \\ 33 & U_{10 \text{ m}} \leq 1 \text{ m s}^{-1} \end{cases} \quad (4)$$

115 2.2 SNOWPACK atmospheric forcing

At the snow surface, we force SNOWPACK with 1980 - 2017 MERRA-2 global atmospheric reanalysis (Gelaro et al., 2017) hourly mean 2 m air temperature, relative humidity, 10 m wind speed, incoming shortwave and longwave radiation (ISWR and ILWR), and precipitation rate. At the bottom of the simulated snowpack, we apply the MERRA-2 1980 - 2017 mean
120 annual surface temperature as a thermodynamic boundary condition. We choose MERRA-2 because it provides a low release latency (approximately one month) and publicly available description of the state of the atmosphere, whereas regional climate models are not always regularly updated. Additionally, Medley and Thomas (2019) reported MERRA-2 to have the lowest accumulation bias compared to observations among comparable reanalysis products. Furthermore, Gossart et al. (2019) reports generally good agreement between MERRA-2 and observed near surface climatology, including 2 m air temperature and wind speeds, however MERRA-2 appears to overestimate SMB, with a mean absolute error of $58.5 \text{ kg m}^{-2} \text{ yr}^{-1}$.

125 We evaluate MERRA-2 atmospheric reanalysis as forcing for SNOWPACK by comparing with monthly averaged observations at nine AWS, whose locations are shown in Fig. 2. The AWS measure temperature, relative humidity, wind speed and direction, air pressure, and the full radiation balance, i.e. incoming and reflected short wave radiation, and incoming and outgoing longwave radiation. Data from these stations are presented in Reijmer (2002) and Jakobs et al. (2020) and have been previously used to evaluate remote sensing retrievals (Trusel et al., 2013), ice core paleoclimate records (Medley et al., 2018),

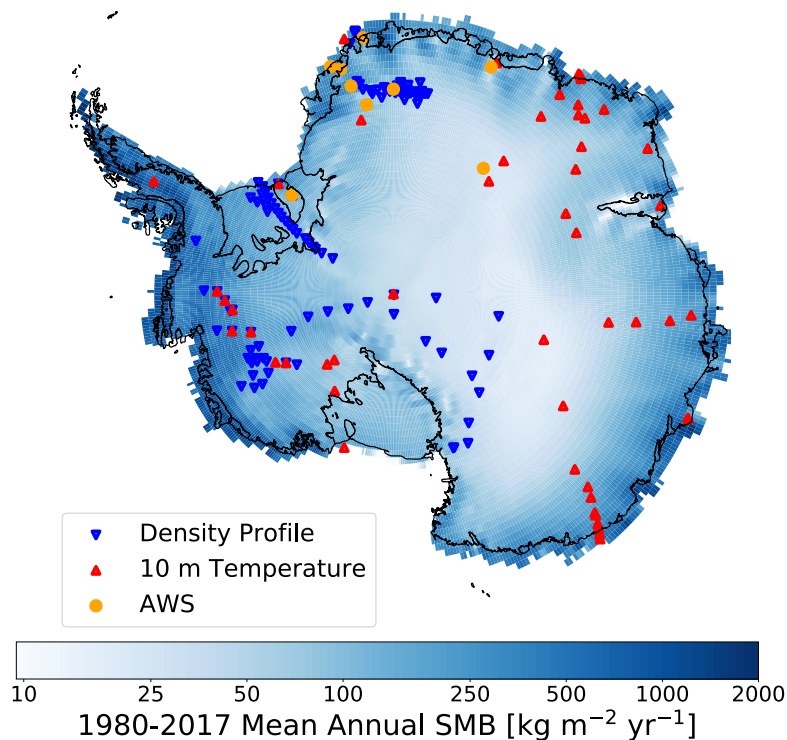

Figure 2. Map of SNOWPACK simulations over the Antarctic ice sheet. Locations of SNOWPACK simulations at 122 observed density profiles (upside down blue triangles), 55 borehole 10 m temperature measurements (red triangles), and nine automatic weather stations (AWS, yellow circles) plotted over MERRA-2 1980 - 2017 mean annual SMB.

130 and climate models (van Wessem et al., 2018). In general, MERRA-2 well captures observed 2 m air temperature, relative humidity, and wind speed, but significantly underestimates both ISWR and ILWR. We calculated an average MERRA-2 bias across all nine AWS of -15.1 W m^{-2} and -16.9 W m^{-2} for ISWR and ILWR, respectively (Fig. A1). In order to reduce this bias in incoming radiation and thus better capture AWS observations, we increase MERRA-2 ISWR by 19.4 % and ILWR by 16.9 W m^{-2} . Following bias correction, MERRA-2 ISWR and ILWR biases are reduced to 8.7 W m^{-2} and -0.6 W m^{-2} ,
135 respectively. Additionally, root mean squared error (RMSE) ISWR is reduced from 22.7 W m^{-2} to 20.3 W m^{-2} while ILWR RMSE is reduced from 21.5 W m^{-2} to 14.1 W m^{-2} . Note that this bias correction only impacts ISWR and ILWR forcing, not 2 m air temperature, relative humidity, 10 m wind speed, and precipitation rate. Additionally, for the rest of this study, all simulations are driven by bias corrected ISWR and ILWR, unless explicitly stated otherwise.

2.3 SNOWPACK model spinup

140 In order to ensure a realistic representation of snow and firn properties throughout the entire near-surface, we complete a SNOWPACK model spinup such that simulated snow depth is 10 m at each site before comparison with observations. We

choose 10 m in order to resolve seasonal variability in snow and firn characteristics as well as energy exchange with the atmosphere. For spinup, we mimic the method presented in Ligtenberg et al. (2011) by repeating the 1980 - 2017 model period until initial simulated snow depth on January 1st, 1980 is at least 10 m. Once spinup is complete, we perform one final 1980 - 2017 model simulation.

