14 **Abstract.** Laboratory experiments are presented on the phase change at the surface of sodium
15 chloride – water mixtures at temperatures between 259 K and 240-241 K. Chloride is a ubiquitous
16 component of polar coastal surface snow. The chloride embedded in snow is involved in reactions
17 that modify the chemical composition of snow as well as ultimately impact the budget of trace
18 gases and the oxidative capacity of the overlying atmosphere. Multiphase reactions at the snow –
19 air interface have found particular interest in atmospheric science. Undoubtedly, chemical
20 reactions proceed faster in liquids than in solids; but it is currently unclear when such phase
21 changes occur at the interface of snow with air. In the experiments reported here, a high selectivity
22 to the upper few nanometres of the frozen solution – air interface is achieved by using electron
23 yield near-edge X-ray absorption fine structure (NEXAFS) spectroscopy. We find that sodium
24 chloride at the interface of frozen solutions, which mimic sea-salt deposits in snow, remain as
25 supercooled liquid down to 240-241 K. ~~Below At~~ this temperature, hydrohalite exclusively
26 precipitates, anhydrous sodium chloride is not detected. In this work, we present the first NEXAFS

27 spectrum of hydrohalite. The hydrohalite is found to be stable while increasing the temperature
28 towards the eutectic temperature of ~~253-252~~ K. Taken together, this study reveals no differences in
29 the phase changes of sodium chloride at the interface as compared to the bulk. That sodium
30 chloride remains liquid at the interface upon cooling down to ~~240-241~~ K, which spans the most
31 common temperature range in Polar marine environments, has consequences for interfacial
32 chemistry involving chlorine as well as for any other reactant for which the sodium chloride
33 provides a liquid reservoir at the interface of environmental snow. Implications for the role of
34 surface snow on atmospheric chemistry are discussed.

35

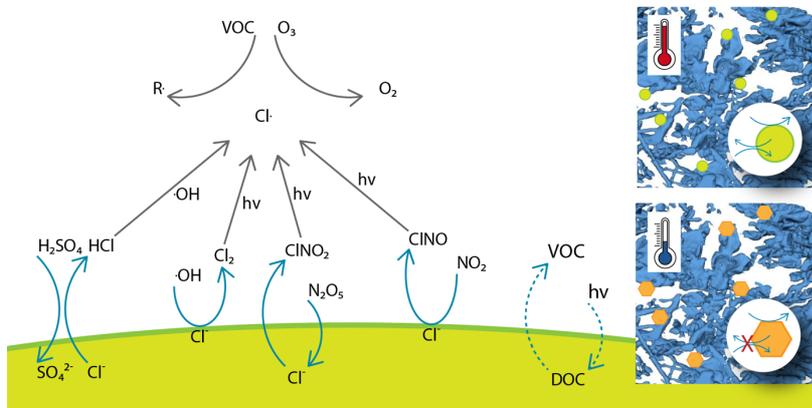

36

37 Abstract Teaser

38 1 Introduction

39 Chemical cycling of halogens affects the composition of the troposphere and via this effect
40 influences climate and impacts human health (Simpson et al., 2007; Abbatt et al., 2012; Saiz-
41 Lopez and von Glasow, 2012; Simpson et al., 2015). Taken the abundance of chloride in the form
42 of sea-salt over wide areas of the globe, the atmospheric chemistry of chlorine has long raised
43 interest in ~~a number of several~~ multiphase reactions that liberate chloride into chlorine species in
44 the gas phase (Simpson et al., 2007; Finlayson-Pitts, 2010). Chlorine has a direct role as a sink for
45 ozone. Further, reactive chlorine species act as a powerful oxidant on atmospheric cycles that
46 destroy or produce ozone and are relevant for the atmospheric oxidation capacity (Finlayson-Pitts,
47 2003; Thornton et al., 2010). Atmospheric ozone is of concern because it directly impacts

48 atmospheric composition, health, and climate (Simpson et al., 2007). Prominent examples of these
 49 reactions in the atmosphere with chloride in sea-salt or salt-dust are shown in Fig. 1 and discussed
 50 in the following. Acid displacements, where the nitric or sulfuric acid are taken up into the aqueous
 51 phase, lead to the emission of hydrochloric acid to the gas phase. Further examples are reactions
 52 with OH radicals (Knipping et al., 2000; Halfacre et al., 2019), and with nitrogen oxides (Osthoff
 53 et al., 2008). Common to all of these reactions is the generation of chlorine gases that either react
 54 with OH radicals or photolyze at wavelengths available in the troposphere to generate reactive
 55 chlorine (Fig. 1 and Finlayson-Pitts (2010)). Given their importance, these multiphase reactions
 56 have intensively been investigated in laboratory studies over the last decade (Abbatt et al., 2012;
 57 Saiz-Lopez and von Glasow, 2012; Simpson et al., 2015). One outcome of these investigations is
 58 the importance of reactions at the liquid – air interface as compared to those proceeding in the
 59 bulk. An example is the oxidation of chloride by OH radicals. In contrast to the aqueous phase
 60 reactions, it does not require the presence of acid to proceed fast at the air–water interface (Laskin
 61 et al., 2006).

62
 63 Figure 1: Simplified scheme of multiphase reactions liberating chlorine from sea-salt deposits to
 64 the atmosphere and subsequent reactions of chlorine with impacts on the ozone budget and air
 65 quality. These reactions may occur both in the bulk phase and at the air-deposit interface for liquid

66 particles. The sea-salt may also maintain a liquid phase for the reaction of other reactants such as
67 the photolysis of organics. The inserts illustrate sea-salt deposits in snow and how phase changes
68 from solid (orange pentagon) to aqueous solutions (green circle) impact the chemical reactivity.
69 See text for details [and references.](#)-

70
71 The relevance of halogen multiphase chemistry for the atmosphere is not limited to chlorine. A
72 more recent example is the oxidation of bromide. Bromide is present in sea-salt, is a key reactant in
73 ozone depletions in polar atmospheres (Simpson et al., 2015), and participates in atmospheric
74 chlorine chemistry by forming interhalogen compounds (Finlayson-Pitts, 2003). Oldridge and
75 Abbatt (2011) have shown that a Langmuir-Hinshelwood type surface reaction of ozone with
76 bromide occurs at the liquid – air interface simultaneously with a corresponding bulk reaction in
77 the temperature range of 263 K to 248 K. A surface-active reaction intermediate was found to
78 explain the high interfacial reactivity for the case of the reaction with ozone (Artiglia et al., 2017),
79 while other bromine species may directly exhibit surface propensity on their own (Gladich et al.,
80 2020). Clearly, this line of research shows how reaction kinetics and mechanisms differ at the
81 interface from those in the bulk and that heterogeneous chemistry is a key driver in atmospheric
82 chemistry.

