26 **Abstract.**

The detachment of large parts of low-angle mountain glaciers, resulting in massive ice-rock avalanches, have so far been
28 believed to be a unique type of event, made known to the global scientific community first for the 2002 Kolka Glacier
detachment, Caucasus Mountains, and then for the 2016 collapses of two glaciers in the Aru range, Tibet. Since 2016, several
30 so-far unknown glacier detachments have been discovered and described, and new ones have occurred. In the current
contribution, we compile, compare and discuss 19 actual or possible large-volume detachments of low-angle mountain glaciers
32 at nine different sites in the Caucasus, the Pamirs, Tibet, Alaska's St. Elias mountains, and the Southern Andes. Many of the
detachments reached volumes in the order of 10–100 million m³. Communalities and differences between the cases investigated
34 suggest that a set of different conditions drives a transient combination of factors related to low basal friction, high driving

stress, concentration of shear stress, and low resistance to exceed stability thresholds. Particularly, soft bedrocks below the detached glaciers seem to be a common condition among the observed events, as they offer smooth contact areas between the glacier and its substratum while being prone to till-strength weakening and eventually basal failure under high pore-water pressure. Surface slopes of the detached glaciers range between around 10° and 20° , possibly on the one hand low enough to enable development of thick and thus large-volume glaciers, and on the other hand steep enough to allow critical basal stresses to build up. Most of the ice-rock avalanches resulting from the detachments in this study have a particularly low angle of reach, down to around 0.1 (apparent friction angle), likely due to their high ice content and connected liquefaction potential, the ready availability of soft basal slurries and large amounts of basal water, and the smooth topographic setting typical for glacial valleys. Low-angle glacier detachments combine elements, and likely also physical processes of glacier surges and ice break-offs from steep glaciers. The surge-like temporal evolution ahead of several detachments or their geographic proximity to other surge-type glaciers suggests the glacier detachments investigated can be interpreted as endmembers of the continuum of surge-like glacier instabilities. Though rare, glacier detachments appear more frequent than previously thought and disclose, despite local differences in conditions and precursory evolutions, the fundamental and critical potential of low-angle soft glacier beds to fail catastrophically.

1 Introduction

Eighteen years after the detachment of Kolka Glacier in the Russian Caucasus, the 17 July and 21 September 2016 detachments of two neighbouring glaciers in the Tibet's Aru range directed attention at a new type of glacier instability that had been rarely observed and little described before (Gilbert et al., 2018; Kääh et al., 2018; Tian et al. 2017). The detachment of Kolka Glacier on 20 September 2002 released a $130 \cdot 10^6 \text{ m}^3$ of ice and rock that claimed ~ 120 lives. Situated on a dormant volcano, it was long assumed that the Kolka Glacier catastrophe was unique and specific to the glacier's location on Mt. Kazbek (Haeberli et al., 2004; Huggel et al., 2005; Drobyshev, 2006; Evans et al., 2009b). The Aru twin glacier detachments – which released 68 and $83 \cdot 10^6 \text{ m}^3$ of glacier ice – have recently raised the questions of whether and where such events may have happened before or need to be expected in the future, which factors (including climate change) ultimately allow low-angle glaciers to detach from their bed in such a catastrophic manner, and what this means for mountain hazard management. Indeed, several detachments similar to the Aru events, though smaller in magnitude, have been detected since (Falaschi et al., 2019; Paul 2019; Jacquemart et al., 2020).

In contrast to glacier detachments, an extensively studied, though still not fully understood type of glacier instability is represented by glacier surges. Characterized by unusually high ice-flow speeds of up to tens of metres per day over large parts of a glacier, glacier surges last weeks to several years (Harrison and Post, 2003; Jiskoot, 2011; Harrison et al., 2015). Clusters of surge-type glaciers are found in many mountain regions around the world (Sevestre and Benn, 2015). The lowering of basal

66 glacier friction that is associated with surging involves abnormally high water pressure, change in the thermal regime, and/or
responses of subglacial till to increasing shear stress and water input (Clarke et al., 1984; Kamb, 1987; Truffer et al., 2000;
68 Fowler et al., 2001; Murray et al., 2003; Frappe and Clarke, 2007; Sevestre et al., 2015; Benn et al., 2019).

A second, well-known type of glacier instability happens over a wide range of magnitudes, from icefalls at steep glacier fronts
70 to large ice avalanches, when partial or entire ice volumes suddenly break off from hanging glaciers that are typically steeper
than around 30° (Alean, 1985; Huggel, 2009; Faillettaz et al., 2015). The latter empirical value from literature offers a slope
72 threshold to separate the definitions of ice avalanches from glacier detachments. Impacts associated with ice avalanches, which
typically have volumes much smaller than $1 \cdot 10^6 \text{ m}^3$, are usually limited to a few kilometres, unless the failed ice transforms
74 into a highly mobile mass flow through liquefaction and incorporation of wet sediments or liquid water in the path (Petra-
kov et al., 2008; Evans and Delaney, 2015). Failure conditions and triggering factors of such steep ice avalanches typically include
76 glacier geometry (steep ramp-type glaciers, bedrock edges), bedrock topography (e.g. convex bed), atmospheric events (e.g.
temperature increase), strong accumulation rates, ice-thermal conditions (e.g. frozen base or changes therein), instabilities of
78 the underlying bedrock that take with them ice resting on it, or seismic events (Alean, 1985; van der Woerd et al., 2004;
Huggel, 2009; Fischer et al., 2013; Faillettaz et al., 2015).

80 Our third type of glacier instability, a sudden large-scale detachment of a mountain glacier, is much less frequent than the two
types above, but shows a mobility at least as high as ice avalanches combined with the large volumes typically involved in
82 glacier surges, and can thus constitute a severe threat to communities and settlements located in remote areas.

In general, mass movements that result from sudden slope failures in ice- or snow-rich mountain environments are often
84 particularly mobile, leading to strongly increased run-out distances compared to ice/snow-free conditions (Petra-
kov et al., 2008; Huggel, 2009; Schneider et al., 2011; Evans and Delaney, 2015). Frictional heating melts ice and snow components,
86 which are either part of the initial slope failure or incorporated along the avalanche path. Liquid water, embedded in the glacier
and sediments before detachment, can amplify the avalanche mobility. Also ice and snow surfaces, in case the avalanche
88 travels over those, are able to reduce basal friction. Here, we define sudden large-volume glacier detachments through their
actual initiation, while the eventually resulting ice-rock avalanches, or other types of mass flows, might be similar to those
90 resulting from other high-mountain slope instabilities. By terming these events *glacier detachments*, we follow the suggestion
by Evans and Delaney (2015) who describe the Kolka case as large-scale detachment of a valley glacier. Other authors, for
92 instance, called these failure events glacier slides, in reference to landslides (Petra-
kov et al., 2008), or glacier collapses (Kääb
et al., 2018).

94 Our following selection focusses on detachments (much) larger than $1 \cdot 10^6 \text{ m}^3$ and from glaciers with surface slopes of lower
than around 20°, i.e. focussing on glaciers from which large-volume detachments were so far typically not expected. In setting
96 these criteria, we are well aware that it can be reasonable to include other events beyond this coarse selection in other types of
analyses, depending on the goal of the investigation. The main scientific purpose of this paper is to provide an overview of all

98 known glacier detachment events, either by summarizing existing detailed studies, or by providing such details for the first
time (see Suppl. Tab. S1 for existing studies and new contributions by the present work). We aim to show and discuss the
100 relation of low-angle glacier detachments to glacier surges and the continuum of high-mountain ice and rock instabilities. The
main applied purpose of our study is to make experts involved in high-mountain hazard management aware of the so far little
102 recognized possibility for glacier detachments and to discuss related potential key indicators.

2 Ice-rock avalanches

104 Ice-rock avalanches can be the result of very different initial types of slope failures and event cascades. A wide range of
magnitudes, avalanche compositions and impacts have been observed (Schneider et al., 2011). In this section, we exemplify
106 the diverse characteristics of ice-rock avalanches and the resultant mass flows in order to contrast them to sudden large-volume
detachments of mountain glaciers. Schneider et al. (2011) compiled a large inventory of ice-rock avalanches and analyzed the
108 relation between avalanche mobility and volume, ice and water content, topography, as well as the presence of low-friction
surfaces. We use their extensive data collection as background data set for our study, extended by events from Petrakov et al.
110 (2008), who concentrated on an event type they term catastrophic glacier multi-phase mass movements. In Fig. 1, each event
of this combined data set is plotted as a gray circle according to its horizontal reach (L), elevation difference (H) and
112 detachment volume (V). The size of the circles in Fig. 1a indicates the event volumes. The ratio H/L is the apparent friction
coefficient or the angle of reach, called also “Fahrböschung”, calculated from the uppermost scarp of the slope failure to the
114 lowermost part of the mass movement deposits.

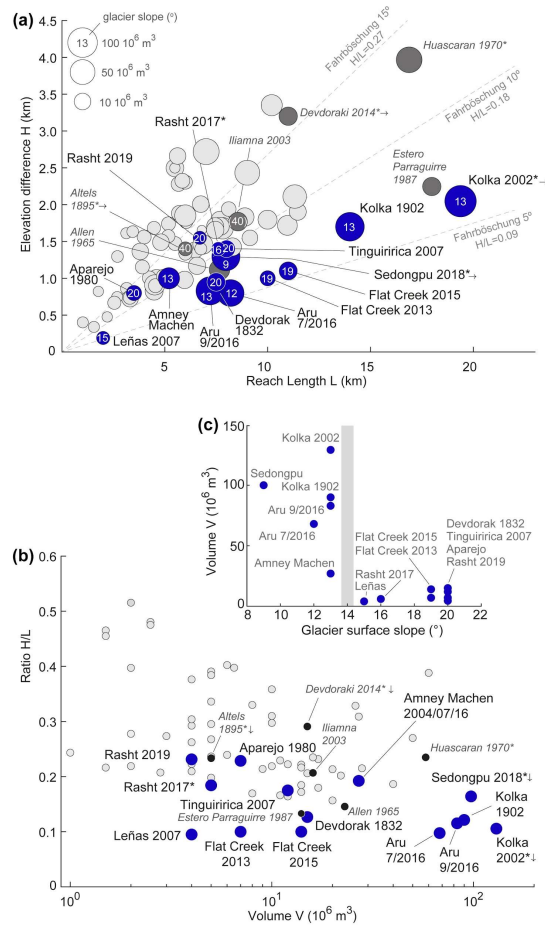

The event collection of Fig.1 includes a wide range of ice-rock failure and mass movement types. Dark grey circles mark the
116 following examples, standing out mainly by type, volume and angle of reach:

- In the 1970 Huascarán (Peru) event (a similar smaller event took place in 1962), a rock-wall failure triggered by a M7.9
118 earthquake, incorporated large amounts of ice from above and below it, leading to a highly mobile and far reaching rock-
ice avalanche of $80 \cdot 10^6 \text{ m}^3$ that claimed up to 20'000 lives (e.g., Evans et al., 2009a). In Fig. 1, we use the solid deposits
120 of the avalanche to define its reach and elevation difference, neglecting that a subsequent water/mud flood travelled much
further (indicated by * symbols in Fig. 1). The 1970 Huascarán avalanche is one of the largest, farthest reaching, and the
122 by far deadliest known, stressing the full catastrophic potential of ice-rock avalanches.
- A rock failure in the Chilean Andes in 1987 incorporated ice, snow and water which transformed the avalanche into a
124 debris flow of $15 \cdot 10^6 \text{ m}^3$ that sped down the Estero Parraguirre valley and killed more than 37 people (Hauser, 2002). In
our collection, this is the farthest-reaching event (lowest angle of reach; H/L ~ 0.12) that did not originate as a glacier
126 detachment.
- The 1964/65 Allen Glacier event, Alaska, is an example for a very large rock avalanche, likely triggered by an earthquake,
128 that was able to run out over an abnormally low angle because it landed on a glacier (Post, 1968). Neighbouring glaciers

show similar rock deposits from the same time, and also later earthquakes caused comparable rock avalanches that travelled
130 far over low-angle glaciers (e.g., Shugar et al., 2012).