2.4 Borehole 10 m temperature as mean annual surface temperature proxy

To test MERRA-2 and SNOWPACK's ability to capture the SEB across a range of AIS surface climates, we compare 1980 - 2017 mean MERRA-2 surface temperature and SNOWPACK snow surface temperature with 10 m depth temperatures from 55 boreholes whose locations are show in Fig. 2. In the absence of significant surface meltwater percolation, 10 m depth temperature equilibrates with mean annual surface temperature, and can therefore be used as a proxy for surface temperature and by extension SEB in the absence of direct observations (van den Broeke, 2008; Lenaerts et al., 2012; van Wessem et al., 2014).

2.5 IMAU-FDM firn densification model

To aid in the evaluation of SNOWPACK modeled near-surface density, we also compare with the widely used Institute for Marine and Atmospheric research Utrecht firn densification model (IMAU-FDM v1.1) (Ligtenberg et al., 2011; Kuipers Munneke et al., 2015; Ligtenberg et al., 2018). The IMAU-FDM is a semi-empirical firn densification model designed to represent snow and firn cover processes including densification, meltwater refreezing and percolation, and surface height change. Gridded IMAU-FDM density profiles are available at 27 km horizontal, 4 cm vertical, and 30 day temporal resolution with atmospheric forcing provided by the regional climate model RACMO 2.3p2 (van Wessem et al., 2018)

2.6 GSFC-FDM firn densification model

In addition to IMAU-FDM we also compare SNOWPACK to the NASA Goddard Space Flight Center firn densification model (GSFC-FDMv1) which provides simulated firn properties over the past 40 years (1980 - 2019) for both the Greenland and Antarctic ice sheets (Medley et al., 2020). GSFC-FDM uses the Community Firn Model, a modular, open-source framework for Lagrangian modeling of several firn and firn-air related processes within a single column (Stevens et al., 2020). The GSFC-FDM simulations are forced by an enhanced resolution hybridized MERRA-2 that was developed by exploiting a 15-year, 12.5 km resolution offline MERRA-2 replay. The hybridized MERRA-2 forcing retains the spatial gradients in the high-resolution replay while maintaining the temporal variations from the original MERRA-2 variables. The dry snow and firn compaction model, based on Arthern et al. (2010), was calibrated to observed depth-density profiles from both Greenland and Antarctica. A simple initial density scheme was implemented based on mean annual MERRA-2 climate, which provides a spatially variable initial density that does not, however, vary in time.

2.7 SNOWPACK comparison with density observations, IMAU-FDM, and GSFC-FDM

We evaluate SNOWPACK's skill in representing surface and near-surface snow and firn density, defined here as depths of 0 - 1 m and 0 - 10 m, respectively, by comparing with community sourced and publicly available density profiles from the Surface Mass Balance and Snow on Sea Ice Working Group (SUMup) data set (Albert, 2007; Medley et al., 2013; Montgomery et al., 175 2018) and the firn densification models IMAU-FDM and GSFC-FDM, both of which have been used in satellite altimetry based MB studies (Shepherd et al., 2012; Smith et al., 2020). We first identified all available Antarctic SUMup density observations in the near-surface and then retrieved spatially and temporally consistent SNOWPACK, IMAU-FDM, and GSFC-FDM model output. This classification yielded 122 unique observed profiles (Fig. 2) that are located primarily on the grounded ice sheet, where surface melt is absent or very rare. Observations and models report different vertical resolution density, therefore we 180 compute the mean and standard deviation of all 122 density profiles at ten 1 m thick vertical levels, beginning at 0 - 1 m and ending with 9 - 10 m depths.

3 Results and Discussion

3.1 Surface energy balance

The large variability in observed 10 m depth borehole temperatures, ranging from -57.0 to -14.4 °C, is well captured by 185 MERRA-2, non-bias corrected SNOWPACK, and bias corrected SNOWPACK, indicating proper representation of average SEB (Fig. 3). In particular, the R-squared values and slope of linear regressions are 0.96 and 1.00 for MERRA-2, 0.97 and 0.98 for non-bias corrected SNOWPACK, and 0.97 and 0.95 for bias corrected SNOWPACK, respectively. MERRA-2 overestimates T_s , with an average bias of 0.52 °C, while non-bias corrected SNOWPACK underestimates T_s with an average bias of -0.99 °C. Meanwhile, bias corrected SNOWPACK yields almost perfect agreement, with an average bias of 0.06 °C. MERRA-2 190 shows the largest RMSE, 2.38 °C, while the non-bias corrected and bias corrected versions of SNOWPACK display an RMSE of 2.16 and 1.94 °C, respectively.

Since the MERRA-2 bias in ISWR and ILWR is determined using only 9 AWS located primarily in Dronning Maud Land (section 2.2), we were initially concerned with the bias' spatial representativeness. However, following bias correction, the reduction in both RMSE and bias ($p < 0.01$) magnitude when compared to 10 m depth temperatures, indicates a clear improve- 195 ment in SNOWPACK's representation of Antarctic SEB.

3.2 SNOWPACK density profiles sensitivity to atmospheric forcing uncertainty.

Although we've performed an evaluation of MERRA-2 SEB, and introduced a bias correction for ISWR and ILWR, uncertainties is bias-corrected MERRA-2 atmospheric forcing likely still exist, and can impact simulated density profiles. To understand the effect of these uncertainties on SNOWPACK simulated density, we perform an ensemble of SNOWPACK simulations at 200 South Pole and the West Antarctic Ice Sheet divide (WAIS), where we perturb MERRA-2 prescribed 10 m wind speed, 2 m air temperature, and precipitation. Because MERRA-2 exhibits mean absolute errors of 2.4 m s^{-1} and 3.1 °C for annual average

Figure 3. Modeled surface temperature evaluation. Comparison between observed borehole 10 m depth temperature ($^{\circ}\text{C}$) and 1980 - 2017 model average non-bias corrected SNOWPACK (blue), bias corrected SNOWPACK (black), and MERRA-2 (red) surface temperature T_s ($^{\circ}\text{C}$). The dashed black line represents a one to one line. Solid lines represent linear regressions. R-squared values, mean bias, and RMSE are reported for non-bias corrected SNOWPACK (blue text), bias corrected SNOWPACK (black text), and MERRA-2 (red text).