83
84 In the cryosphere, where the snowpack is strongly impacting the chemistry in the overlaying
85 atmosphere (Dominé and Shepson, 2002; Thomas et al., 2019), halogen compounds are also found
86 within the snow. Sea-salt components, a source of halogens in snow in coastal snowpack, might
87 originate from migration from underlying sea-ice or from deposition of wind-transported sea-spray
88 aerosol (Dominé et al., 2004). One characteristic of the cryosphere are its subfreezing
89 temperatures and the consequent precipitation of chemical constituents at specific temperatures,
90 their eutectic temperature, as also observed in sea-ice (Petrich and Eicken, 2009). It is known that
91 the precipitations or phase changes of the reactants critically impact the reactivity (Bartels-Rausch
92 et al., 2014; Kahan et al., 2014). [Reduced chlorine production in frozen systems was observed by](#)
93 [Wren et al. \(2013\) and by Sjostedt and Abbatt \(2008\), at temperatures below the eutectic](#)

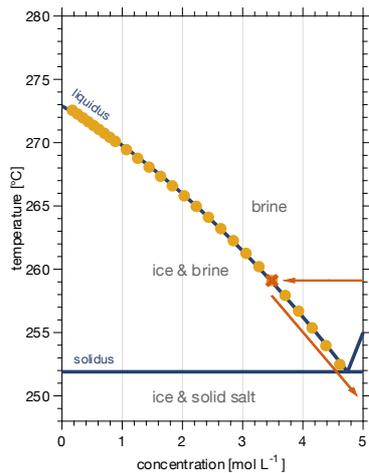

94 temperature of sodium chloride – water mixtures in laboratory experiments that was attributed to
95 the precipitation of the salt. -In an arctic field study. Custard et al. (2017) observed reduced Cl₂
96 production when temperatures dropped and suggested limited availability of chloride as
97 consequence of the precipitation in this surface snow. Further, Lopez-Hilfiker and Thornton (2012)
98 proposed the precipitation of sodium chloride salts to explain the changes in the production yield
99 of ClNO₂ from the reaction of N₂O₅ with saline frozen systems with temperature.

100
101 Importantly, More generally, it is not only the chlorine chemistry that responds to the phase of
102 sodium chloride present in frozen systems both in the laboratory and in the environment. Oldridge
103 and Abbatt (2011) showed that the rate of the heterogeneous reaction of ozone with bromide in
104 sodium chloride -- water mixtures is strongly reduced once ~~sodium chloride~~ the chloride salt
105 precipitates below 252 K. The author explained this with the reduction in liquid volume that serves
106 as reaction medium for the bromide in the sample due to the precipitation of sodium chloride.
107 Similar, the photolytical reaction of nitroanisol with pyridine was found to depend on the amount
108 of liquid in frozen samples and thus to critically respond to precipitation of sodium chloride
109 (Grannas et al., 2007). Next to its role in atmospheric halogen chemistry, sodium chloride is thus
110 further of importance as salt to establish and maintain liquid solutions at subfreezing temperature.
111 Its importance arises from its atmospheric abundance but also because its eutectic temperature of
112 252 K falls into typical springtime Arctic temperatures – a region and time period when
113 atmospheric halogen chemistry is most active. For example, at the Arctic coast near Utqiagvik
114 (Alaska) temperatures have been reported to fluctuate between 247 K and 259 K within days
115 (Custard et al., 2017). Another region of Earth's cryosphere, where temperatures drop below 252 K
116 is the troposphere (Thomas et al., 2019). Wang et al. (2015) have proposed a significant role of
117 tropospheric heterogeneous halogen chemistry on the ozone budget there. More recently, Murphy
118 et al. (2019) have shown that the amount of sea-salt aerosol lifted to the upper troposphere is small,
119 casting some doubt on the environmental relevance of sea-salt as matrix for multiphase chemistry
120 there.

121

122 While the phase diagram of sodium chloride – water binary mixtures and the thermodynamic
123 stability domains of salt, solution, and ice are well known (Koop et al., 2000a), the precise
124 occurrence of nucleation and sodium chloride precipitation is still debated (Koop et al., 2000a;
125 Wise et al., 2012; Peckhaus et al., 2016). Figure 2 shows a part of ~~the~~ phase diagram of sodium
126 chloride – water mixtures and can be used to illustrate the appearance of the individual phases.
127 Below 251.9 K, the eutectic temperature of sodium chloride (Koop et al., 2000a), ~~anhydrous~~ solid
128 sodium chloride ~~dihydrate (hydrohalite, NaCl•2H₂O) (NaCl, halite)~~ and solid water (ice) are the
129 energetically favoured phases. ~~Increasing the temperature of such a hypothetical sample to above~~
130 ~~251.9 K, the sodium chloride will change its phase from solid halite to an aqueous sodium chloride~~
131 ~~solution. Ice remains the second phase at temperatures between 251.9 K and 273.2 K. Above~~
132 ~~273.2 K, the ice will melt completely and an aqueous sodium chloride solution will be the only~~
133 ~~phase present. A characteristic of these systems is that B~~ between the eutectic temperature and ~~the~~
134 ~~melting point of ice, the system moves along the so-called ice stability~~ liquidus line, ice and
135 sodium chloride solution (brine) co-exist. The ice will melt completely above the liquidus line, and
136 an aqueous sodium chloride solution is the only phase present. The focus of this work was to
137 experimentally observe phase changes of sodium chloride below the eutectic temperature. A
138 typical experimental procedure started with a dry sample of anhydrous sodium chloride (halite,
139 NaCl) which was exposed to increasing gas-phase water at constant temperature of 259 K. More
140 general, by ~~By~~ absorbing and evaporating water from the surrounding air, ~~composition and volume~~
141 ~~of the brine will change. Such changes with varying relative humidity (hygroscopic growth) have~~
142 ~~long been discussed for aerosol in the troposphere. The changes include, a~~ phase transitions from
143 the solid salt to ~~the a~~ liquid solution (deliquescence) took place. Upon increasing the gas-phase
144 water dosing further (Fig. 2, red arrow) ice crystallised and a two-phase system of ice and brine
145 occurred (Fig. 2, red cross). After probing the sample at this position in the phase diagram (see
146 below), temperature was lowered and the dosing of the water-vapor adopted to move along the
147 liquidus line to below the eutectic temperature, and from the liquid to the solid (efflorescence) in
148 aerosol particles at specific temperature and water partial pressure conditions. ~~During this cooling~~
149 ~~period, salt composition concentration and volume of the brine will changes. Such changes with~~