- In 1895, $5 \cdot 10^6 \text{ m}^3$ of at least partially cold-based ice sheared off 40° -steep bedrock of malm limestone underlying Altels
132 Glacier in the Swiss Alps (glacier surface slopes indicated as numbers within the circles in Fig. 1a). The resulting ice
avalanche rushed up the opposite side of the valley and thus did not reach its maximum runout distance (indicated by \rightarrow
134 symbols in Fig. 1; Faillettaz et al., 2011). The Altels event is an example of a very large, pure ice avalanche, stemming
from the detachment of a very steep glacier. Until it sheared off, the glacier was probably held in place by transverse
136 bedrock riegels and cold patches/zones where it was frozen to its bed (Wagner, 1996).
- A number of ice-rock avalanches have occurred from different locations on Iliamna volcano, Alaska, the last of which is
138 documented for June 2019 (Toney et al., 2020). Failure surfaces were typically on the order of 40° , and volumes reached
up to around $20 \cdot 10^6 \text{ m}^3$ (Caplan-Auerbach and Huggel, 2007; Huggel et al., 2007). These events show that enhanced
140 geothermal heat fluxes can be involved in causing ice-rock avalanches.

142

144 **Figure 1: (a) Known avalanches of rock-ice mixtures plotted by elevation drop H versus Reach L . The event volumes**
 146 **are indicated by circle size (see legend). Blue circles are sudden large-volume detachments of low-angle mountain**
 148 **glaciers, with the surface slope of the detached glacier parts given in white numbers on the circles. The grey circles are**
 150 **other ice-rock avalanche events, with dark grey events mentioned specifically in the text to illustrate different event**
 152 **types collected in this figure. The diagonal dashed lines indicate the angle of reach, Fahrböschung, at 5°, 10° and 15°.**
 154 **(b) Events from (a) plotted by apparent friction coefficient (elevation drop H / Reach L) versus avalanche volume V . Note the logarithmic scale of the x-axes (volume). Most events stem from Schneider et al. (2011), extended by data from Petrakov et al. (2008) and the present study. * after the event name indicates that a mud or debris flow continued from the rock-ice avalanche deposits, which is not considered in the calculation of the reach. Arrows behind the event name indicate that the avalanche was stopped by some obstacle and would have else travelled further. The direction of the arrow indicates the direction in which the event symbol would have shifted in the plot without the obstacle. (c) Glacier detachment volume against glacier surface slope.**

3 Glacier detachment events

156 In the following, we summarize events that we categorize as glacier detachments, i.e. large-volume ice-rock avalanches from
157 the sudden failure of low-angle parts of mountain glaciers (blue circles in Fig.1). Based on previously published findings from
158 several of the events, we focus our descriptions specifically on disposition factors that could contribute to or hint at the presence
of particularly low basal friction and high shear stresses. These factors include soft sediments, polythermal ice conditions,
160 abnormal geothermal heat flux, high water input and basal water pressure, glacier surging, or significant steepening in surface
slope. As it has been shown that also thermal conditions can play a role in the detachments of glaciers (Gilbert et al., 2018;
162 Jacquemart et al., 2020), we also try to evaluate permafrost conditions for each event.

We sort the following events by regions, and proceed within the regions from short summaries of well-documented events to
164 more detailed descriptions of not or little studied cases. Discussions of individual events, e.g. regarding pre-satellite era events
or a possible recurrence by glacier recovery, are included in the respective subsections, whereas the main discussion section 4
166 focuses on the overall comparison between events.

3.1 Mount Kazbek, Caucasus mountains

168 3.1.1 Devdorak, 18th century, 19th century, 2014

A number of glacier detachments and rock-ice avalanches happened around Mt. Kazbek at the border between Russia and
170 Georgia. During the 18-19th centuries, surges of the Devdorak (Devdoraki in Georgian language) Glacier on the north-eastern
flank of Mount Kazbek (Fig. 2; Tab.1) were moving along the Amilishka River (Kabakhi River in its lower part), which drains
172 the glacier, in 1776, 1778, 1785, 1808, 1817, and 1832 (Zaporozhchenko and Chernomorets, 2004). On August 13, 1832, parts
of the surging Devdorak glacier tongue detached and the subsequent ice-rock avalanche blocked the main Terek valley, an
174 important transportation route between Russia and Georgia (Petraikov et al., 2008). Eyewitness of the 1832 event, engineer-
captain Grauert estimated a volume of $15.5 \cdot 10^6$ m³ of ice and rock mass blocked the Dariali Gorge of the Terek valley
176 (Zaporozhchenko and Chernomorets, 2004). The causes and mechanisms of this (and other) detachments are not well known,
and vary throughout the literature. Ice-rock avalanching on the glacier, overloading and associated increase in subglacial water
178 pressure could well have played a role.

Except for their source area, these at their time well known “Kazbek blockages” followed the same avalanche path as the 2014
180 Devdoraki event described below. Therefore, the 1832 event could instead have been similar to the 2014 event, starting as a
rock failure rather than a surge (Chernomorets, 2014, Chernomorets et al., 2016).

182 In 2014, parts of a rock wall and overlying hanging glaciers failed from Mount Kazbek (Figs. 2-3). The resulting highly mobile
rock-ice avalanche of $2\text{-}5 \cdot 10^6$ m³ rushed down the Amilishka / Kabakhi Valley and blocked the main road between Russia and

184 Georgia, killing 9 people (Chernomorets et al., 2016; Tielidize et al., 2019). This event might also have had a longer runout
(Fig. 1) but was stopped by a sharp 90°-turn at the confluence of the Devdoraki gorge and the Dariali (or Terek) gorge.

186 Currently, the entire narrow lower part of Devdorak Glacier has a surface slope of around 23°, its tongue closer to 17°. The
volcanic nature of Mount Kazbek, the documentation of a number of violent mass flows from the mountain in the past
188 (Chernomorets et al., 2007), field visits, and visual analysis of very high resolution satellite images and terrestrial photos all
suggest highly erodible rock and an abundance of fine sediments at many places on Mount Kazbek. On all high-resolution
190 satellite images available since around 2002 (GoogleEarth, Bing Maps, Maxar, Pleiades), Devdorak Glacier appears heavily
crevassed, and is partly covered by fine sediments, likely deposited by mass movements from the surrounding mountain flanks.

192 Since 2015, a glacier directly south of Devdorak Glacier has been overriding the main tongue of Devdorak glacier in a surge-
like destabilisation, perhaps triggered by the 2014 Kazbek/Devdoraki rock-ice avalanche that overran it (Fig. 3). Possibly as a
194 consequence of the tributary surge, Devdorak Glacier itself is currently also advancing (Dokuin et al., 2020). A 1-km global
permafrost model (Obu et al., 2019), not particularly tuned for mountain permafrost, though, suggests the elevation of the
196 Devdorak Glacier tongue is roughly at or below today's lower boundary of the discontinuous permafrost zone in the region.

198

202 **Figure 3: Lower part of Devdorak Glacier and northeastern flank of Mount Kazbek. The position of the image section is indicated in Fig. 2. Satellite image: Pleiades, © Airbus, 19 Aug 2019.**

204

3.1.2 Kolka, 1902 and 2002

206 The $130 \cdot 10^6 \text{ m}^3$ Kolka Glacier detachment (Figs. 2 and 4, Tab. 1) of 20 September 2002 has been described and discussed in
a number of studies (Haerberli et al., 2004; Kotlyakov et al., 2004; Huggel et al., 2005; Drobyshev, 2006; Evans et al., 2009b).
208 During these investigations, it became clear that a similar event must have already happened at least once, at the beginning of
July 1902 (and probably also around 1700), whereby the glacier tongue detached after a roughly two-week long surge-like
210 advance. Heavy rain and snow melt may have played a role in triggering the 1902 advance. Damming or erosion by water
could then have caused the actual detachment and subsequent rock/mud/ice flow (Drobyshev, 2006; Petrakov et al., 2008;
212 Kotlyakov et al., 2010b). The glacier surged again in autumn/winter 1969/1970 and advanced by 4 km with speeds of up to
220 m/day (Fig. 4), but without catastrophic consequences (Hoinkes, 1972; Rototayev et al., 1983). It is not known to us,
214 which differences in conditions, compared to 1902 and 2002, caused the glacier to not detach in 1970. Several other glaciers
in the Caucasus are known to have surged in the past (Kotlyakov et al., 2010b). We found that Kolka Glacier had a low surface
216 slope of around 13° prior to the 2002 detachment. Evans et al (2009b) estimated a bed slope of 9° after the detachment. Over
the course of several weeks before the 2002 detachment, perhaps triggered by earthquakes (Kotlyakov et al., 2004), heavy rock
218 and ice falls from the northern flank of the Kazbek massif deposited several 10^6 m^3 of material on the glacier. During this

period of mass-wasting activity, the glacier changed in unusual ways: it bulged and became heavily crevassed (Fig. 4), it developed a scarp at the location of the later detachment, and supraglacial ponds formed (Kotlyakov et al., 2004; Evans et al., 2009b; Kotlyakov et al., 2010b). Unusually high geothermal heat fluxes underneath the glacier (fumaroles and sulphur smell were reported in the glacier bed shortly after detachment), the impact energy of a large rock/ice fall, and successive loss of shear stress due to excess water pressure have been proposed as possible factors and ultimate triggers of the 2002 detachment (Kotlyakov et al., 2004; Evans et al., 2009b; Kotlyakov et al., 2010b). Similarly, the additional loading of Kolka Glacier from the rock and ice falls has more recently been proposed to have increased the basal shear stress until it exceeded a frictional threshold given by the glacier bed material, topography, and hydraulic conditions (Kääb et al., 2018). After the detachment, lakes were visible on the Kolka Glacier bed, pointing to the involvement of large amounts of subglacial water in the detachment. The high mean avalanche velocities of 50-80 m/s (Huggel et al., 2005) suggest availability of large amounts of water and/or saturated fine-grained till.