10 m wind speeds and near-surface temperature (Gossart et al., 2019) and typical relative accumulation errors of 20 % (Medley and Thomas, 2019), we independently increase and decrease MERRA-2 10 m wind speed, 2 m air temperature, and precipitation at South Pole and WAIS by 2.4 m s^{-1} , $3.1 \text{ }^{\circ}\text{C}$, and 20 %, respectively. SNOWPACK simulated density sensitivities to uncertainties in 10 m wind speed are considerably larger than that of 2 m air temperature and precipitation and range from -46.6 kg m^{-3} at 0 - 1 m in the South Pole - 2.4 m s^{-1} simulation to 58.5 kg m^{-3} at 2 - 3 m in the WAIS + 2.4 m s^{-1} simulation (Fig. 4). Meanwhile, across our 2 m air temperature and precipitation ensemble, differences in simulated density are generally small, less than 5 % of non-perturbed density in 75 out of 80 cases, and never exceed 10 %. Because these simulated density differences are typically small compared absolute density, we conclude that uncertainties arising due to 2 m air temperature and precipitation alone are smaller in magnitude than uncertainties arising from firn densification model choice (sections 3.3 - 3.5). Alternatively, density differences in the 10 m wind speed experiments are larger, particularly from 0 - 3 m depth, and exceed 5 % of non-perturbed density in 24 out of 40 cases. In the context of our study, simulated density uncertainties arising from uncertainties in MERRA-2 wind speed cannot be easily reduced because, consistent with Gossart et al. (2019), we

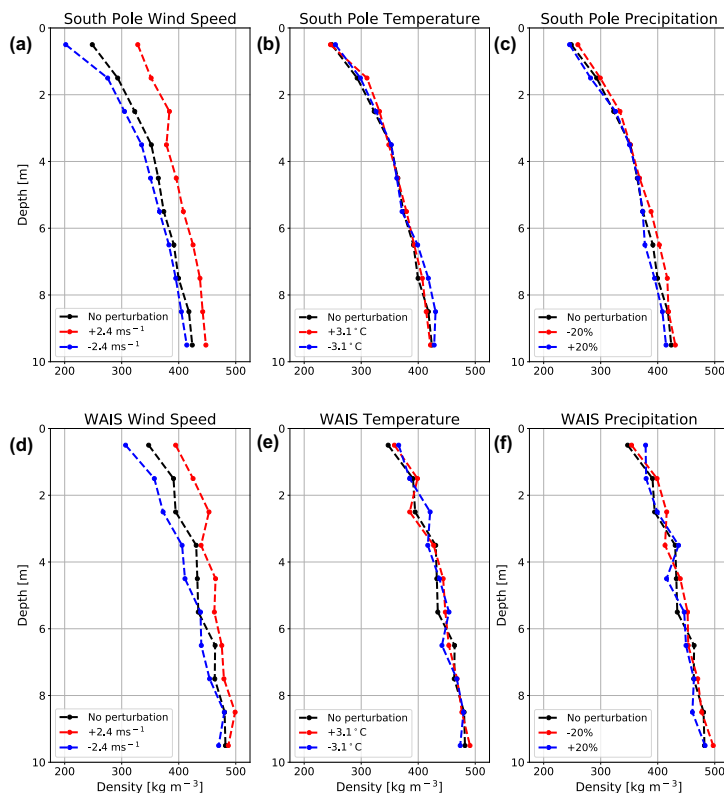

Figure 4. SNOWPACK simulated density profile sensitivity to uncertainties in atmospheric forcing. SNOWPACK simulated density profile sensitivity at South Pole (a,b,c) and WAIS (d,e,f), to wind speed (a,d), temperature (b,e), and precipitation (c,f). The increased wind speed ($+2.4 \text{ m s}^{-1}$), increased temperature ($+3.1 \text{ }^\circ\text{C}$), and reduced precipitation (-20%) perturbations are shown in red, while decreased wind speed (-2.4 m s^{-1}), decreased temperature ($-3.1 \text{ }^\circ\text{C}$), and increased precipitation ($+20\%$) perturbations are shown in blue. In all panels, density profiles are valid for December 31st, 2017 and black curves represents unperturbed atmospheric forcing simulations.

find no consistent bias in MERRA-2 wind speed compared to observations (section 2.2). We must therefore acknowledge that
215 wind speed represents the largest source of uncertainty with regard to SNOWPACK simulated near-surface density, and in fact,
exceeds uncertainties arising from firn densification model choice.

3.3 Surface snow density

A comparison between both SNOWPACK, IMAU-FDM, and GSFC-FDM simulated surface snow density, defined as the top
220 meter, with 79 unique observations is shown in Fig. 5. Observations range from $272 - 507 \text{ kg m}^{-3}$, with a mean of 362 kg m^{-3}
and standard deviation of 39 kg m^{-3} . Since it is known that meteorological conditions including annual accumulation and
temperature influence Antarctic snow and firn density (Herron and Langway, 1980), we tested for explanatory variables. We

find a modest relationship between MERRA-2 1980 - 2017 mean annual SMB and observed surface snow density ($p < 0.001$, $R^2 = 0.23$) as well as a significant, but weak correlation between elevation and observed surface snow density ($p < 0.001$, $R^2 = 0.16$), likely due to the relationship between elevation and surface climate. Note that, perhaps surprisingly, we find no
225 significant correlation between MERRA-2 1980 - 2017 mean wind speed and observed surface density ($p = 0.14$, $R^2 = 0.03$). Because drifting snow compaction is known to partially control snow density on daily to hourly timescales (Sommer et al., 2018), the lack of a significant relationship between mean annual wind speed and surface snow density indicates the importance of resolving drifting snow compaction with high temporal resolution (daily to hourly) meteorological forcing as opposed to annual means or climatology.