150 varying relative humidity (hygroscopic growth) have long been discussed for aerosol in the
151 troposphere. The changes includeIn other words, the concentration of the sodium chloride in
152 solution changes with temperature to maintain both phases in equilibrium. At the air-ice interface
153 where both phases are in equilibrium with water vapour in the gas phase, this can be understood by
154 considering that the aqueous sodium chloride solution and ice need to have the same vapour
155 pressure. Otherwise, the phase with the higher water vapour pressure would vanish by evaporation
156 and the one with the lower vapour pressure would grow by condensation. The vapour pressure of
157 ice decreases with decreasing temperature while that of an aqueous solution decreases with
158 increasing concentration of solute. With a fixed amount of sodium chloride present in our
159 experiments and also in individual sodium chloride deposits in snow, consequently the amount of
160 liquid is given by temperature (Koop et al., 2000a). ~~More general, by absorbing and evaporating~~
161 ~~water from the surrounding air, composition and volume of the brine will change. Such changes~~
162 ~~with varying relative humidity (hygroscopic growth) have long been discussed for aerosol in the~~
163 ~~troposphere. The changes include phase transitions from the solid to the liquid solution~~
164 ~~(deliquescence) and from the liquid to the solid (efflorescence) in aerosol particles at specific~~
165 ~~temperature and water partial pressure conditions.~~ Because relative humidity is such a strong driver
166 of the hygroscopic growth, we base the discussion of phase changes in this work on the relative
167 humidity the sample was exposed to. The relative humidity is a measure of the partial pressure of
168 water relative to the vapour pressure of (supercooled) liquid at the same temperature {Marti,
169 1993}. ~~An advantage of this experimental approach with environmental relevance is that the~~
170 ~~relative humidity precisely matches that in the atmosphere in contact and in thermodynamic~~
171 ~~equilibrium with ice clouds or snow cover, because the relative humidity is a sole function of~~
172 ~~temperature in the presence of ice. Therefore, the chemical concentration of such particles exactly~~
173 ~~matches those of same composition in snow or in the atmosphere under environmental conditions.~~

174
 175 Figure 2: Phase diagram of the NaCl-water binary system. The data show the freezing point
 176 depression of sodium-chloride solutions (yellow filled circles) and give the concentration of an
 177 aqueous sodium chloride solution in equilibrium with ~~water-ice~~ in the temperature range of 273 K
 178 to 254 K (Rumble, 2019). The dark blue lines indicate the phase boundaries (Koop et al., 2000b;
 179 Rumble, 2019), that is it denotes the so-called liquidus and solidus line, respectively, and thus
 180 shows the temperature and concentration range where ice and aqueous sodium chloride solution
 181 co-exist. The eutectic temperature of sodium chloride – water binaries is 251.9 K (Koop et al.,
 182 2000a). Also shown is a typical experimental procedure (red arrows and cross).

183
 184 Koop et al. (2000a) were the first to show that because precipitation of sodium chloride can be
 185 kinetically hindered, ~~i.e. precipitation may not occur even though temperature has dropped below~~
 186 ~~the eutectic temperature where the solid is the thermodynamically favoured phase,~~ supercooled
 187 sodium chloride solutions in the presence of ice can prevail down to 240 K. Precipitation of
 188 sodium chloride may not occur even though temperature has dropped below the eutectic

189 [temperature where the solid is the thermodynamically favoured phase](#). Cho et al. (2002) have
190 observed a liquid fraction in sodium chloride – water mixtures at even lower temperatures of
191 between 228 K and 273 K based on the evaluation of ¹H-NMR signals. Cho et al. (2002) proposed
192 the presence of liquid below the eutectic temperature to be an interfacial phenomenon, stabilized
193 by surface forces in analogy to the disordered interface observed for neat ice surfaces when
194 approaching the melting point (Bartels-Rausch et al., 2014).

195
196 The goal of this study is to investigate the precipitation and the occurrence of liquid features in
197 sodium chloride – water binary mixtures in the interfacial region. Both Cho et al. (2002) and Koop
198 et al. (2000a) have applied methods that are not specifically sensitive to the interface, but are
199 probing the bulk. Near Edge X-ray Absorption Fine Structure (NEXAFS) spectroscopy is
200 inherently sensitive to the upper few nanometre of interfaces when detecting electrons as done in
201 this work. Oxygen K-edge NEXAFS spectra of H₂O are an established tool to investigate the
202 hydrogen bonding structure of water and ice with its clear differences for solid and liquid water
203 (Bluhm et al., 2002; Nilsson et al., 2010; Krepelova et al., 2013; Newberg and Bluhm, 2015;
204 Orlando et al., 2016; Bartels-Rausch et al., 2017; Ammann et al., 2018; Waldner et al., 2018). In
205 our earlier NEXAFS study (Krepelova et al., 2010a), it was shown by probing the X-ray absorption
206 of oxygen atoms in sodium chloride – water binary mixtures that the hydrogen bonding network
207 did not reveal the presence of any liquid features at the interface below the eutectic temperature.
208 Interpretation of these oxygen NEXAFS spectra was complicated by the appearance of crystal
209 water in the hydrohalite and by the presence of adsorbed H₂O. Also, the oxygen spectra might be
210 dominated by ice that is present in equilibrium with the sodium chloride solution and thus small
211 fractions of liquid might have been difficult to detect. In this work, we therefore discuss Cl K-edge
212 NEXAFS that have previously been used to inspect the chemical speciation of chlorine in glasses
213 and in coal (Huggins and Huffman, 1995; Evans et al., 2008). Interest in the local environment of
214 chloride at the interface in sodium chloride – water binary mixtures [eomescome](#) also from earlier
215 work on nitric and hydrochloric acid adsorbed at the ice-air interface. We have shown that nitrate
216 and chloride forms solvation shells with a hydrogen-bonding structure similar to that in aqueous

217 solution in the interfacial region of ice at concentrations low enough to prevent melting (Krepelova
218 et al., 2010b; Kong et al., 2017). The aim of this study is thus also to investigate the occurrence of
219 solvated chloride at the interface of sodium chloride – water mixtures at temperatures close to the
220 eutectic. Motivation comes from the role of heterogeneous chemistry in atmospheric science in
221 general and in particular on the impact that the microchemical environment has on the reactivity.
222

223 1 Experimental Part

224 Experiments were performed at the PHOENIX beam line of the Swiss Light Source (SLS) at the
225 Paul Scherrer Institute using the Near Ambient Pressure Photoemission (NAPP) set-up previously
226 described (Orlando et al., 2016). NAPP is equipped with a differentially-pumped electron analyser
227 (Scienta R4000 HiPP-2). The central feature of NAPP is a flow-through cell with a sample holder
228 the temperature of which is computer-controlled by a flow of cooled helium gas. The
229 measurements were performed with partial pressures of water between 0.3 mbar and 1.8 mbar in
230 the flow-through cell and temperatures of the sample between 259 K and ~~240~~241 K.