The Kolka Glacier tongue is, like Devdorak Glacier, roughly at the lower elevation of the regional discontinuous permafrost zone, and the glacier must have been temperate throughout, except for the likely polythermal, or even cold steep hanging glaciers avalanching from the northern flank of the Kazbek massif onto its surface. The ice-rock avalanche resulting from the 2002 detachment is described in detail in the above literature about the event, but we want to draw attention to the streamlined debris stripes, in the following called striations, that were visible in the detachment zone after the event (Fig. 4d; Huggel et al., 2005), because similar patterns have also been found in several of the other cases of this study. Currently, the detached glacier depression is refilling and the glacier is gaining mass again. The fast recovery of the glacier volume between the 1970 surge and 2002, and again after the 2002 detachment, is associated with Kolka Glacier's positive mass balance, which stands in stark contrast to the predominant strong glacier shrinkage in the Caucasus Mountains (Kutuzov et al., 2019; Zemp et al., 2019). Kolka Glacier had already reached almost 50% of its pre-detachment volume by 2017 and is projected to accumulate 60–70% of its pre-detachment volume by 2025 (Petraikov et al., 2018; Aristov et al., 2019).

detachment. The position of the image sections is indicated in Fig. 2.

248 3.2 Rasht, Pamir/Tajikistan

In 2017 and 2019, two glacier detachment events happened on the north side of the Peter the First Range (or Petra Pervogo
250 Range, or Peter the Great Range), in the Pamir Mountains of Tajikistan. The resulting mass flows of both events flowed north
into the Rasht Valley through which the Surkhob River flows that later forms the Vakhsh River (Fig. 5).

252 3.2.1 Event of 2017

253 The 2017 event, first mentioned in Dokukin et al. (2019), happened between 10 and 11 July 2017 (Planet images). A glacier
254 of roughly 1000 m length and 240 m width detached (upper scarp ca. at 3600 m a.s.l.) and the resulting ice-rock avalanche
flowed down a narrow valley towards the village Tojikabod in the Rasht Valley (Figs. 5 and 6, Tab. 1). In satellite imagery
256 taken shortly after the event (Planet, Maxar), ice remains can be recognized over a horizontal distance of about 8 km, down to
an elevation of about 2160 m a.s.l. Beyond this point, a considerable debris/mud flow must have continued for another 2 km
258 or so. The detached glacier had a surface slope of around 16° (High Mountain Asia DEM; Shean, 2017). We measured
increased surface speeds of up to 5.8 m/day in early July 2017 (compared to a few dm/day in 2016; velocities from repeat
260 Planet data) and detected unusual lateral crevasses delineating the later detachment area in images from as early as May 2017
(Fig. 6). The glacier is likely not surrounded by permafrost (Obu et al., 2019).

262 To roughly estimate the event volume we derive the ice thickness along the center flow line of the glacier based on an estimated
basal shear assuming a driving stress of $1.2 \cdot 10^5$ Pa as suggested for mountain glaciers, a slope of 16° , and a form factor of 0.8,
264 which then results in a thickness of around 60 m (Cuffey and Patterson, 2010). Multiplying half of this depth (i.e. assuming a
triangular cross-section) with the detached area (ca. $200,000 \text{ m}^2$) gives a first volume estimate of roughly $6 \cdot 10^6 \text{ m}^3$. Whereas
266 satellite images after detachment suggest that much of the glacier bed might actually have a triangular cross-section, it may
have been more shallow in the lowermost and uppermost parts. As an order of magnitude, we suggest a detachment volume of
268 $5 \cdot 10^6 \text{ m}^3$ and assign a conservative error of $\pm 1 \cdot 10^6 \text{ m}^3$ to this estimate.

The cirque from which the 2017 event originated was also the source of other slope instabilities over recent years. Another
270 (much smaller) ice-rock avalanche from a neighbouring glacier occurred between 15 and 24 July 2016 (dates from Planet
images), with a horizontal reach of roughly 5.5 km. A large debris flow descended the same valley in late August 2016, starting
272 from the same cirque, likely entraining deposits of the July 2016 avalanche, and reaching the Surkhob River 19.4 km
downstream where it destroyed several buildings, bridges and agricultural fields

274 3.2.2 Event of 2019

Between 2 and 3 August 2019 a second glacier, ca. 14 km to the west of the one that collapsed in 2017, detached (Figs. 5, 7).
276 This glacier was slightly smaller than the 2017 one, and had a surface slope of around 20° . The resulting ice-rock avalanche
travelled north down a narrow valley towards the Rasht Valley, over a horizontal reach of 6.5 km and a vertical drop from
278 3350 (upper scarp) to 1850 m a.s.l. Superelevations of the ice-rock avalanche path of up to almost 200 m above valley bottom
suggest high avalanche speeds (McClung, 2001). We estimated the detached volume in the same way as described for the 2017
280 event (section 3.2.1) and computed a volume of $4.5 \pm 1 \cdot 10^6 \text{ m}^3$ (glacier area ca. $230,000 \text{ m}^2$; centreline depth 50 m). Based on
pre- and post-event WorldView stereo DEMs Leinss et al. (2020) estimate a maximum erosion depth of 90 m and a detachment
282 volume of $8\text{-}9 \cdot 10^6 \text{ m}^3$, i.e. significantly more than our rough general model.

284 This glacier also showed increased sliding speeds and crevassing around the later detachment area for at least 2-3 weeks before
the failure. For the end of July 2019 we found surface speeds of roughly 2.5 m/day, a marked increase compared to roughly <
0.1 m/day during 2017–2018 (repeat Planet data). The glacier did not show any visual signs of destabilisation between 2015
286 and 2018 (Planet images). In 2007 (Maxar; see Supplement) the glacier looked heavily crevassed, possibly an indication of a
surge-like advance. This condition is still visible in Landsat data 5-6 years later, though less certain due to the lower resolution
288 of Landsat data (no other data is available to us between 2007 and 2015). Landsat data also suggest that the glacier experienced
a similar advance in the early 1990s. Under the limitation of the reduced spatial resolution of the Landsat data, however, we
290 do not find signs of a large detachment event or large ice-rock avalanche. Nevertheless, we draw attention to a surprisingly
vegetation-free landform visible downstream of the 2019 detachment in pre-event imagery (Fig. 8). The lack of vegetation,
292 the streamlined microtopography, and zones of rough and chaotic microtopography that resemble avalanche or debris flow
deposits (Fig. 8; Supplement), led us earlier to interpret this landform as a possible geomorphological imprint of an ice-rock
294 avalanche (Kääb, 2019). Meanwhile, this landform has been overrun by the August 2019 ice-rock avalanche, leaving in parts
similar new forms, and suggesting that the landform now buried could have stemmed from a similar detachment event,
296 probably before 1961 (year of earliest Corona satellite image). Between the 1961 Corona images and very high-resolution
images from just before the 2019 avalanche no significant changes are visible on the landform.

298 Very-high resolution satellite images over the Peter the First Range suggest abundance of weak bedrock and fine sediments.
All over the range, signs after large debris flows, rock avalanches or ice-rock avalanches are visible in high resolution satellite
300 images (Maxar, CNES/Airbus, Planet; Leinss et al, 2020). The Pamirs in general are known to be geomorphologically very
active, with a number of associated hazards (Mergili et al., 2012; Gruber and Mergili, 2013; Strom and Abdrakhmatov, 2018)
302 and a cluster of surge-type glaciers (Kotlyakov et al., 2008; Kotlyakov et al., 2010a; Gardelle et al., 2013; Sevestre and Benn,
2015; Lv et al., 2019). A number of glaciers in the Peter the Great Range are surging at the time of writing or have done so in
304 the recent past (Fig. 5). Didal Glacier (ca. 12° steep) surged during the winter 2015/16 and advanced by 2.5 km over a few
months. In the valley below Didal Glacier we note lack of vegetation in the valley and landforms that could well stem from a
306 former ice-rock avalanche. Kotlyakov et al. (2010a) mention a 2.2 km long ice avalanche from Didal Glacier in 1974. In
comparison, the bottom of the valley through which the 2017 ice-rock avalanche descended (section 3.2.1) was partly tree
308 covered before, suggesting that no event like the 2017 one has happened there in the recent past.

Even if not documented in detail in an internationally accessible format so far, to our best knowledge, both the 2017 and 2019
310 detachments and their downstream effects were very likely noted by the local communities as the lowermost ice/rock deposits
stopped not far from settlements, agricultural fields, and pastures, and very-high resolution images (Maxar) show that flooding
312 happened close to houses and two irrigation channel bridges were partially destroyed.

Before the 2019 event, traces of a potential former large mass flow were visible (lack of trees in the valley, sparse vegetation, striations).**

332

3.3 Aru, 2016, western Tibet

334 On 17 July 2016, a massive volume of glacier ice detached from the lower part of an unnamed glacier in the Aru Range (Rutok
County, China) in the western Tibetan Plateau (termed Aru-1). The fragmented ice mass ran out 6 km beyond the glacier
336 terminus, killing nine herders and hundreds of their animals, and reached the Aru Co lake (Tian et al., 2017; Kääh et al., 2018).
The ice debris covered 8–9 km² and a volume of the detached glacier part of 68 10⁶ m³ was calculated. On 21 September 2016,
338 a second glacier (Aru-2) detached just a few km south of Aru-1 (Fig. 9). Similar to the July event, the glacier ice fragmented
and transformed into a mass flow. The glacier debris in the second detachment covered 6–7 km² with a detached glacier volume
340 of 83 10⁶ m³. (Before-after elevation differences are available in Kääh et al. (2018)). The mean speeds of the Aru ice-rock
avalanches were estimated to 30–50 m s⁻¹, with maximum speeds of 70–90 m s⁻¹ (Kääh et al., 2018). (For a satellite image of
342 the current situation of the Aru glaciers and the deposits, see the Supplement).