230 SNOWPACK (linear fit slope = 0.51, $R^2 = 0.20$), IMAU-FDM (linear fit slope = 0.20, $R^2 = 0.19$), and GSFC-FDM (linear fit slope = 0.22, $R^2 = 0.36$) all modestly capture observed surface snow density variability. Both SNOWPACK and IMAU-FDM underestimate surface snow density with an average bias of -8.2 and -20.4 kg m^{-3} and RMSE of 45.3 and 40.7 kg m^{-3} , respectively. Meanwhile GSFC-FDM, on average overestimates surface snow density, with a bias of 20.4 kg m^{-3} and RMSE of 38.5 kg m^{-3} . For all models, we identify no clear relationship between geographic location and model bias. However, we
235 find a significant but weak negative relationship between observed density and modeled surface density bias for SNOWPACK ($p < 0.001$, $R^2 = 0.19$) as well as a moderately strong negative relationship for IMAU-FDM ($p < 0.001$, $R^2 = 0.80$) and strong negative relationship for GSFC-FDM ($p < 0.001$, $R^2 = 0.87$).

According to our analysis, SNOWPACK better captures the range in observed surface density when compared to IMAU-FDM, as evidenced by a lower magnitude bias, higher R^2 , and a linear fit slope closer to unity, but the typical error is larger,
240 as expressed by a slightly larger RMSE. Likewise, when compared to GSFC-FDM, SNOWPACK exhibits a lower surface density bias magnitude and has a linear slope closer to unity, but exhibits a larger RMSE and lower R^2 . Additionally, we calculate a p-value of 0.06 for a two-sided test in which the null hypothesis states that SNOWPACK and IMAU-FDM have identical average biases. This information combined with SNOWPACK's larger RMSE compared to IMAU-FDM and GSFC-FDM, and smaller R^2 compared to GSFC-FDM, leads us to conclude that neither model is superior, and instead that all
245 three models perform comparably with regard to surface density. Note that all three models perform particularly poorly when observed surface density exceeds 400 kg m^{-3} (SNOWPACK: Bias = -23.7 kg m^{-3} , RMSE = 65.8 kg m^{-3} ; IMAU-FDM: Bias = -65.4 kg m^{-3} , RMSE = 74.7 kg m^{-3} ; GSFC-FDM: Bias = -20.4 kg m^{-3} , RMSE = 35.6 kg m^{-3}). The origin of this poor performance at high observed surface densities is not known for certain, and likely cannot be explained by topographic slope as we find no significant relationship between surface slope derived from a 1 km horizontal resolution digital elevation model
250 (Helm et al., 2014) and modeled surface density bias. Alternatively, this model degradation at high observed surface densities could potentially be explained by an underestimation of new snow density and/or the frequency/intensity of simulated drifting snow compaction due to the presence local meteorological phenomena not captured by MERRA-2 or RACMO2. Additionally, we cannot rule out model degradation at high observed densities due to errors in the observations themselves. For example, some surface density observations, particularly those from deep firn and ice cores, may not be representative of an undisturbed
255 snow surface and could therefore report an artificially high surface density. Moreover, surface snow samples taken from cores