231 1.1 Sample Preparation and Water Dosing

232 To prepare a sample, 1 μl of a 2.12 g sodium chloride (Fluka Trace Select 38979-25G-F) solution
233 in 80 ml of water (Fluka Trace Select 142100-12-F) was dropped at the centre of the sample holder
234 and dried at 60 °C. The sample holder was then moved into the flow-through cell and kept at UHV
235 and at 60 °C to 80 °C for 45 minutes to remove volatile impurities. Water vapour was dosed to the
236 flow-through cell via a 0.8 mm i.d. steel capillary from the vapour above liquid water (Fluka Trace
237 Select 142100-12-F) in a vacuum-sealed, temperature-controlled glass reservoir. Before dosing, the
238 water was degassed by 4 freeze-pump-thaw cycles. ~~The relative humidity~~water dosing and thus the
239 partial pressure or relative humidity that the sample was exposed to ~~-was increased~~varied by
240 increasing~~setting the temperature of the reservoir to change~~ -the flux of water vapour into the
241 experimental cell. Pressure in the flow-through cell was monitored by a capacitance manometer
242 (Baratron 626A) with a measurement range from 5×10^{-4} mbar ~~-~~ to 10 mbar and an accuracy of

243 0.25 % of the reading. Temperature was monitored with a Pt-1000 sensor located at the edge of the
244 sample holder. The sensor was calibrated prior to the experiments by growing ice on the sample
245 holder and noting its vapour pressure which is a direct measure of the temperature at the sample
246 spot (Marti and Mauersberger, 1993). During the experiments, the calibration was confirmed when
247 ice was present. At 253 K, the offset between temperature reading and calibration was found to be
248 4.3 ± 0.2 K.

249 1.1 X-ray excited Electron Spectroscopy

250 Partial Auger-Meitner electron-yield NEXAFS spectra at the Cl K-edge were acquired with a fixed
251 kinetic energy window of 2370 eV to 2390 eV, which includes the KL_{2,3}L_{2,3} Auger-Meitner peak
252 of chlorine. The pass energy and dwell time were set to 200 eV and 300 ms, respectively. The
253 distance of the sample to the electron analyser inlet (working distance) was 1 mm, and the
254 electron analyser was operated with an electron sampling aperture with a diameter of 500 μm,
255 which results in sampling roughly an area on the icy sample with a diameter of 500 μm from which
256 the emitted electrons reach the detector. NEXAFS spectra were measured by sweeping the
257 incident X-ray photon energy across the chlorine K-edge from 2815 eV to 2845 eV with steps
258 ranging from 0.2 eV to 1 eV. The NEXAFS spectra were processed by dividing by the photon flux
259 (I_0) as derived *in-situ* using a Ni coated membrane, by subtracting the mean pre-edge intensity as
260 background, and by normalising to the mean intensity at 2830 eV to 2833 eV X-ray photon energy.
261 Photoemission spectra (XPS) of O1s, Cl2p, Na1s, C1s, and Au4f were recorded at an incident X-
262 ray photon energy of 2200 eV and a pass energy of 100 eV and a dwell time of 120 ms. To
263 quantify, a linear background was applied, and the photoemission signal was integrated in
264 Matlab without any peak fitting.

265 **1 Results and Discussion**

266 **NEXAFS of brine, halite, and hydrohalite**

267 Figure 3 shows chlorine K-edge X-ray absorption spectra of [NaCl-sodium chloride salts](#) and of
268 frozen NaCl-water binary mixtures in the presence of ice. [This](#) NEXAFS spectroscopy probes the
269 X-ray absorption by chlorine atoms, corresponding to the resonant excitation of core electrons into
270 unoccupied molecular orbitals. As exactly those outer orbitals are forming chemical bonds,
271 NEXAFS spectra directly reflect changes to the local chemical environment and structural
272 arrangement. NEXAFS spectroscopy of halogen salts has thus been used to discuss their phase and
273 chemical speciation in geological examples (Huggins and Huffman, 1995; Evans et al., 2008). In
274 this work, the X-ray absorption spectra were derived by recording the intensity of Auger-Meitner
275 electrons at 2370-2390 eV, which corresponds to the KL_{2,3}L_{2,3} transition in chlorine (Cleff and
276 Mehlhorn, 1969). Detecting electrons, as done in this work, makes X-ray absorption inherently
277 surface sensitive, because electrons have a limited escape depth in matter (Ammann et al., 2018).
278 The escape depth can be quantified by relating it to the inelastic mean free path (IMFP) of
279 electrons in matter and to the take-off angle of detected [electrons](#) relative to the surface normal.
280 The IMFP of electrons with a kinetic energy of 2380 eV is about 7 nm in NaCl and in ice (Tanuma
281 et al., 1991). The take-off angle of electron detection is 30° in our set-up (Orlando et al., 2016),
282 which gives an escape depth of 6 nm, meaning that cumulatively, 95% of the electrons detected
283 originate from 18 nm, with an exponentially decreasing contribution from the surface towards the
284 bulk. In the following, we report the NEXAFS spectra derived from this interfacial region of NaCl-
285 water binary mixtures to discuss changes in the solvation of chloride by water as we explore the
286 regions of the phase diagram where precipitation of sodium chloride has been described for bulk
287 samples.