344 Glaciers in the wider region around the Aru range are part of the Karakoram – West Kulun Shan – Eastern Pamir anomaly
345 (Treichler et al., 2019) and experienced a slight increase in thickness of around 0.20– 0.30 m/a water equivalent since the early
346 2000s (Brun et al., 2017; Kääb et al., 2018). Positive mass-balances of the Aru glaciers (modeled based on ERA-interim
347 reanalysis data; Kääb et al., 2018) and the widespread growth of endorheic lakes confirmed a precipitation increase in the
348 region from the late 1990's on (Treichler et al., 2019). Driven by these positive mass balances, the two Aru glaciers underwent
349 surge-like accelerations and mass transfers over years before the detachments (Gilbert et al., 2018; Kääb et al., 2018). In
350 apparent contrast to the positive mass balances and the surge-like mass transfers, the Aru-1 and Aru-2 glaciers both retreated
351 by around 500 m between 1970 and 2015.

352 Since at least 2011 and until 2014, the sections above the eventual detachment zones of both Aru glaciers subsided.
353 Simultaneously, glacier sections below bulged upwards. The rates of elevation change derived for 2011–2014 indicate that a
354 down-glacier mass transfer had already begun during the second half of the 2000s (Gilbert et al., 2018). A modelling study
355 based on the observed elevation changes reconstructed changes in basal friction and horizontal velocity prior to the
356 detachments (Gilbert et al., 2018). It showed that the two glaciers were close to their steady state geometry with no/little sliding
357 until 2010. Thereafter, decreasing friction under the whole detachment area of Aru-1 and in more localized zones of Aru-2
358 started to trigger the surge-like mass transfer. Modelling the glaciers' thermal regimes revealed that the frictional changes
359 likely occurred in temperate areas of the two glaciers and that stress concentration occurred on the cold-ice margins (Gilbert
360 et al., 2018). The surge-like changes of basal friction under the Aru glaciers were thus likely not associated with a change of
361 the glaciers' thermal regimes but rather with a change in friction due to increasing water pressure in the already temperate
362 areas. During the instability development, basal shear stresses in the detachment area dropped by an order of magnitude,
363 leading to significant stress concentrations at the detachment margins and in a few spots under the glaciers. These stress
364 concentrations led to strongly enhanced crevassing at the glacier margins and the zone of the later scrap head several months
365 prior to the Aru-1 detachments. Fast-developing crevasses appeared only three weeks before the Aru-2 detachment and were
366 discovered in satellite images in time to alert Chinese authorities.

367 The Aru glaciers are surrounded by continuous permafrost of -3 to -4 °C mean annual ground temperature (Obu et al., 2019).
368 Field observations in the detachment and runout zones showed no presence of a hard-bed lithology beneath the glaciers, and
369 no large boulders were observed anywhere in the runout paths. Rather, extensive deposits of soft, unconsolidated and fine-
370 grained lithologies were identified. The Aru glaciers, situated in a region of positive or zero mass balances (Brun et al., 2017;
371 Treichler et al., 2019) could well build up again to a size similar to the one before their 2016 collapses. Especially in the path
372 of the Aru-1 avalanche, streamlined striations, not present before the event, are well visible at several locations in high-
373 resolution satellite data (not shown).

374 **Figure 9:** Satellite images of the Aru glaciers, western Tibet, and their detachments. (a) Planet infra-red false-colour

378 (SPOT7, © Airbus). Time t refers to detachment date (17 July 2016 for Aru-1, 21 September 2016 for Aru-2). Note the
particular crevassing at the northern curve of the glacier. (c), Aru-1 (Planet). (d), Aru-2 (SPOT7, © Airbus). (e), Aru-
2 (© Planet), six days before collapse. The horizontal line in panels (b-e) indicates the scarp head positions of the later
detachments.

380

3.4 Amney Machen, 2004, 2007, 2016, and 2019, eastern Tibet

382 A sequence of surge-like advances, some of them ending in detachments of the glacier tongue, have been observed for a glacier
in the Amney Machen mountain range, Eastern Tibet (Fig. 10, Tab. 1; Paul, 2019). The isolated mountain range is home to
384 several surging glaciers (Wenying, 1983). The first ice-rock avalanche happened between 26 January and 3 February 2004,
and the involved volume was estimated to be 20-25 10^6 m³, perhaps up to 36 10^6 m³ according to a local information sign-
386 board (Paul, 2019). Three years later, between 23 September and 2 November 2007, a second detachment followed a surge-
like advance, or surge-like recovery, of the glacier tongue that had detached in 2004. The 2007 detachment was considerably
388 smaller in volume than the one in 2004. A third detachment, also smaller than the 2004 one, occurred between 4 and 7 October
2016 (date from Planet images). Following this event, the glacier tongue started to recover again, and another small avalanche
390 occurred from it between 9 and 20 July 2019. Paul (2019) notes the weak rocks and fine sediments visible in the rock ribs in

the glacier's steep source area. The glacier recovered rapidly after each detachment, suggesting that it is largely nourished by
392 ice and rock fall from the headwall, and that a rock/ice melange likely makes up the glacier tongue. The surface slope of the
detaching lower part of the glacier is around 15° . The glacier lies in an area of continuous permafrost with ground temperatures
394 in the order of -3 to -6°C (Obu et al., 2019). Streamlined striations in the avalanche path are visible in high-resolution satellite
images (not shown).

9 Jul 2019, and (d) 25 Jul 2019. Detachments of the glacier tongue happened before (a), between (a) and (b), and between
(c) and (d). (Satellite images © Planet).

400

3.5 Sedongpu/Gyala, 2018, south-eastern Tibet

402 During 2017 and 2018 the Sendongpu basin below the western flank of the Gyala Peri peak (7294 m.a.s.l.; Fig. 11) in south-
eastern Tibet was the source of a series of large mass flows. Some of them dammed the Yarlung Tsangpo river, which posed
404 a serious flood hazard to the upstream Gyalha village and large downstream areas, and triggered hazard management and

investigations of the causes (Tong et al., 2018; Liu et al., 2019; Chen et al., 2020). The largest of the mass flows stemmed
406 from the detachment of a large, low-angle glacier in 2018.

3.5.1 Events before 2018

408 In order to elucidate significant elements of the recent mass-flow history from the basin that might have conditioned the 2018
detachment and that are not documented in detail elsewhere, we start our description with the oldest satellite data available to
410 us. In Corona satellite reconnaissance data of 8 Dec 1969, a narrowing in the Yarlung Tsangpo river where the Sendongpu
valley joins the river, points to deposits from previous mass flows. However, trees on these deposits suggest no recent large
412 mass flow activity. The main glacier in the basin, here called Sedongpu Glacier (Fig. 11), shows some signs of enhanced flow
such as large crevasses. On Corona satellite data of 6 Nov 1974 the glacier has advanced some 800 m into steeper terrain.
414 Fresh traces of a large mass flow are visible between the glacier front and the main Yarlung Tsangpo river, and fresh deposits
seem to have covered or destroyed the forest on the older deposits in the river, but the main glacier is still in place. The glacier
416 showed one single tongue in 1969, but had split into two tongues during its advance by 1974, a feature that it still exhibited in
2016. Chen et al. (2020) describe an ice avalanche from the Sedongpu basin that dammed the Yarlung Tsangpo river in 1968,
418 but do not mention any other events before 2014. From our interpretation of the Corona satellite data there was either one more
event(s) between 1969 and 1974, or the '1968' event actually happened a few years later. The next large mass flow (listed as
420 ice avalanche in Chen et al. (2020) and debris flow in Tong et al. (2018); we interpret at least a large debris content) happened
in 2014. The source of the mass flow must have been in the upper part of the main Sedongpu Glacier or its headwall, as both
422 lateral moraines of the glacier were heavily eroded from the glacier side (RapidEye satellite data of 2013–2015). The glacier
surface was not visibly changed along the glacier centre line, suggesting that the mass flow must have flowed along both
424 glacier margins. Although difficult to determine in the satellite data available to us, the flow may have eroded the lowermost
part of the glacier tongue.

426 Between 20 and 27 Oct 2017 (Planet and Sentinel-2 images) a huge rock avalanche started high up from the north ridge of
Gyala Peri and ran over large parts of the Sedongpu basin and down to Yarlung Tsangpo, damming the river (Figs. 11 and 12).
428 The event seems to have had a severe impact on Sedongpu Glacier. We generated two elevation models from 13 Nov 2015
Spot6 and 30 Dec 2018 Pleiades tri-stereo data that produced robust results despite the extreme topographic conditions.
430 Differencing the two DEMs indicates that the October 2017 rock avalanche removed around 17 and 33 10^6 m³ of material
from two close-by but separated areas, respectively (Fig. 11c). If both failures happened as part of the same event, the total
432 volume of 50 10^6 m³ makes this one of the larger rock avalanches detected in recent decades. Based on visual inspection of
satellite data, we consider it very likely that the avalanche also involved small glaciers from the west wall of Gyala Peri and
434 incorporated ice from the surface of the glaciers lower down, as it ran over them. The Chinese seismic database registered two
large 'landslide' events on 22 Oct 2017: A M3.2 event at 6:20 about 16 km west of Sedongpu and a M4.0 event at 6:22 directly
436 at Sedongpu. Chen et al. (2020) and Tong et al. (2018) confirm that at least the latter signal stems from the Gyala Peri rock-

ice avalanche. Subsequent satellite images suggest that the avalanche must have changed the surface of Sedongpu Glacier
438 drastically. It covered the glacier and much of the basin with debris and dust. A small, surge-like lobe with ponds on it appeared
at the transition between the headwall and the tongue of Sedongpu Glacier (Fig. 12, and GoogleEarth, BingMaps). The eastern
440 tributary glacier to Sedongpu Glacier also showed a surge-like lobe (Sentinel-2, Planet, GoogleEarth). Driven by the
geomorphological changes in the basin, a series of debris flows, some involving ice and likely nourished from the large
442 amounts of unconsolidated debris left behind by the rock-ice avalanche, occurred after 22 Oct 2017 and into 2018 (Tong et al.,
2018; Chen et al., 2020). The two 18 Nov 2017 M5.2 and M6.9 Linzhi/Milin/Nyingchi earthquakes, with epicentres only a
444 few km from Sedongpu, may have contributed to triggering of the debris flows (Hu et al., 2019). Lastly, we report hundreds
of small earthquakes recorded under the Gyala Peri massif in 2017 and 2018, most up to M2, some up to M3, which we have
446 not analysed further in the present study (Chinese Earthquake Data Center, 2020).