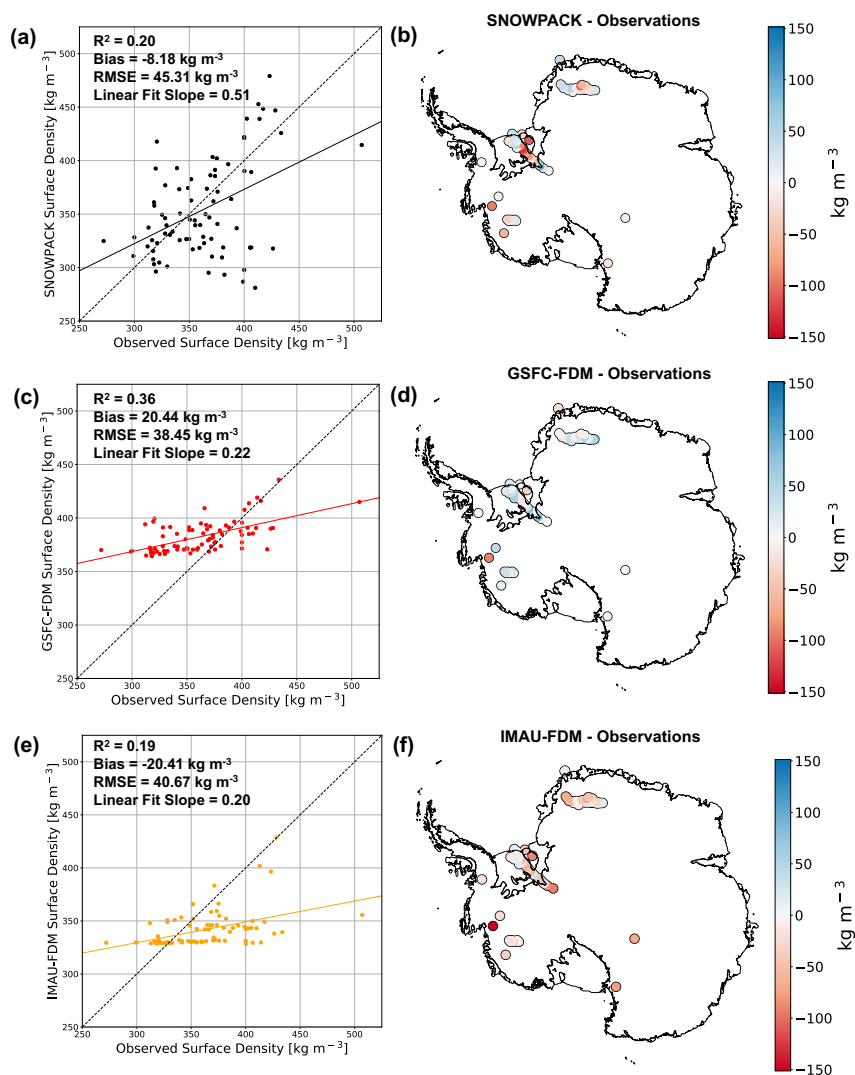

Figure 5. Modeled and observed surface density comparison. Scatter plot of observed vs. SNOWPACK modeled surface density at 79 locations across the AIS (a). Scatter plot of observed vs. GSFC-FDM modeled surface density at 79 locations across the AIS (c). Scatter plot of observed vs. IMAU-FDM modeled surface density at 79 locations across the AIS (E). Map of SNOWPACK minus observed surface density at 79 locations across the AIS (b). Map of GSFC-FDM minus observed surface density at 79 locations across the AIS (d). In panels a, c, and e, dashed black lines represent one to one lines while solid lines represent linear regressions.

are often compressed by the drill and can sometimes break into multiple pieces, therefore confounding density measurements. Finally, simulated surface density errors could be explained by uncertainties in MERRA-2 10 m wind speeds (section 3.2).

3.4 Near-surface snow and firn densification

In a comparison at 122 unique observed density profiles, SNOWPACK, when compared to IMAU-FDM, exhibits a lower mean density bias magnitude throughout the entire near-surface, and when compared to GSFC-FDM from 0 - 7 m depth (Fig. 6). Observed mean densities range from 362 kg m^{-3} at depth 0 - 1 m to 510 kg m^{-3} at 9 - 10 m. Meanwhile, SNOWPACK mean densities range from 354 kg m^{-3} at depth 0 - 1 m to 489 kg m^{-3} at 9 - 10 m. SNOWPACK underestimates observed density at depth with biases varying from a minimum of -0.6 kg m^{-3} at depth 2 - 3 m to a maximum of -25.3 kg m^{-3} at 8 - 9 m. Note that SNOWPACK mean density bias magnitudes from 0 - 7 m are typically small ($< 10 \text{ kg m}^{-3}$), and are approximately the same magnitude as uncertainties arising from uncertainties in atmospheric forcing (Section 3.2). The IMAU-FDM likewise underestimates near surface density with biases ranging from -20.4 kg m^{-3} at depth 0 - 1 m to -40.1 kg m^{-3} at 8 - 9 m. Meanwhile, GSFC-FDM overestimates surface density with biases ranging from 8.5 kg m^{-3} at depth 8 - 9 m to 23.7 kg m^{-3} at 2 - 3 m. Furthermore, SNOWPACK correctly predicts observed variability in mean density, as shown by similar standard deviations between SNOWPACK and observations (Fig. 6, panel A). Alternatively, the IMAU-FDM and GSFC-FDM both underestimate observed mean density variability at the surface, but converge towards the observed variability with increasing depth.

To test for the potential effect of compensating biases on our analysis of near-surface densification, we partition the 122 observed density profiles into 35 high SMB and 87 low SMB categories based off a MERRA-2 mean annual SMB threshold of $200 \text{ kg m}^{-2} \text{ yr}^{-1}$ (Fig. 7). We choose $200 \text{ kg m}^{-2} \text{ yr}^{-1}$ because it roughly approximates the area weighted mean annual SMB over the grounded AIS ($172.8 \text{ kg m}^{-2} \text{ yr}^{-1}$ according to Agosta et al. (2019)). Again, for both high and low SMB sites, we find that SNOWPACK, when compared to IMAU-FDM, shows reduced mean density bias throughout the entire near-surface firn column, from the surface down to 10 m depth. While compared to GSFC-FDM, SNOWPACK exhibits a reduced near-surface density bias only from 0 - 8 m and 9 - 10 m at low accumulation sites. Note generally good agreement between SNOWPACK and observations at both high and low SMB sites. For high SMB sites, SNOWPACK mean biases range from -55.9 kg m^{-3} at 8 - 9 m to -3.9 kg m^{-3} at 0 - 1 m, while for low SMB sites, mean biases are generally reduced in magnitude and range from -14.3 kg m^{-3} at 9 - 10 m to 8.3 kg m^{-3} at 5 - 6 m. Given SNOWPACK's mean bias reduction, when compared to IMAU-FDM, and comparable performance relative to GSFC-FDM, we have demonstrated our physics-based modeling approach is capable of reliably capturing Antarctic near-surface snow and firn density.

3.5 Simulated near surface firn densification at sites not included in GSFC-FDM model calibration

Semi-empirical firn densification models, including IMAU-FDM and GSFC-FDM, are calibrated against observed density profiles in order to improve model agreement with observations. However, because near-surface density observations are sparse, not evenly distributed in space, and typically collected in summer, semi-empirical models may be biased towards climate regimes which are well sampled by observations. Alternatively, SNOWPACK, and other physics-based models, simulate density profiles which are not calibrated against observations and could therefore, potentially outperform semi-empirical models in climate regimes not well sampled in semi-empirical model calibrations. To test this hypothesis, we examine the 69 of 122

Figure 6. Density profile comparison. Mean observed (blue dashed), SNOWPACK modeled (black dashed), GSFC-FDM (red dashed) and IMAU-FDM modeled (yellow dashed) near surface (0 - 10 m) density profiles at 122 locations across the AIS (a). Shading represents plus and minus one standard deviation across observed and modeled density profiles. Mean SNOWPACK minus observed (black dashed), GSFC-FDM minus observed (red dashed), and IMAU-FDM minus observed (yellow dashed) density profiles at 122 locations across the AIS (b).

observed density profiles which were not included in the GSFC-FDM calibration, hereafter referred to as the 69 independent sites. We then compare the mean near-surface density biases of SNOWPACK and GSFC-FDM at these 69 independent sites against the same statistics calculated for all 122 sites (Section 3.4). Unfortunately, we do not know which of the 122 observed density profiles were used in the IMAU-FDM calibration, therefore we exclude IMAU-FDM from this analysis.