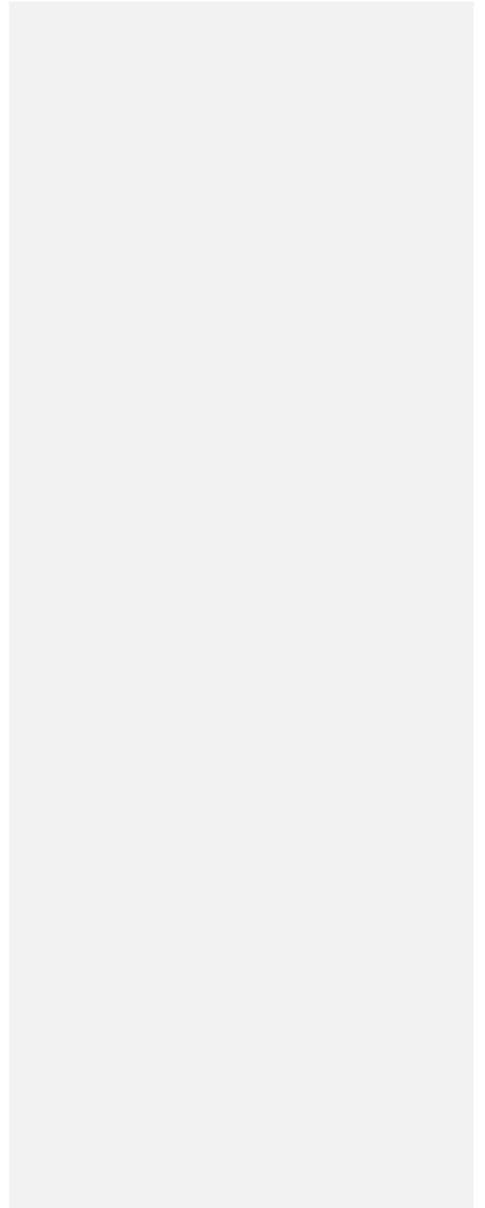

288
289 All chlorine K-edge spectra show a strong absorption peak at 2825-2830 eV (region I), the
290 absorption edge, corresponding to the transition of electrons from the 1s to the empty 4p orbitals.
291 Halite salt, in Fig. 3 A, shows a strong absorption in region I, and a characteristic feature at

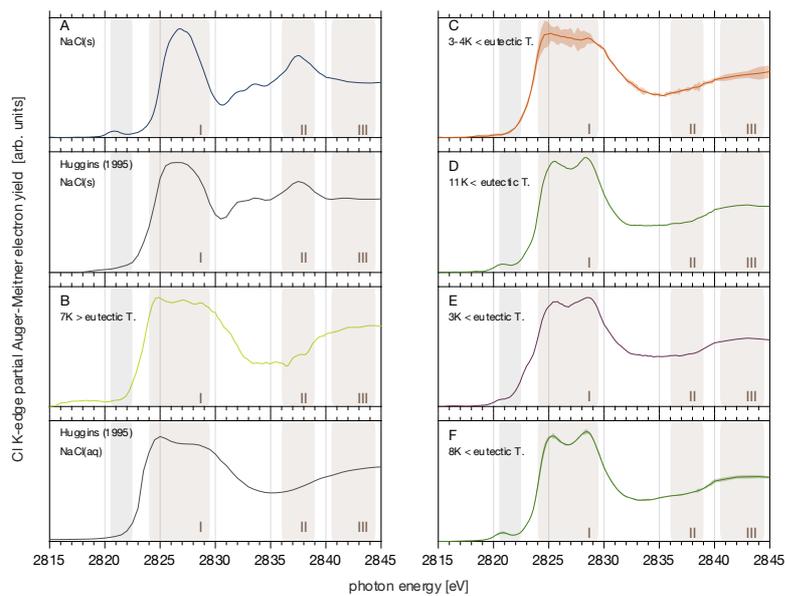

292 2838 eV (region II) (Huggins and Huffman, 1995; Evans et al., 2008). The difference in the
293 relative intensity of region I as compared to the intensity at photon energies > 2830 eV between
294 Fig. 3A and Huggins and Huffmann (1995) comes from the latter using fluorescence as detection
295 mode. Detecting X-ray absorption with fluorescence probes deeper into the bulk of the samples
296 and therefore often suffers from self-absorption which leads to less signal intensities at the
297 absorption edge (region I).

298

299 The small feature at 2821 eV can be assigned to C-Cl bonds that may form in-situ due to reactions
300 involving secondary electrons and organic impurities (Fujimori et al., 2010). The sample
301 composition in the interfacial region was further investigated by X-ray photoemission
302 spectroscopy. The C1s and Cl2p spectra support the presence of C-Cl compounds in the samples
303 (Appendix A): A small feature in the Cl2p spectra at 3 eV higher binding energy than the main
304 chlorine signal might be attributed to organic carbon species. The C1s photoemission spectra show
305 a feature at 1.5 eV higher binding energy than the main feature, typical for C-Cl compounds. The
306 main feature of the C1s photoemission spectra is attributed to C-H bonds, the dominant component
307 of adventitious carbon that forms in a cascade of reactions with secondary electrons during the
308 experiments. A further source of carbon might be omnipresent traces of carbon in the NaCl and
309 introduced when preparing the NaCl samples. The atomic ratio of the total carbon to oxygen from
310 water present at the interface was below 0.25, except for samples in Fig. 3A and F where total
311 carbon to oxygen atomic ratios were 0.5-0.75. Adsorbed water molecules were present at the
312 interface of all samples, and ice or liquid water formed in some samples, as gaseous water was
313 present in all experiments with pressures between 0.3 mbar to 1.8 mbar. The atomic ratio was
314 derived based on the measured C1s/O1s photoemission intensities and a calibration to account for
315 the analyser efficiency and total X-ray photoionization cross section using C1s/O1s photoemission
316 intensities of 0.8 mbar CO₂ gas following a procedure used before (Krepelova et al., 2013). Direct
317 comparison between the individual samples and estimation of surface coverages of the carbon
318 impurities is hampered by the varying water content at the sample's interface as adsorption and
319 water uptake varies with the individual relative humidity settings.