3.5.2 Detachment in 2018

448 Following the 2017 rock-ice avalanche the main Sedongpu Glacier underwent drastic changes (Fig. 12). Ponds developed on
its surface and along the margins. Surface velocities increased from a background velocity of ~ 0.3 m/d (ca. 100 m/a) in 2017
450 to 1–3 m/d end of January 2018, 10 m/d in mid-September 2018, and 25 m/d in mid-October 2018 (velocities derived from
offset tracking in repeat Planet, Sentinel-1, and Sentinel-2 data). The glacier surface showed several crevassed bulges (Fig.
452 12b) in January 2018, and progressively more crevasses appeared as the glacier tongue expanded (Fig. 12c). The lower, flat
glacier part separated from the steep head wall. Between 19 Sep 2018 (last optical image due to later cloud cover) and 13 Oct
454 2018 (Sentinel-1) the glacier advanced by almost 1 km. On 17 or 18 October (Tong et al., 2018; Chen et al., 2020), the entire
tongue of Sedongpu Glacier detached over a length of about 3.5 km (glacier width between 250 and 550 m) (Figs. 11 and 12).
456 Planet images of 27 Oct 2018 and Chinese media images confirm that large amounts of ice blocked the Yarlung Tsangpo river
(Fig. 11d). Parts of the emptied glacier bed filled up with enough ice debris that another mass flow originated from there on
458 29 Oct 2018. The dam in the Yarlung Tsangpo river was estimated to be roughly $40\text{--}60 \cdot 10^6 \text{ m}^3$ in volume (Chen et al., 2020).
Differencing our 2015 SPOT6 and 30 Dec 2018 Pleiades tri-stereo DEMs (Fig. 12d) shows two areas of distinct volume loss:
460 around $80 \cdot 10^6 \text{ m}^3$ are missing from the main branch of the glacier, and around $50 \cdot 10^6 \text{ m}^3$ from its terminus and frontal moraine.
An ASTER satellite stereo DEM of 11 Nov 2017 suggests that the volume loss over the glacier tongue and frontal moraine
462 cannot have occurred before November 2017. From our data we cannot tell how much of the total $130 \cdot 10^6 \text{ m}^3$ stems from the
main first glacier detachment event of 17/18 Oct 2018, and how much from the 29 Oct 2018 event. However, satellite images
464 indicate that the first event involved by far the largest volume. The detached glacier part had an overall slope of only $8\text{--}9^\circ$.
According to Obu et al. (2019) it should have been several hundred meters below the regional permafrost limit, but cold or
466 polythermal ice is certainly found in the west wall of Gyala Peri, and could theoretically be advected into the basal parts of the
glacier near its tongue.

468 Between 19 Sep and 26 Oct 2018 (Planet) a $\sim 9 \cdot 10^6$ m³ rock(-ice) avalanche (volume from 2015 SPOT6 and 2018 Pleiades tri-
stereo DEM difference) originated from the south-western flank of Gyala Peri and likely reached Sedongpu Glacier (Fig. 11).
470 The avalanche covered a small glacier below its starting zone which started a surge-like advance early 2018. Due to insufficient
satellite data (cloud cover in optical data; low resolution and radar shadow in SAR data), though, we cannot tell if this avalanche
472 happened before, during or after the 17/18 Oct 2018 glacier detachment, and could thus have triggered the glacier detachment.
Seismic records are also inconclusive regarding the rock avalanche and the glacier detachment, with two dozens of M1–2
474 earthquakes recorded under the Gyala Peri massif between mid September and end of October 2018.

From all the evidence collected above, it seems very likely that the 22 Oct 2017 Gyala Peri rock avalanche, which travelled
476 over the Sedongpu Glacier, primed the glacier for its detachment a year later, perhaps with additional influence of the 18 Nov
2017 earthquakes, though the exact controlling mechanisms remain unclear. The effects that the ongoing mass-wasting
478 activities from Gyala Peri had on Sedongpu Glaciers can have been manifold: additional loading on the glacier can have
increased normal and shear stresses, and the 2017 rock avalanche and earthquakes could have mechanically weakened the
480 glacier and its bed, potentially disrupting the subglacial drainage system. The large amounts of fine dust deposited on the
glacier will likely have changed (enhanced?) its surface melt rates. Lastly, independent factors like high temperatures and
482 precipitation amounts (Tong et al., 2018; Liu et al., 2019), associated with large water input into the glacier, could have
complicated the changes caused by rock-avalanche impact. The supraglacial and glacier-marginal ponds, unusual on temperate
484 glaciers (see Haeberli et al. 2002, Kääb et al. 2004), suggest that the glacier was under high internal water pressure. The bulging
ice and the strong downstream gradient in surface velocities suggest that a surge-like instability first developed in the upper
486 section of the low-angle part of the glacier. Just how this instability propagated down-glacier, whether by exerting pressure on
the lower glacier from above, or by a propagation of exceptionally low basal friction values (Thogersen et al., 2019) remains
488 unclear. High-resolution imagery and media photos of the glacier bed and detachment deposits, as well as the various debris
flows that originated from the basin, suggest that the detached glacier rested on a soft bed with substantial amounts of fine
490 material. The geology of the area is described as marble (Liu et al., 2019), which at least opens up the possibility of fine-
grained sediments.

492 It remains to be seen to which extent the Sedongpu Glacier is able to rebuild, given the strongly negative mass balances in the
region (Kääb et al., 2015; Brun et al., 2017; Treichler et al., 2019, Shean et al., 2020).

494 3.5.3 Zelunglung Glacier surge-like instabilities

The region around Sedongpu does not seem to host any obvious surge-type glaciers. However, the events at Zelunglung Glacier
496 (29.62° N, 95.00° E; GLIMS G095018E29637N, RGI60-13.01428), 20 km south of Sedongpu, are worth mentioning. In 1950,
1968, and 1984 extraordinary instabilities propelled the glacier forward and blocked the Yarlung Tsangpo river (Zhang, 1992).
498 The 1984 event seems to have involved only a smaller section of the glacier. Corona reconnaissance satellite images of 1969
show a massive advance (by about 4.5 km compared to 2018), but no detached glacier. However, the glacier had obviously

500 overridden its frontal moraine, reaching almost down to Yarlung Tsangpo. Deposits, visually similar to those of ice-rock
502 avalanches in general cover much of the main Yarlung Tsangpo river bed on a length of about 2.5 km downstream measured
504 event close to a sudden detachment in the sense of the present contribution.

506 **Figure 11: Location of the 17/18 Oct 2018 Sedongpu glacier detachment, south-eastern Tibet. (a) Sentinel-2 (EU**

522 3.6 Flat Creek, 2013, 2015 and 2016, Alaska

524 Flat Creek glacier, a small glacier in the north-eastern corner of Alaska's St. Elias mountains (Fig. 13), produced two large
526 glacier detachments in 2013 and 2015. This region in Alaska is home to many surging glaciers (e.g., Harrison et al., 2015;
Sevestre and Benn, 2015; Kochtitzky et al., 2019), and a glacier in a valley adjacent to Flat Creek surged between 2012 and
528 2016. Located in the rain shadow of the St. Elias range, the area receives on average about 350 mm of precipitation annually
(2008 – 2018). A mean annual air temperature of -14°C at the former terminus of Flat Creek glacier, ground temperature
measurements, and electrical resistivity tomography surveys strongly suggest that the headwall is underlain by continuous
permafrost (Jacquemart et al., 2020).

530 On 5 August 2013, the lower 500 m of the glacier detached, releasing 6.8-11.2 10^6 m^3 of ice and lithic material. On 31 July
2015, most of the remaining glacier ice (up to the drainage divide) detached, evacuating an additional 17.6-20.1 10^6 m^3
532 (Jacquemart et al., 2020). Both events produced runouts of over 11 km (angle of reach 6-7°), deposited vast amounts of lithic

534 material, and buried several km² of old growth forest (400+ years old). The large amount of fine-grained sediment found in
the deposits suggests that the failures occurred within the glacier bed rather than at the ice-bed interface. The detachment slope
was determined to be 21°.

536 A remarkable feature of Flat Creek glacier was a ~70 m tall bulge upstream of a stagnant, crevasse-free tongue. A similar
bulge on Trapridge glacier, a polythermal surge-type glacier 80 km south-east of Flat Creek, was shown to have formed because
538 a cold-ice tongue buttressed temperate ice upstream (Clarke and Blake, 1991). Based on the low annual air temperature and
the presence of continuous permafrost, Jacquemart et al. (2020) concluded that the bulge on Flat Creek glacier was also the
540 consequence of a polythermal regime. Measurements of the bulge position in satellite images suggest that the bulge advanced
between 2011 and 2013, likely increasing driving stresses locally.

542 The 2013 and 2015 detachments both occurred at the peak of their respective melt seasons. Using a degree-day model,
Jacquemart et al. (2020) found that the water availability during the exceptionally warm summer of 2013 was primarily melt
544 driven and up to 4.8 standard deviations (σ) above the long term mean (1979–2015). No detachments were detected in 2014,
when water availability was below average (-0.5σ). Water availability was again higher in 2015 ($+1 \sigma$), when the second
546 detachment occurred.

In 2016, a third glacier detachment released from a much steeper glacier (~30°) in the same cirque (not described in Jacquemart
548 et al. (2020) but mentioned in Jacquemart and Loso (2019)). We differenced a 13 March 2016 Arctic DEM and a structure-
from-motion DEM from a 2019 aerial survey and estimate the volume of this detachment to be $4.7 \pm 0.18 \cdot 10^6 \text{ m}^3$. Its causes
550 have not been investigated, but the moving mass of ice was caught on video by rangers on a coincidental overflight. The speed
of the observed mass flow was about three times slower than that of the 2013 and 2015 events. Nevertheless, the churning
552 mass of ice blocks (termed a “slush-alanche” by Jacquemart and Loso (2019)) provides a sense of what the much larger flows
may have looked like.

562

3.7 Aparejo, 1980, Chilean Andes

564 On 1 March 1980, $7 \cdot 10^6 \text{ m}^3$ (85% of its total volume) sheared off the debris-covered Aparejo Glacier in the Chilean Andes,
mobilizing the detached mass 3.7 km down-valley with an estimated speed of 110 km/h (Ugalde et al., 2015; Ugalde, 2016;
566 Ugalde et al., 2017) (Fig. 14). The slide deposit covered an area of 0.55 km^2 with ice and rock debris piled up to 17 m thick.
The volume of the deposit was estimated at $8.1 \cdot 10^6 \text{ m}^3$ (Marangunic, 1980). Five mountaineers witnessed the event and noted

568 several supraglacial ponds and 2-3 cm of wet snow on the surface of the glacier (Marangunic, 1980). These observations
570 suggest that the triggering mechanism of the glacier detachment likely involved an extreme reduction of the basal drag due to
high water saturation of the glacier bed. Aparejo glacier appears to sit on a glacier bed composed primarily of weak subglacial
572 till, and the slope on the lower two thirds of the glacier averages 7° . Snowmelt infiltration and warm precipitation due to a
sudden increase of the zero-degree isotherm elevation could have provided the main source of infiltrated water, leading to
574 enhanced water pressure at the glacier bed. During a field inspection on 12 March 1980, Marangunic (1980) found that the
nearby debris-covered glacier to the east, glacier no 51 according to the Chilean glacier inventory at the time (Fig. 14), also
576 showed significant signs of surge-like instability, such as a heavily crevassed front and patches of freshly exposed ice along
its entire length. The prominent terminal moraine of this glacier may have contained its detachment, though.