295 By examining only the 69 independent sites, mean GSFC-FDM density bias magnitudes increase throughout the near-surface compared to all 122 sites, on average by 6.9 kg m^{-3} , whereas the mean SNOWPACK density bias magnitude remains nearly unchanged, increasing by only 0.02 kg m^{-3} (Fig. 8). Because the mean near-surface density bias increases for GSFC-FDM while remaining nearly the same for SNOWPACK, we conclude that semi-empirical firm densification models exhibit reduced model performance at sites not included in density calibration, whereas SNOWPACK does not demonstrate a significant change
 300 in model accuracy.

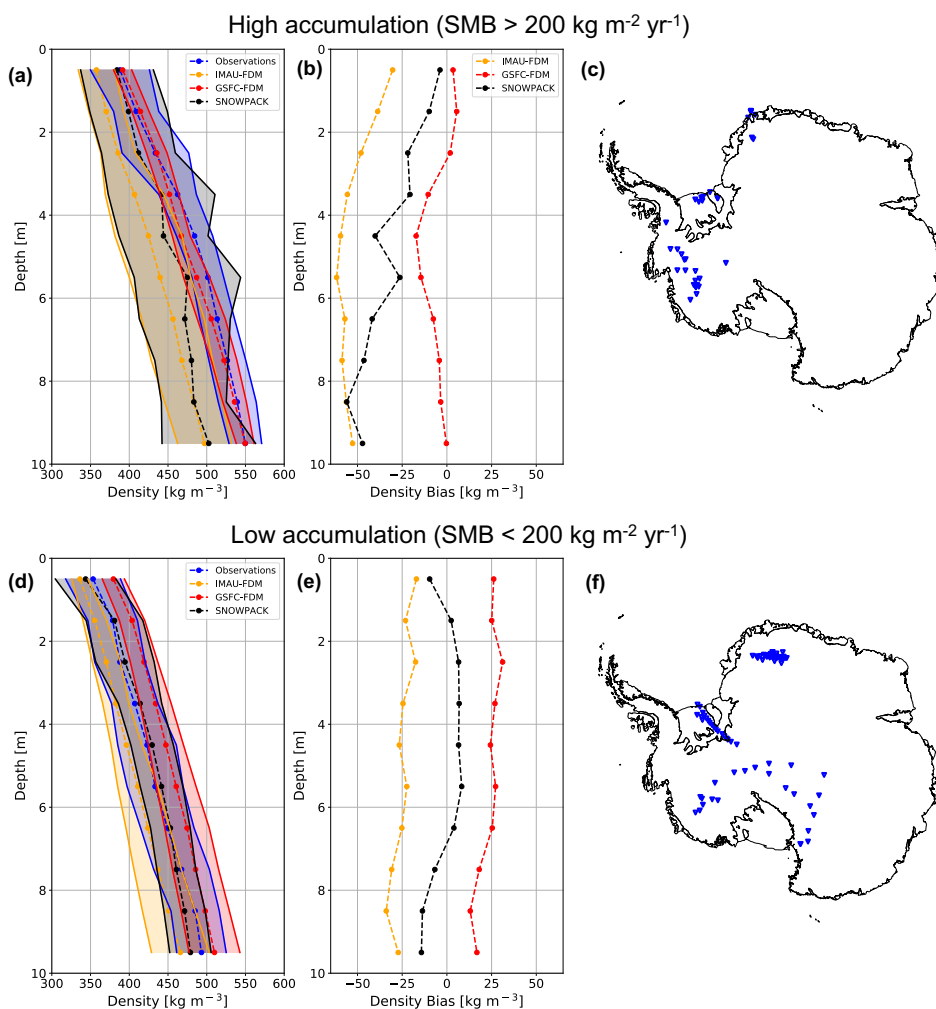

Figure 7. High and low SMB density profile comparison. Average observed (blue dashed), SNOWPACK modeled (black dashed), GSFC-FDM modeled (red dashed), and IMAU-FDM modeled (yellow dashed) near surface (0 - 10 m) density profiles at high (a) and low (d) SMB sites. Shading represents plus and minus one standard deviation across observed and modeled density profiles. Mean SNOWPACK minus observed (black dashed), GSFM-FDM minus observed (red dashed), and IMAU-FDM minus observed (yellow dashed) at high (b) and low (e) SMB sites. Maps of locations of high (c) and low (f) SMB sites. High and low SMB sites are delineated by a MERRA-2 1980 - 2017 mean annual SMB threshold of $200 \text{ kg m}^{-2} \text{ yr}^{-1}$.

3.6 SNOWPACK and semi-empirical models hierarchical complexity

Although all three models are presented on similar footing, it is important to contextualize their performance by noting the different original purposes for developing SNOWPACK, IMAU-FDM, and GSFC-FDM, as well as their different level of process representation complexity. The IMAU-FDM and GSFC-FDM are relatively simplified semi-empirical firm models