320

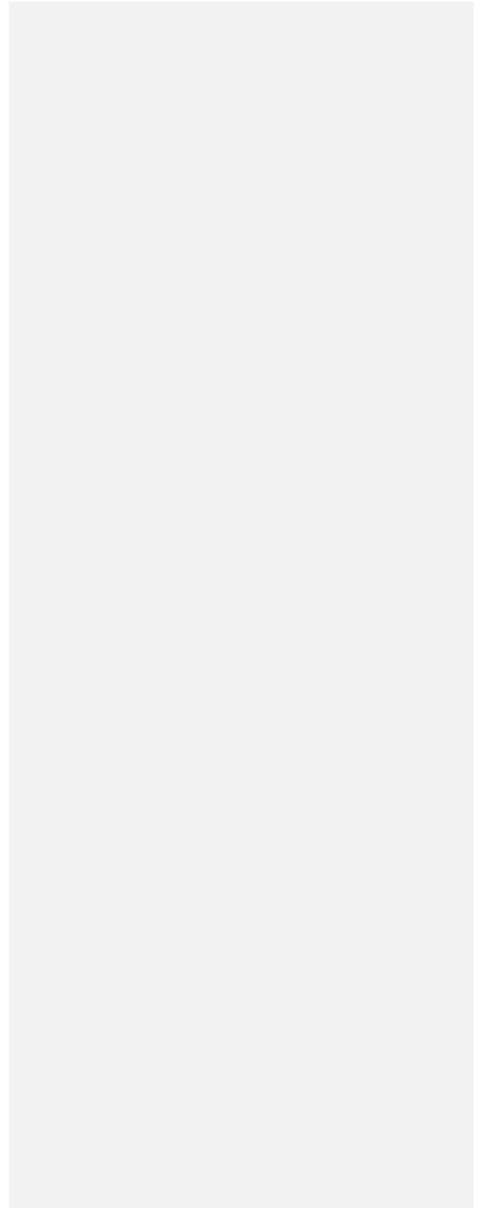

322

323 **Figure 3:** Partial electron yield chlorine K-edge NEXAFS spectra of the sodium chloride -- water binary system: A Solid NaCl at
 324 248 K and 44 % relative humidity (0.34 mbar water vapour pressure). B Aqueous NaCl solution in equilibrium with ice at 88 % RH
 325 (1.82 mbar) and 259 K. C An averaged spectrum at the thermodynamic ice stability line at 248 K to 249 K and 78 % (0.60 mbar) to
 326 80 % RH (0.71 mbar). D An individual spectrum upon further cooling to 241 K and 74 % RH (0.29 mbar). E An individual spectrum
 327 upon heating back to 249 K in the ice stability domain at 79 % RH (0.69 mbar). F The averaged spectrum at 244 K and a relative
 328 humidities RH of 59 % (0.32 mbar) and 73 % (0.40 mbar), lower than the ice stability domain. See Fig. 4 for precise measurement
 329 settings. The shaded area in the colour of the graph in C and F denote the standard deviation of 3 and 2 repeated NEXAFS acquisitions.
 330 Also shown are NEXAFS spectra of NaCl salt and aqueous solutions for comparison that were detected in fluorescence mode and not
 331 in partial electron yield (Huggins and Huffman, 1995). The brownish shaded area (I-III) highlights regions in the NEXAFS spectra
 332 discussed in the text. The grey shaded area at 2821 eV highlights the photon energy region where carbon-chlorine bonds from
 333 carbon contamination might show an absorption feature (see text for details).

334

335

336 The spectrum of sodium chloride in aqueous solution, Fig. 3B, shows a broader absorption peak in
337 region I compared to the spectra of the halite and a second feature at 2840 eV (region III) (Huggins
338 and Huffman, 1995). In this work, the NEXAFS spectrum of NaCl in aqueous solution was
339 recorded in a solution-ice binary mixture based on the phase diagram (see Efflorescence at the
340 Interface). Based on freezing point depression data, the concentration of sodium chloride in such
341 an aqueous solution in equilibrium with ice is 3.5 mol l⁻¹ (Rumble, 2019). The spectrum in Fig. 3B
342 generally agrees with the X-ray absorption spectra reported for 0.1 mol l⁻¹ and 1 mol l⁻¹ aqueous
343 solutions (Fig. 3 Huggins and Huffman (1995)) as it captures the general decrease in intensity in
344 region I with excitation energy and the increase in absorption in region III (Fig. 3). Discussing
345 differences in the hydration structure of chloride at the water—air interface as compared to the
346 bulk solution is beyond the scope of this work. Harada et al. (2011) has reported differences in the
347 hydration structure of Br⁻ at the aqueous surface compared to in bulk. Due to the low spectrum
348 quality, evident by the wiggles in region I, we refrain from discussing the two distinct features in
349 region I, at 2824 eV and 2829 eV, that have been observed in previous work on NEXAFS spectra
350 of aqueous chloride solution (Huggins and Huffman, 1995; Antalek et al., 2016).

351
352 Figure 3C-E-E show NEXAFS spectra acquired in the ice stability domain at temperatures below
353 the eutectic temperature of 251.9 K (Koop et al., 2000a). By comparing these spectra to the spectra
354 in Fig. 3 A-B, the phase of the sodium chloride in the presence of ice below the eutectic
355 temperature will be discussed. At When cooling to 248-249 K from above the eutectic temperature,
356 the NEXAFS spectrum resembles that of a typical aqueous solution (Fig. 3C). Figure 3C shows an
357 average of 3 individual NEXAFS spectra which still shows substantial scatter that results in low
358 spectra quality. We assign the spectral quality is to the low amount of salt within the interfacial
359 region and to potential thermal circulations and thus redistribution of the liquid upon irradiation by
360 the beam. Despite this uncertainty, the results in Fig. 3A-C allow to clearly differentiate between
361 solid halite and aqueous solution.

362

363 Upon cooling further to 241 K, the spectrum changed significantly. The NEXAFS spectrum in Fig.
364 3D shows a wide peak in region I with two well resolved features about 3 eV apart. That both
365 features have a similar intensity, makes this spectrum clearly distinct from those of an aqueous
366 NaCl solution with its decreasing trend of absorption in region I. Compared to the spectrum of
367 aqueous NaCl solution (Fig. 3B, C), the absorption edge is shifted to higher photon energies in the
368 spectrum in Fig. 3D. The absence of a feature in region II makes the spectrum in Fig. 3D distinct
369 from the spectrum of anhydrous NaCl salt. Notably, the spectrum quality is greatly improved and
370 is similar to that of the solid, anhydrous halite sample (Fig. 3A). One factor impacting the spectral
371 quality is the stability of the sample during the NEXAFS acquisition. The analysis of the Cl 2p
372 photoemission spectra acquired before and after each NEXAFS run showed that the amount of
373 chlorine detected in the sample volume fluctuated by less than 10%, between 0 % and 9 %, in
374 samples shown in Fig. 3 C, D, E, and F (Appendix A). For comparison, samples in Fig. 3 A and B
375 showed a decrease of 39 % and 43 % in the integrated Cl 2p signal intensity, respectively, from
376 prior- to after the NEXAFS was recorded. Possible reasons for these trends are an increase in
377 adsorbed water with time masking the intensity of the underlying chlorine (Fig. 3A) and changes in
378 the distance of the sample to the electron analyser with time leading to a reduction in the intensities
379 of all compounds (Fig. 3 B). ~~Both of these~~Both processes would also affect the NEXAFS signal by
380 inducing changes in intensity with time. Direct quantitative comparison is beyond the scope of this
381 ~~work, and work and~~ is hampered by the different probing depth of XPS and NEXAFS as given by
382 the kinetic energy.