The Aparejo glacier is situated in a region of complex geology with a number of weak rock formations, including sandstones
578 and fine-grained conglomerate in the immediate vicinity of the glacier. (Ugalde, 2016). Ugalde (2016) sampled the grain size
distribution of the remains of the lower ice-rock avalanche deposits and did not find them to contain more fines than a typical
580 moraine, but notes that spatial variability was high and that the 35 years since the detachment may have depleted the deposits
of fine particles. In the former avalanche path, modern satellite images show streamlined striations similar to those reported
582 from several other detachments in this contribution. Remarkably, similar striations are also visible in Hycon airphotos from
1956. Interestingly, the geomorphology of the deposit area is similar between the 1956 airphotos and the post 1980-event high-
584 resolution satellite images. One possible interpretation of this is that large mass flows had already originated from the Aparejo
cirque at earlier times. A detailed field investigation would be required to determine whether the striations consist of glacial
586 flutes formed under a previous glacier extent or stem from a catastrophic detachment.

In 2015, the glacier had around 15% of its pre-detachment volume, covering much of the original area, and with a surface
588 slope of around 20° (Ugalde, 2016). The current glacier terminus lies at around 3400 m a.s.l., slightly below the lower regional
limit of discontinuous permafrost, estimated by Brenning (2005) to be at around 3500 m a.s.l. Consistent with regional glacier
590 mass balance trends (Falaschi et al., 2018b; Braun et al., 2019; Dussailant et al., 2019), decreasing ice thicknesses have been
identified on the lower and middle section of the Aparejo glacier (Ugalde et al., 2017), pointing to the glacier shrinking under
592 current climate conditions.

598

3.8 Leñas, 2007, Argentinean Andes

600 The $4 \cdot 10^6 \text{ m}^3$ detachment of Leñas Glacier between 5 and 14 March 2007 was discovered only recently, since it happened in
a very remote region and had no down-stream impacts. Meanwhile, the case is described in detail by Falaschi et al. (2019).
602 The detached lower glacier section had a surface slope of around $15\text{-}16^\circ$. The glacier tongue at around 3450 m a.s.l. is suggested
to lie within the zone of discontinuous permafrost in the region. The bed characteristics of the glacier are not known, but large
604 amounts of fine sediments were found over the run-out area of the event. A number of glacier surges are documented in the
wider region but not for Leñas Glacier itself (Falaschi et al., 2018a, 2019). At the location of the later head scarp of the
606 detachment, pronounced transverse crevasses are visible in airphotos from 1970 and in a satellite image from a few weeks
before the event (SPOT5). It is hard to determine, however, if these crevasses could have been signs of abnormal glacier
608 behaviour, or rather a pre-existing feature that then naturally formed the upper failure scarp. Transverse undulations of the
glacier surface as indicated in the 2000 SRTM DEM, and a slight increase of surface gradients at the location of the crevasse
610 zone favour the latter scenario.

616 3.9 Tinguiririca, 1994 and 2007, Chilean Andes

618 3.9.1 The 1994, 2007 and a possible 1962 event

618 A detachment from a glacier on the southern flank of the Tinguiririca Volcano (Fig. 16) happened between 27 June (Landsat
5 TM) and 6 July 1994 (Landsat 5 TM). For the event, we estimate a detached glacier area of 0.2 km^2 . Using glacier thickness
620 estimates derived for the 2007 case (described below), we estimate a detachment volume of roughly $4\text{--}5 \cdot 10^6 \text{ m}^3$. The climatic
conditions between 1994 and 2007 were obviously favourable enough (i.e. little negative or even balanced regional glacier
622 mass balances; Masiokas et al, 2016; Dussailant et al. 2019) for the glacier to recover to its pre-detachment geometry.

At the same location, a glacier area of 0.46 km^2 detached between 7 January (Landsat ETM+ image without collapse) and 14
624 January 2007 (Landsat ETM+ with collapse), producing an ice/debris avalanche of $10\text{--}14 \cdot 10^6 \text{ m}^3$ volume (Schneider et al.,
2011; Iribarren Anacona et al., 2015; Figs. 16, 17). We estimate that the detached glacier had a surface slope of around 20° .
626 Before the 2007 detachment, the glacier's lowest elevation was at about 3500 m a.s.l., roughly at the lower regional limit of
discontinuous permafrost (Brenning, 2005). The volcanic nature of Tinguiririca should be associated with weak rocks and
628 sediments. There are fumarolic fields and hot springs within a few km of the detached glacier (Pavez et al., 2016), and an
inactive volcanic crater lies just a few hundred metres to the west of the detached glacier. In very high-resolution satellite
630 images of 2007 and later (GoogleEarth, BingMaps), clear signs of hydrologic activity are visible in the upper part of the
detachment area: freshly eroded channels, wet looking areas, and deposits from small debris flows – all perhaps signs of
632 geothermally-enhanced melt of snow and ice (Fig. 17). In the path of the ice-rock avalanche we find streamlined striations
similar to those found in the Kolka, Rasht 2019, and Aparejo avalanche paths (Fig. 17). As of late 2019, the glacier has not
634 recovered from its 2007 detachment and there are only a few small snow (or ice?) fields visible at its location. Elevation
differences between 2000 (SRTM DEM, before detachment), 2007–2010 (ALOS PRISM, after detachment), and 2010–2015
636 (TanDEM-X; both the ALOS PRISM and TanDEM-X DEMs are multi-year composites and therefore their date range is given)
suggest that the detached glacier had average and maximum thickness of 21–28 m and 50 m, respectively. Combined with the
638 detached glacier area of about 0.5 km^2 we estimate a detachment volume of roughly $10.5\text{--}14 \cdot 10^6 \text{ m}^3$, which is in good
agreement with Iribarren Anacona et al. (2015). The Tinguiririca case illustrates how glacier removal by the 1994 detachment
640 was largely reversible as the glacier built up again to failure conditions under the climate at that time, whereas the 2007 glacier
removal seems irreversible under current climate and associated negative glacier mass balances in the region (Falaschi et al.,
642 2018b; Braun et al., 2019; Dussailant et al., 2019).

In airphotos from 1962 and Corona-series reconnaissance-satellite images from 1967 we notice striations in the valley similar
644 to the ones visible after the 1994 and 2007 events, and other cases described in this contribution. Over the glacier, the 1962
airphotos clearly show that a glacier detachment similar to the 1994 event must have occurred not long (weeks, months or a

646 few years?) before the image was taken. Stripes of debris or ice remains after the avalanche are still well preserved in the 1962
images over the glacier (Fig. 17d). (The associated terrain sections are under snow cover in the 1967 Corona images).

648 **3.9.2 A potential large pre-1970s detachment of the neighbouring glacier**

In the neighbouring valley to the east (Fig. 18) we note geomorphological traces that could be investigated further with regard
650 to their origin from volcanic mass movements, earlier glacier stages, glacier surging, or more glacier-detachment like events.
In the lower part of this potential event path we find striations, similar to the ones from the Tinguiririca, Aparejo and other
652 avalanches of this study, largely unchanged since the first available Corona-series reconnaissance-satellite images in 1967
(Fig. 18c), and airphotos from 1962. Only detailed field work would be able to rule out the possibility that this striations consist
654 of glacial flutes or small lateral moraines formed during a previous glacier extent, or were produced by a glacier surge. It
should also be investigated whether such striations can remain largely intact after having been overrun by an ice-rock avalanche
656 or if it is an indicator of the most recent event (see also Aparejo, where similar questions turned up).

In the upper part of this valley, or in the potential event source area, we observe two noticeable changes over time. First, the
658 tongue of this unnamed glacier (RGI60-17.01112, GLIMS ID: G289692E34781S) was much smaller in 1962 airphotos than it
is in 2020. Its advance of roughly 1.5 km since 1962, most of which occurred between 1975 and 1986 (Landsat), is in stark
660 contrast to the pronounced shrinkage of the other glaciers in the area (Fig. 16 and 18). Indeed, differencing a DEM, which we
produced from 1962 stereo-airphotos, from the SRTM or TanDEM-X DEMs confirms elevation gains on the glacier tongue
662 of up to 120 m between 1962–2000 (SRTM), or up to 150 m between 1962 and 2010–2015 (TanDEM-X; Fig. 18c). This
development could point to the recovery of the glacier tongue after a removal some time before 1962. The volume gain of the
664 glacier tongue between 1962 and 2000 is around $70 \cdot 10^6 \text{ m}^3$, or $100 \cdot 10^6 \text{ m}^3$ between 1962 and 2015.

Second, we detected an elevation decrease of the glacier forefield of around 10–15 m between 1962 and 2000, which could
666 point to the deflation of debris-covered ground ice, deposited by a possible surge or glacier detachment (Fig. 18c). Third, a
comparison of the 1962 airphotos to contemporary images revealed a heavily bulged glacier surface between 3900 m a.s.l. and
668 4650 m a.s.l. (Fig. 18a,b). Visually, this bulging is similar to the bulge found on Flat Creek Glacier prior to its 2013 detachment
(section 3.6). The slope of the glacier tongue is around 8–10°, and around 35° for the steep upper part. The bulging upper part
670 of the glacier is far above the regional permafrost limit so that polythermal ice conditions might well be found in parts of it.

We also examined a 1955 Hycon aerial photo (no stereo data to produce a DEM available to us), but visual interpretations
672 from it remain inconclusive. Under illumination conditions that are very different from those of the 1962 images, the headwall
glacierisation and the tongue seem larger in 1955 than in 1962, resembling rather its shape and extent of the 1980s. Below the
674 position of the current (2020) glacier terminus, there seem to be dead-ice remains visible in the 1955 images. These are also
visible in the 1962 images, though shrunk. It remains thus to be clarified at this point to which extent the features observed

676 can be explained by a surge, or series of surges of the glacier before 1955, or between 1955 and 1962, or by a detachment-like
677 event.