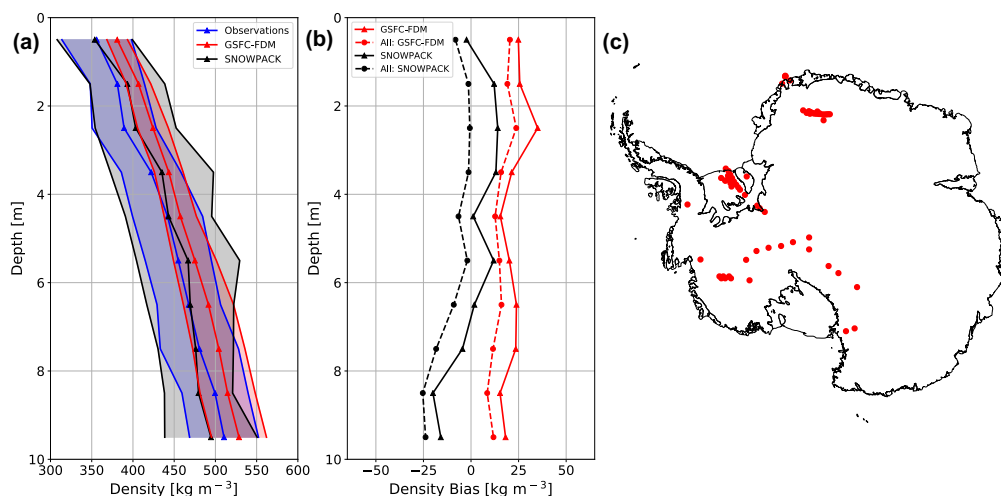

Figure 8. SNOWPACK and GSFC-FDM density simulation at sites not included in GSFC-FDM calibration. Average observed (blue triangles), SNOWPACK modeled (black triangles), and GSFC-FDM modeled (red triangles) near surface (0 - 10 m) density profiles at 69 sites not included in the GSFC-FDM density calibration (a). Shading represents plus and minus one standard deviation across 69 observed and modeled density profiles. Mean SNOWPACK minus observed (black) and GSFC-FDM minus observed (red) density profiles at the 69 of 122 sites not included in the GSFC-FDM density calibration (solid with triangles) and all 122 observed density profiles (dashed with circles, b). Map of 69 observed density profiles not included in the GSFC-FDM density calibration (c).

305 designed to represent spatial and temporal evolution of firn density and surface height. On the other hand, SNOWPACK is
a higher order complexity physics-based land-surface snow model originally intended for simulating snow microstructural
properties relevant for avalanche formation in seasonally snow covered terrain. IMAU-FDM and GSFC-FDM are usually used
to study the entire ice sheet firn column, which can be greater than 100 m thick, while SNOWPACK is typically used to
simulate seasonal snowpacks a few meters thick. Despite the much thicker simulated firn column in IMAU-FDM and GSFC-
310 FDM (40 - 120 m) when compared to our imposed restriction for SNOWPACK to the near-surface (i.e. depths 0 - 10 m),
SNOWPACK is considerably more computationally expensive to run. It is therefore important to acknowledge the inherent
trade off between process representation and cost, particularly for simulations which require long spinups or involve long time
frames, e.g. paleoclimate applications or future climate scenarios.

Because SNOWPACK exhibits a lower mean snow and firn density bias throughout most of the near-surface compared
315 to IMAU-FDM and GSFC-FDM, it is necessary to describe particular model distinctions which could explain their differ-
ent behavior. First, SNOWPACK and IMAU-FDM rely on different meteorological forcing (MERRA-2 and RACMO2 2.3p2,
respectively) which somewhat confounds their direct comparison. Next, in our implementation of SNOWPACK, new snow density
is determined by hourly mean MERRA-2 weather conditions while in IMAU-FDM and GSFC-FDM, new snow density is
determined by annual average meteorologic variables including accumulation rate, 10 m wind speed, and surface temperature.
320 SNOWPACK therefore calculates a variable new snow density driven by both seasonal and synoptic scale variability in surface

meteorology, while IMAU-FDM and GSFC-FDM do not resolve this process. Additionally, SNOWPACK allows for drifting snow compaction of previously fallen snow (Fig. 1), while IMAU-FDM and GSFC-FDM only account for the impact of wind on density by including this processes in the new snow density parameterization. This difference in process representation of new snow density and drifting snow compaction is reflected by SNOWPACK's larger variability in predicted surface density (281 - 479 kg m⁻³) compared IMAU-FDM (328 - 429 kg m⁻³) and GSFC-FDM (364 - 436 kg m⁻³). By allowing for initial low density new snow accumulation and subsequent drifting snow compaction, SNOWPACK, more in line with observations (272 - 507 kg m⁻³), predicts a wider range of surface snow densities than IMAU-FDM and GSFC-FDM (Fig. 5, panels a, c, e). Finally, SNOWPACK's higher temporal resolution density output (daily) compared to IMAU-FDM (30 days) and GSFC-FDM (5 days), can resolve processes relevant for surface snow density which act on timescales of less than 30 and 5 days, respectively (e.g. snowfall and drifting snow compaction).

3.7 Simulated snow cover properties for remote sensing interpretation

In addition to snow and firn density, SNOWPACK can be used to calculate other snow cover properties (e.g. snow grain diameter, temperature, albedo, and liquid water content) necessary for detailed interpretation of ice sheet remote sensing data. In Fig. 9, we provide an example of SNOWPACK simulated winter time temperature profiles and time series of 2010 - 2015 average surface (top 1 m) density and grain diameter at sites near the South Pole and WAIS. Note that due to limited available observations, we make no effort to validate these particular variables; instead, we merely offer them as a demonstration. As expected, South Pole is colder than WAIS throughout the entire near-surface, on average by 18.3 °C. WAIS surface density is on average 125 kg m⁻³ larger than that of South Pole while there is also significant predicted temporal variability of up to 16 % and 11 % of mean density for South Pole and WAIS, respectively. Additionally, surface grain diameter is larger at South Pole while both sites show a large seasonal cycle, peaking in late summer and gradually declining throughout the winter.

By describing snow cover properties at South Pole (mean annual $T_s = -52.4$ °C and SMB = 56 kg m⁻² yr⁻¹) as well as WAIS (mean annual $T_s = -29.4$ °C and SMB = 207 kg m⁻² yr⁻¹), we present model evidence which demonstrates large regional variability in near-surface temperature as well as both regional and temporal variability in surface density and grain diameter. Although we do not directly evaluate simulated temporal variability in snow microstructural properties (e.g. surface density and grain diameter) against temporally distributed observations, time series of simulated snow properties can be useful when developing new and or interpreting existing remote sensing observations.