383
384 We assign the spectrum in Fig. 3D to that of sodium chloride dihydrate (hydrohalite, $\text{NaCl}\cdot 2\text{H}_2\text{O}$).
385 The NEXAFS spectrum of the hydrohalite has to the best of our knowledge not been described
386 before. The double peak feature in region I, ~~that~~ we observe ~~herein this work~~, is typical for other
387 chloride hydrates such as $\text{MnCl}_2\cdot 4\text{H}_2\text{O}$, $\text{CaCl}_2\cdot 2\text{H}_2\text{O}$, and $\text{MgCl}_2\cdot 6\text{H}_2\text{O}$ (Evans et al., 2008). It is
388 also present in the NEXAFS spectra of sodium chloride solution (Huggins and Huffman, 1995),
389 with a different ratio of the two features as observed here for the hydrohalite. Antalek et al. (2016)
390 has explained this double peak feature in NEXAFS spectra of aqueous chloride solutions by the

391 formation of two distinct solvation shells with two distances between the chloride and the solvating
392 water molecules based on NEXAFS and extended X-ray absorption fine structure spectroscopy as
393 well as molecular dynamics simulations. We propose here that the NEXAFS spectra of the
394 hydrohalite can be understood based on the same argument, as the chloride in $\text{NaCl}\cdot 2\text{H}_2\text{O}$ is
395 coordinated by two sodium and four water molecules with differences in the distance of each Cl to
396 the neighbouring oxygen of the water molecules (Klewe et al., 1974).

397
398 Figures 3E and 3F shows a hydrohalite spectrum after warming the sample back to 249 K in the
399 presence of ice. Clearly, the observed shape in region I show that hydrohalite and not liquid brine
400 is the dominant phase of this sample. In Fig. 3 F an averaged spectrum and at 244 K in absence of
401 ice is shown, again the shape is in good agreement to spectrum shown in Figure 3D. We'd like to
402 note the excellent reproducibility of the spectra as seen in Fig. 3F by the small standard deviation
403 of two samples (shaded area). In summary, we have clearly presented three different chlorine K-
404 edge NEXAFS spectra and argued that these derive from the halite, chloride solution, and the
405 hydrohalite. Hydrohalite at the air-ice interfacial region was thus observed in the temperature range
406 241 K – 249 K.
407

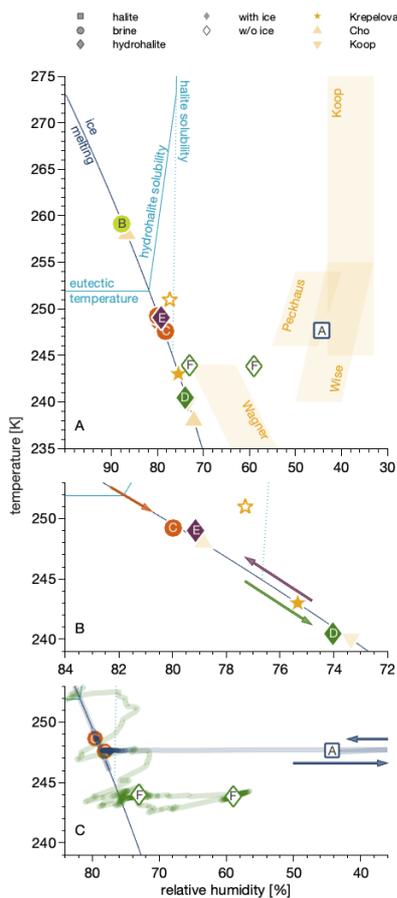

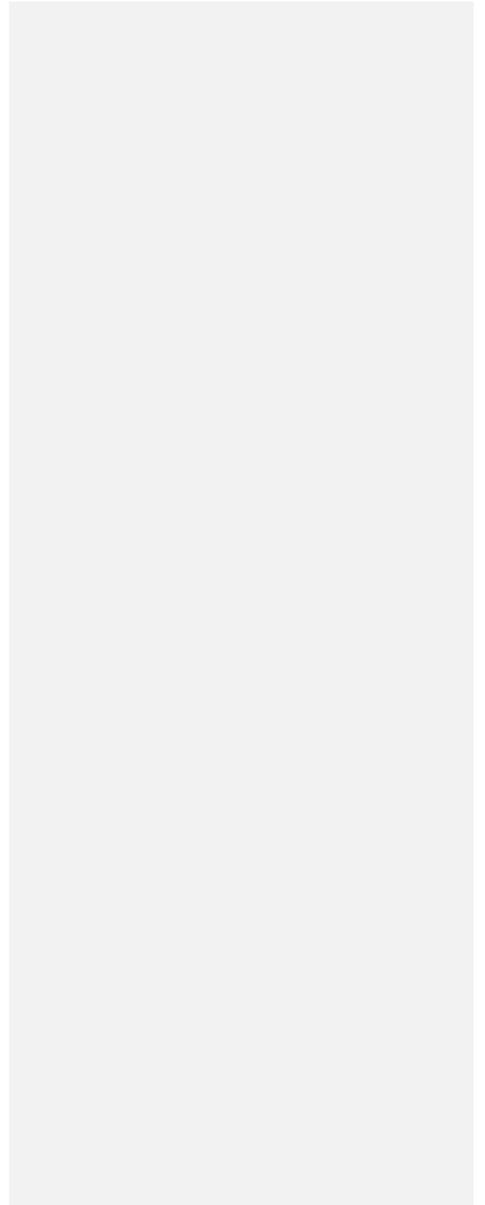

Figure 4: Phase diagram of the NaCl-water binary system showing the conditions and trajectories of the data in Fig. 3 in the relative humidity – temperature space. The relative humidity is the partial pressure of water relative to the vapour pressure of (supercooled) water as parameterised by Marti and Mauersberger (1993). The dark blue line denotes settings where ice is stable as the partial pressure of water matches the vapour pressure of ice. Above the eutectic temperature, it thus separates regions where ice and NaCl solution coexist from those where only NaCl solutions exist. The light blue lines denote conditions where anhydrous NaCl salt (‘halite solubility’) and where NaCl•2H₂O (‘hydrohalite solubility’) forms a solution when increasing the relative humidity at constant temperature; and where NaCl•2H₂O dissolves with increasing temperature at constant relative humidity (“eutectic temperature”).