678

680 **Figure 16: Tinguiririca Volcano, Chilean Andes. Outlines of the 1994 and 2007 ice-rock avalanches, and the 1993 and**
681 **2005 area of the detached glacier as dotted or dashed lines, respectively. These outlines have been digitised for this**
682 **study but were found to agree well with the ones in Iribarren Anaconda et al. (2015). Satellite image: Sentinel-2 (EU**
Copernicus), 14 Mar 2020.

684

686

Figure 17: (a) Glacier detachment area at Tinguiririca Volcano on 24 Jan 2007 (satellite image: © Google Earth and Maxar). Glacier outlines from 26 Feb 2005 Landsat data (latest snow-free image before 2007 detachment) indicated by dashed line. From the 30-m resolution Landsat data it is unclear whether the dash-dotted ice section was connected to the main glacier. (b) Striations left by the 2007 ice-rock avalanche (30 Jan 2019; © Google Earth and CNES/Airbus). (c) A Landsat image of 19 Mar 1995 (first snow-free image after 1994 detachment) shows that the southern part of the glacier detached in the 1994 event. Glacier outlines of 2005 dashed as in (a). (d) The glacier on an aerial image of 8 Apr 1962 (© National Geographical Institute of Argentina). Clearly, a glacier section similar to the 1994 event has detached not long before the image date, leaving also a similar ice cliff. Striations or streamlined features of debris/ice remains from the resulting avalanche are still well visible.

696

698 **Figure 18:** Glacier valley with potential former surge or glacier detachment, east of Tinguiririca Volcano. See Fig. 16

704 retreating glaciers in the area. (c) Elevation differences between DEMs from 1962 stereo airphotos and the 2000 SRTM
show gains over the glacier tongue of up to 120 m, and losses of around 10-15 m in the forefield. (d) Corona satellite
image of 23 Feb 1967 with striations. (e) Satellite image of 19 Mar 2007 (© Google Earth and Maxar). (a) and (b), and
(d) and (e) show the same terrain section each. Locations of (c), (d) and (e) indicated as white rectangles in (a) and (b).

706 4 Discussion

4.1 Commonalities and differences

708 The most apparent similarities among the detachments compiled in this contribution (Tab. 1) are their geographic proximity
710 to surge-type glaciers – in some cases the detached glaciers themselves exhibited surging or surge-like behaviour – as well as
712 the existence of weak bedrock and/or fine sediments around and likely at the base of the glaciers (Tab. 2). Both commonalities
714 suggest that the sudden detachments of low-angle glaciers discussed here could be seen as rare and extreme endmembers of
716 the range (Quincey et al., 2015; Herreid and Truffer, 2016) of surge-type and surge-like glacier instabilities. The detachments
could be a specific kind of glacier surge where the force balance cannot be achieved by a global control, typically by geometric
adaptation, when basal friction is suddenly reduced. In combination with a low bed roughness and an absence of sufficient
topographic support, the reduced amount of stress accommodated by basal resistance has nowhere to be transferred to and
leads to an expanding force imbalance (Thogersen et al., 2019). This ultimately leads to a runaway acceleration and
detachment.

718 In this context, we note that the surface slopes of the detached glaciers were between 9° and 21° (average 15.9° , standard
720 deviation 3.6°), which is at the upper end for slopes of surge-type glaciers, yet surprisingly low for glaciers causing ice
722 avalanches. The slope range of around $10\text{--}20^\circ$ may be a necessary condition for glacier detachments, as these – for surge-type
724 glaciers – comparably high slopes are large enough to increase the probability of exceeding a critical shear stress and thus
allowing for sudden basal failure. At the same time, glaciers within the $10\text{--}20^\circ$ slope range still have considerable thickness
and thus volume, while higher slopes sustain thinner glaciers and much smaller volumes involved in a potential failure (Fig.
1c). Our very limited data base of detachment events suggests a transition between larger and smaller detachment volumes at
roughly around 14° (Fig. 1c).

726 From a more mechanical point of view, low-angle glacier detachments can also be seen as part of the continuum between
728 surges and ice break-offs from steep glaciers. Not least owing to their slope, glaciers have a range of possibilities to adapt to
730 changes in their stress regimes (see Fig. 18). Flat glaciers can respond by adjusting their geometry, for instance through advance
and surging. On very steep terrain, glaciers may not be able to adjust their geometry smoothly and ice breaks off. In contrast
732 to the factors involved in typical ice break-offs from steep glaciers (see section 1), glacier detachments appear to have in
734 common basal failure on soft beds. Therefore, low-angle glacier detachments combine the elements of both instability
736 processes: the inability to rapidly adjust geometry in response to stress changes, similar to steep glaciers, and a surge-like
process that propagates an initial instability through large parts of the glacier (Thogersen et al., 2019), allowing entire glacier
tongues to be mobilized. The latter framework for low-angle glacier detachments and the above one of surge endmembers are
not mutually exclusive but rather linked by the role of glacier slope, fine basal tills, and the surge-like propagation of
instabilities.

738 The role of basal water pressure in the detachments is difficult to examine in detail, but most detachments could have involved
severe reduction in friction due to high basal water pressure (likely at least for Kolka 2002, Aru, Flat Creek, Sedongpu,
Aparejo). Ways to rapidly increase basal water pressure include: an increase in water input (e.g., large high-altitude rain events
740 (Kääb et al., 2018) or increased surface snow/ice melt) into a subglacial drainage system not capable of adjusting fast enough;
inefficiencies or blockages of this drainage system; or increased permeability of the glacier through enhanced crevassing
742 (Dunse et al., 2015). Sudden weakening of the strength of subglacial till under high pore water pressure and over large parts
of the glacier bed was shown to be a key process leading to the Aru detachments (Gilbert et al., 2018). Ongoing surge-like
744 activity may enhance sensitivity to water input (Flowers et al., 2016).

In Figure 18 we attempt to summarize the main drivers of the glacier detachments described here. We define a detachment's
746 *disposition* as the sum of long-term factors that might promote glacier detachments and refer to *triggers* to describe short-term
factors that might suddenly tip the scale toward a catastrophic failure. Fundamentally, it seems that different combinations of
748 dispositions and triggers are able to produce instability. Aside from the commonalities mentioned above, the observed
detachments all present some unique conditions, many of which remain shrouded in uncertainty. The observed failure
750 conditions (Tab. 2) include ruptures during surge-like glacier instabilities (Kolka 1902, Aru, Amney Machen, Sedongpu;
unclear for Devdorak), or increase of driving stress due to thickening caused by snow accumulation (Aru) or rock-ice
752 avalanches (Kolka 2002, Sedongpu?). Geothermal activity could have played a role at Tinguiririca and Kolka, but is unlikely
for the other events. The thermal setting of the detached glaciers can play a role if permafrost around the glaciers potentially
754 causes frozen margins or the glaciers exhibit a polythermal structure (Aru, Flat Creek, Tinguiririca?, Leñas?). However, other
detachments happened under conditions very likely free of cold ice. Some of the detached glaciers seem to have been composed
756 of a mixture of debris and ice (Amney Machen, Flat Creek; likely at least for Devdorak, Kolka, Sedongpu). Such mixtures can
be profoundly weaker than clean glacier ice, particularly at temperatures close to the melting point (Moore, 2014), but it is
758 unclear at this point whether and how these mixtures and their weakness may have contributed to the detachments. In contrast,
the ice of the Aru glaciers clearly consisted of rather clean ice. Failure circumstances are particularly unclear to us for Aparejo
760 and Leñas.

The angles of reach of the ice-rock avalanches associated with glacier detachments (Fahrböschung between about 5° and 10°),
762 both absolutely and relative to their volume, are lower or at the lower end of those observed for other types of ice-rock
avalanches (Fig. 1a, b). The particularly high ice content of glacier detachments might reduce friction of the mass movements
764 through liquefaction (Schneider et al., 2011), promoting the long runouts. Remarkably, many (all?) detached glaciers appear
to have sat on particularly fine-grained glacier beds. The large amounts of soft sediments under the glaciers, combined with
766 the presence of (unusually?) large amounts of basal water at the time of detachments, may have decreased the friction angle
by lubrication and allowed the detachments to accelerate particularly fast on a basal slurry. In addition, smooth u-shaped glacial
768 valleys might favour low angles of reach by channelizing the mass flows, reducing energy dissipation, and presenting few
topographic obstacles along the path (Schneider et al., 2011).

770 **4.2 Influence of climate change**

Inevitably, questions arise as to what extent climate change could be a driving factor of glacier detachments. Some cases investigated here suggest situations where repeated detachments could be part of a cycle from reservoir refilling up to occasional threshold exceedance, similar to what is found for glacier surges (Benn et al., 2019; Amney Machen, Tinguiririca, Devdorak, Kolka, Rasht?). But several cases of this study also illustrate developments where climate change can cause transient conditions that lead to failure. The twin Aru detachments, which detached within just two months of each other, strongly point to a common meteorological trigger as the only possible external driver able to synchronize the two events. A number of dispositions and triggers listed in Fig. 18 may be impacted by climatic changes and may bring a glacier closer to failure.

Repeated detachments of the same glacier, or detachments connected to surge-like behaviour, require that the climate conditions and associated glacier mass balances enable reservoir recovery or built-up of accumulation areas (Devdorak, Aru, Amney Machen, Kolka 1902). Climate change might shift glaciers out of the envelope of conditions that are favourable for surging, or shift them into it (Hock et al., 2019). Whereas glacier rebuilding seems to be underway at Kolka and Aru, it is open for Sedongpu, and unlikely for Tinguirica. The glacier's potential to regain a substantial size is critically linked to the potential for repeated detachment events, and thus important for hazard management.

The enhanced rock-ice avalanching onto Kolka Glacier in 2002, possibly responsible for its detachment, or the 2017 Gyala Peri rock avalanche over the Sedongpu Glacier, are likely a reflection of climate change impact on polythermal, glacierised rock walls, where the reduction of ice cover and permafrost thaw increases the rock and ice fall frequency (Fischer et al., 2013). Indeed, summers were exceptionally warm and glacier mass balances negative in the Caucasus Mountains, which host Kolka Glacier, over 1998–2001 (Zemp et al., 2019). Glacier shrinkage due to negative mass balance (Larsen et al., 2015; Treichler et al., 2019; Zemp et al., 2019) has exposed large parts of the – at earlier times mostly ice-covered – headwalls of Flat Creek, Amney Machen, Leñas, and likely Petra Pervogo/Rasht. This exposes bedrock to erosion making it available for mass flows and incorporation in and underneath the glaciers, a process that is particularly important for soft rock lithologies. The partial loss of glacier cover may also interrupt existing patterns of stress transfer and cause new temporary stress concentrations (see also Fig. 18) that may exceed stability thresholds in certain locations. Some glacier detachments could thus be connected to the transient development of headwall glacier loss.