4 Conclusions

Accurate snow and firn density models are required to reliably determine ice sheet mass balance using satellite altimetry. However, firn densification models currently used in altimetry studies do not resolve observed temporal increases in surface snow density under the influence of wind. In this study, we demonstrate improved simulation of Antarctic near-surface (depths ≤ 10 m) snow and firn density upon implementation of a new drifting snow compaction routine into SNOWPACK, a detailed, physics-based land surface snow model. In particular, we show that when compared to two other semi-empirical firn densifica-

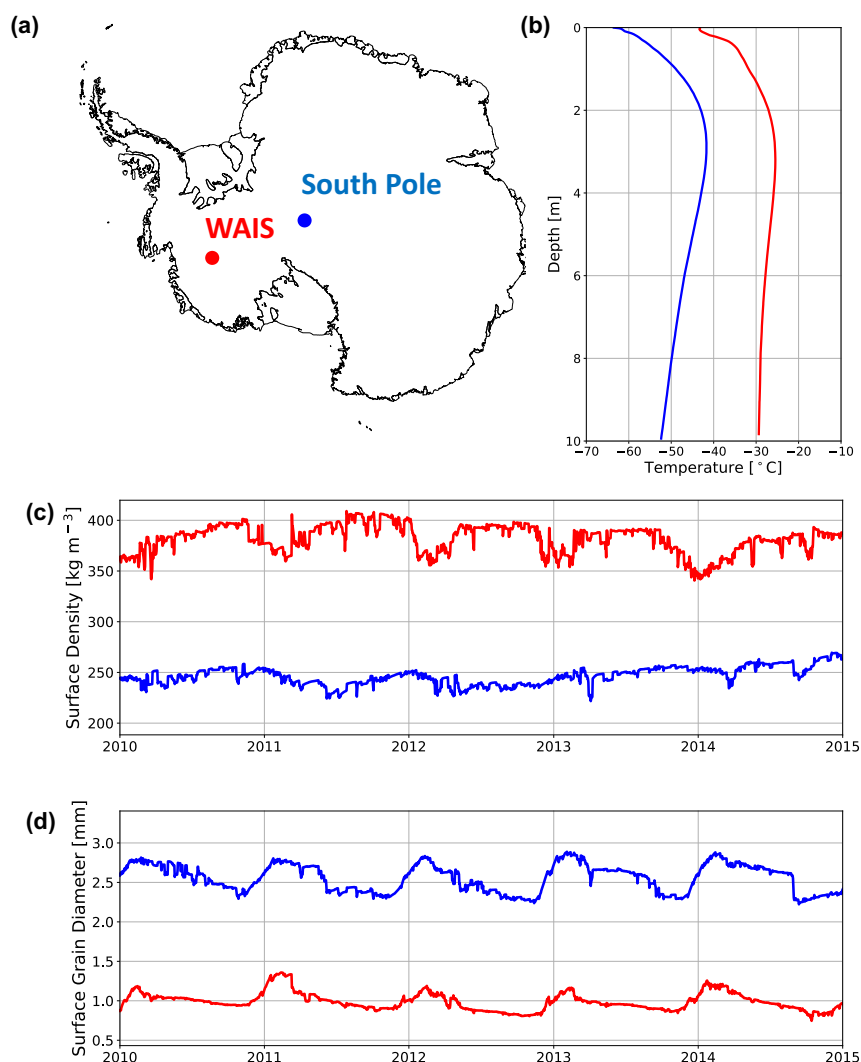

Figure 9. SNOWPACK simulated firn properties. Map indicating locations of South Pole and WAIS (a). SNOWPACK simulated near-surface temperature profiles ($^{\circ}\text{C}$) at South Pole and WAIS on June 21, 2010 (b). Time series of 2010 - 2015 SNOWPACK simulated average surface grain diameter (mm) at South Pole and WAIS (d). In all panels South Pole is shown in blue and WAIS is shown in red.

tion models (IMAU-FDM and GSFC-FDM), SNOWPACK exhibits a lower mean snow and firn density bias throughout most of the near-surface at 122 observed density profiles across the Antarctic ice sheet. Despite this improvement, SNOWPACK generally underestimates density, with a mean surface density bias of -8.2 kg m^{-3} and mean near-surface biases ranging from -0.6 kg m^{-3} at 2 - 3 m to -25.3 kg m^{-3} at 8 - 9 m. Meanwhile, IMAU-FDM exhibits a mean surface density bias of

360 -20.4 kg m⁻³ and mean near-surface biases between -20.4 kg m⁻³ at depths 0 - 1 m to -40.1 kg m⁻³ at depths 8 - 9 m while GSFC-FDM shows a mean surface density bias of 20.4 kg m⁻³ and mean near-surface biases from 8.5 kg m⁻³ at depths 8 - 9 m to 23.7 kg m⁻³ at 2 - 3 m. Because SNOWPACK is a physics-based model, extensive model tuning in order to fit obser-
vations is not required. For this reason, SNOWPACK, when compared to GSFC-FDM, more accurately simulates snow and
firn density at sites whose density observations are not included in the GSFC-FDM density calibration. Because SNOWPACK
outperforms the GSFC-FDM at sites not included in calibration, SNOWPACK, compared to semi-empirical models, may more
reliably simulate firn density in regions without extensive observations and under future climate scenarios, where firn properties
are expected to diverge from their current state.

365 *Code and data availability.* Upon publication, all software and code required to replicate this study will be made open-access at https://github.com/EricKeenan/Keenan_et_al_2020_TC. SNOWPACK model source code can be accessed at <https://github.com/snowpack-model/snowpack>, while the precise version used in this study can be accessed at <https://doi.org/10.5281/zenodo.3891846>. MERRA-2 atmospheric reanalysis is available at <https://gmao.gsfc.nasa.gov/reanalysis/MERRA-2/> and can be retrieved and processed using our workflow available at https://github.com/EricKeenan/download_MERRA2. SUMup density data are available at <https://arcticdata.io/catalog/view/doi:10.18739/A26D5PB2S>.