Climate change increases the amount of meltwater and transitions from snowfall to rainfall, and may thus favour development of instabilities, at least for the polythermal glaciers (Aru and Flat Creek) where such amount of meltwater is unusual at the scale of the last century. The relative increase of meltwater can be particularly significant for cold/dry climate glaciers.

798 **4.3 Hazard management**

From a more applied hazard management perspective, sudden massive glacier detachments pose a high magnitude/low-frequency problem, and their low probability/high consequence nature makes them hard to incorporate in hazard management

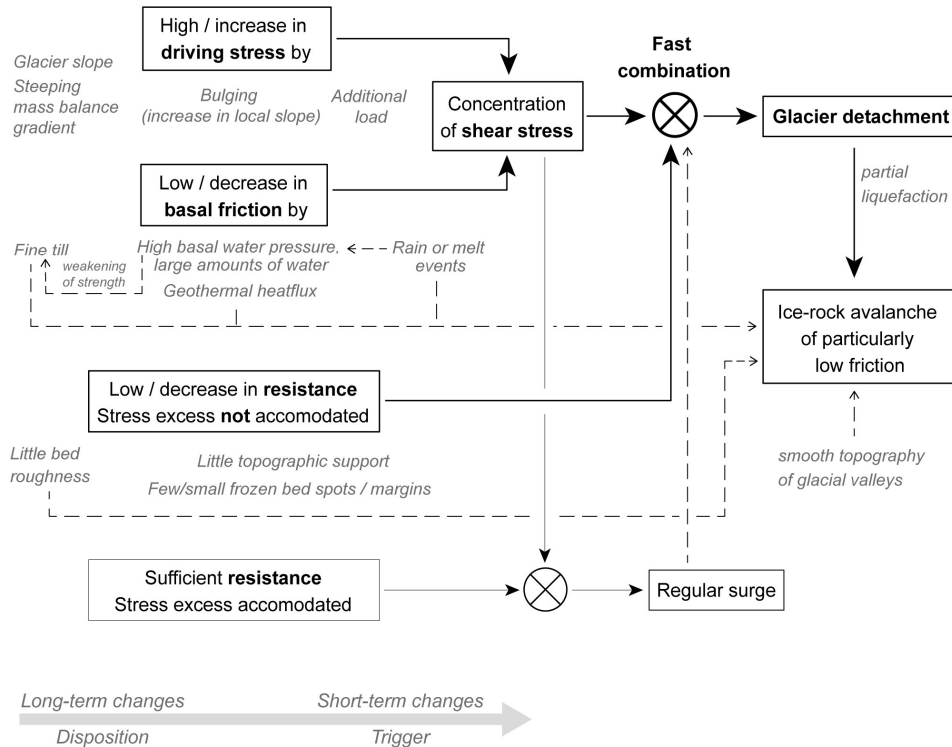

and planning. The particularly low friction coefficients (H/L) involved in the detachments enable them to travel over low slopes (where other types of ice-rock avalanches would stall) and to cover large distances. The detachment events seem very rare, but their large volumes, fast evolution, and the exceptionally long reaches and high speeds hold the potential for severe impacts even far away from the source. Our compilation of all (so far) known cases shows that low-angle glacier detachments might have, though rare, more frequently occurred than thought. The differences between the events suggest that there is no straightforward way to predict where they might occur, but the following list of the most common conditions might support a more systematic assessment. Events happened at places

- (i) with abundant weak bedrocks/fine sediments,
- (ii) where glacier surface slope is between about 10° and 20° ,
- (iii) where surge-like glacier instabilities are observed in the region, or for the detached glacier itself, and
- (iv) where similar events or other violent ice-rock mass flows have happened before (based on direct observation or a geomorphological imprint).

This set of very rough qualitative criteria might allow a first-order assessment of whether glacier detachments are possible in any given region. It is crucial to be aware of, however, that these criteria and their interplay are likely transient so that in particular criterion (iv) can be misleading. For several of the events we find streamlined debris features or striations in the avalanche paths, but highlight that more research is necessary to correctly interpret these signatures and differentiate them from glacial flutes, small moraines, and other longitudinal glacial and geomorphodynamic features. Particularly important for hazard management is – yet again – the conclusion that climate change is able to shift hazard zones beyond historical precedence, so that also so far unaffected areas might suddenly be susceptible (Hock et al., 2019).

Systematic monitoring turns out to be one of the most feasible responses to changes in hazard conditions, and the increasing temporal and spatial resolution, and improving availability of satellite imagery, is particularly helpful for glacier detachment assessment. For several of the cases in this contribution, abnormal glacier crevassing and accelerating precursory speeds were visible days to weeks before failure (Kolka 2002, Rasht, Aru, Sedongpu, Flat Creek?), but the significance of such a development was realized for the second Aru detachment only due to its spatial and temporal proximity to the first Aru detachment. On the other hand, abnormal crevassing does not necessarily indicate an impending detachment, see Rasht 2007 or Leinss et al. (2019), where the glacier geometry has likely stabilized a detaching ice mass. Overall, predicting glacier detachments can likely only be achieved by strong efforts in detailed remote-sensing based monitoring and, if feasible, by ground-based measurements, which contribute to an improved understanding of conditions and relevant processes, past events, glacier velocities and slope deformations, glacier bed geology and lithology, surge behaviour and dynamics, and short-term and long-term temperature and precipitation records (Kääb et al. 2018).

832

834 **Figure 18: Schematic on which conditions and changes to a low-angle mountain glacier can in combination lead to the**
 835 **spatio-temporal interference of particularly high and concentrated shear stresses and low resistance, eventually**
 836 **exceeding stability thresholds and causing detachment. The failure conditions can change at a range of time scales, so**
 837 **that detachment is the result of a highly transient and rare interplay of factors. It is key that the low basal friction and**
 838 **high driving stresses, the resulting concentration of high shear stresses, and the lack of sufficient resistance develop**
 839 **fastly, or are combined fastly, preventing the glacier to adjust to changing forces in a steady way. Several of the factors**
 840 **potentially involved in the detachment are subsequently also able to strongly reduce basal friction of the resulting ice-**
 841 **rock avalanche and lead thus to particularly low angles of reach. Boxes in the figure indicate main physical conditions,**
 842 **grey italic text indicates different actual processes that can fulfil these conditions, sorted from long-term (left) to short-**
term (right) variability.

5 Conclusions

844 In this contribution we describe around a dozen ice-rock avalanche events that we characterize as sudden large-volume
 845 detachments of low-angle glaciers. Overall, these events seem to be more frequent than previously thought. The detached
 846 volumes ranged from a few up to more than $100 \cdot 10^6 \text{ m}^3$. We described one new event in the same size-class as the 2002 Kolka

848 and the 2016 Aru glacier detachments (Sedongpu 2018) and as a side-result quantified one of the larger high-mountain rock
849 avalanches of recent decades (Gyala Peri 2017).

850 Despite the relatively low number of low-angle glacier detachments and their site-specific variations that leave considerable
851 uncertainties, we were able to identify a set of conditions and evolutions likely involved in these glacier failures. We consider
852 this an important step, given that a few years ago the possibility for low-angle mountain glaciers to detach and produce massive
853 ice-rock avalanches was hardly known. Interestingly, the fact that the spatio-temporal factor combinations leading to
854 exceptionally low basal friction and very high shear stresses, and eventually to detachment, are different among the cases,
855 suggests that there exists an exceptional but still fundamental possibility of low-angle glacier beds to fail catastrophically.
856 Awareness of this fundamental potential for catastrophic basal instability expands our understanding of glacier flow.

857 Many of the glacier detachments show some relation to surge-type glacier movement, and could be seen as a rare and extreme
858 endmember of this much more common glacier instability. Glacier detachments combine elements of surging, where the glacier
859 adjusts its geometry to satisfy the force balance, with those of ice break-offs from steeper glaciers, where the glacier is not
860 able to adjust in a steady way. The surface slopes of 9–21° of the detached glacier parts, though quite low for glaciers that
861 produce ice avalanches, rank rather high in comparison with surge-type glacier tongues. Slopes in this range exert higher shear
862 stresses than is typical for surge-type glaciers and favour thus the possibility of exceeding a critical stress level that then leads
863 to sudden failure. At the same time, in comparison to glaciers in very steep terrain that tend to be thin, glaciers of 10–20°
864 surface slope can build up thicker ice, which leads to the larger volumes typically involved in detachments.

865 Weak bedrock and/or the existence of soft and highly erodible sediments under the detached glaciers was identified for most
866 of the observed glacier detachments, plausible for the ones we determined retroactively, and hints at till-strength weakening
867 under high pore water pressure as a concrete failure process. There appear to be different trajectories into, or out of, the narrow
868 envelope of potential failure conditions, not least driven by climatic changes. The fact that most collapses happened during
869 local spring/summer suggests that a meltwater or high-altitude rain driven increase of basal pore water pressure can play an
870 important role in triggering the events, whether directly or in some delayed form. Atmospheric warming enhances such hazard
871 conditions. For some detachment sites, negative regional glacier mass balances can prevent detached glaciers from fully
872 rebuilding and thus from detachments to repeat over time, at least at earlier volumes.

873 Detailed investigations of the events described in this study showed that a wide variety of dispositions and triggers can lead to
874 a glacier detachment. This makes it challenging for practitioners working in high-mountain hazard management to anticipate
875 and predict such events. From this practical standpoint, however, this study attempts to raise awareness about the – albeit low
876 – possibility of sudden, large-volume detachments of low-angle glaciers at locations with

- 876 • particularly soft and erodible lithologies, and, likely related, the
- existence of surge-type glaciers and surge-like glacier evolution.

- 878 • Repeated events or geomorphological imprints of potential earlier collapses or other violent ice-rock mass flows can
880 be further investigated, but events can also happen without historical precedence through shifts in the array of failure
882 conditions.
- Several of the glaciers investigated here showed abnormal crevassing and enhanced precursory surface speeds in the
882 days to weeks before detachment.
 - The surface slopes found in this study for the detached glaciers ranged between roughly 10° and 20°.

884 Due to the large amounts of snow and ice involved in glacier detachments, the high chance of lubrication and of liquefaction
886 of glacier ice and subglacial sediments, and smooth geometries of glacial valleys, avalanche friction is typically greatly
888 reduced. This results in the particularly high mobility of the ice-rock avalanches resulting from low-angle glacier detachments
890 and can lead to substantial damage far from the source. Between the large runout distances and the varying factors that can
890 impact a glacier's detachment probability, high-mountain hazard management will, after the first general assessment provided
890 in this study, benefit from more detailed investigations of glacier detachments, the conditions that lead to them and the
890 mechanics that drive them.

892