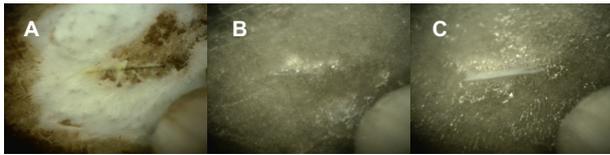

A Data from this work compared to previous results. Also shown are the data ranges where efflorescence has been observed in earlier work as shaded areas (Koop et al., 2000a; Wagner et al., 2011; Wise et al., 2012; Peckhaus et al., 2016). **B** Zoom into data below the eutectic temperature. The arrows show the sequence of changes in experimental temperature and relative humidity conditions. **C** Zoom to the data in absence of ice. The lines indicate the relative humidity and temperature trajectories to reach the experimental conditions for these data points. The arrows illustrate that the relative humidity was reduced to 0% prior to returning to the conditions of the measurement.

462

463

464

465 **Efflorescence at the interface**

466 Now that we have identified halite, the hydrohalites, and ~~the chloride in an~~ aqueous solution by
467 means of the NEXAFS spectra at the interfacial region, we discuss their observation in the phase
468 diagram. ~~Generally, we have observed solid sodium chloride as halite or hydrohalite at~~
469 ~~temperatures below~~ in the temperature range of 2410 K to 249 K and at 44 % to 79 % RH and brine
470 in the temperature range of 248 K to 259 K and RH of 78 % - 88 %.

471

472 Interesti

473 ngly, the NEXAFS spectra have revealed the dominant presence of brine in one sample and of
474 hydrohalite in other samples below the eutectic temperature. This clearly shows that not only the
475 temperature and relative humidity, but also the trajectory to reach these settings (or the history of
476 the sample) determines the phase. Therefore, we will detail the humidity and temperature history
477 of each sample in the following. Also, we will compare our findings to the extensive literature
478 work of observed phases in the presence and absence of ice. This discussion will be based on the
479 Figure 4A shows the sodium chloride – water phase diagram in the temperature – relative humidity
480 space (Figure 4) as initially constructed by Koop et al. (2000a). In this work, the relative humidity
481 (RH) is referenced to the vapour pressure of (supercooled) water as parameterised by Marti and
482 Mauersberger (1993). There are two sets of experiments, those where ice is presentpresent - -and
483 the sodium chloride is in equilibrium with ice (filled symbols) - and experiments in absence of ice
484 (open symbols) that were done with a relative humidity less than the ice stability line in the phase
485 diagram (dark blue line). Generally, we have observed solid sodium chloride as halite or
486 hydrohalite at temperatures below 240 K and at 44 % to 79 % RH and brine in the temperature
487 range of 248 K to 259 K and RH of 78 % - 88 %.

488

489 **Liquid below eutectic and nucleation**

490 In a typical experiment, anhydrous salt was exposed to increased relative humidity at a fixed
491 temperature of 259 K. ~~The relative humidity was increased by increasing the flux of water vapour~~

492 ~~into the experimental cell.~~ Once the relative humidity reached 72 %, the sample started to dissolve
493 by water up-take from the gas-phase and an aqueous solution was formed (brine). This phase
494 change was evident by the sample becoming shiny and then forming transparent spheres as
495 observed by an endoscope digital camera (Fig. 5B'). Then, the relative humidity was further
496 increased ~~and/or temperature was lowered~~ to cross the ice stability line until ice nucleation
497 occurred at a modest ~~oversaturations~~ supersaturation of typically 90 % to 95 % relative humidity at
498 259 K. This relative humidity range corresponds to a supersaturation with respect to ice of 103 %
499 to 109 %. Ice nucleation was evident by a sharp pressure drop from the pressure dosed to the cell
500 to the water vapor pressure of ice at that temperature, for example 88 % relative humidity at 259 K.
501 In some experiments, temperature was lowered 1 K to 2 K as well to trigger ice nucleation. Please
502 note, that temperature was always well above the homogenous freezing temperature, which was
503 found at 210 K to 230 K at relative humidity of 60 % to 90 % (Koop et al., 2000a). Generally, in
504 the presence of ice, the partial pressure of water in the flow-through cell is given by the vapor
505 pressure of ice and is thus a sole function of temperature. If the water vapour pressure upstream of
506 the flow through cell exceeds this value, the ice on the sample holder is growing, if it is set below,
507 the ice sublimates. Based on the calibration of the dosing reservoir temperature and partial pressure
508 of water in the flow-through cell (in absence of ice), the incoming H₂O vapour flux was adjusted
509 such that the equilibrium pressure in the cell matched the vapour pressure of ice.
510
511 A NEXAFS spectrum was acquired at 259 K and 1.82 mbar on the ice stability line and taken as
512 reference for aqueous sodium chloride solution (Fig. 3B). When the temperature was lowered
513 while adapting the flux of water into the set-up to match the vapour pressure of ice at 248 K -
514 249 K, thus 3 K to 4 K below the eutectic temperature (Fig. 4B), the NEXAFS spectra revealed
515 that the chloride at the air-ice interface is in an environment identical to aqueous chloride (Fig.
516 3C). While cooling further and adjusting the vapor pressure to match that of ice at each
517 temperature, a sudden change in the sample appearance, becoming less transparent, was observed
518 by the digital endoscope, indicating efflorescence of the sample. A NEXAFS spectrum recorded
519 reveals that hydrohalite has precipitated from the brine at ~~241~~240.5 K and 74 % RH (Fig. 3D).

520 Krepelova et al. (2010a) has studied phase changes of sodium chloride at the interfacial region of
521 sodium chloride – water binary mixtures previously. They have probed the oxygen with XPS and
522 ~~by~~ partial electron yield NEXAFS spectroscopy and concluded that, in the presence of ice,
523 hydrohalite forms about 11 K below the eutectic (filled star in Fig. 4). Consistent with that, the
524 chloride has a local environment indistinguishable from that of the hydrohalite 11.4 K below the
525 eutectic temperature and in the presence of ice in the current study (Fig. 3D). Our results of
526 precipitation in the presence of ice surfaces agree with the crystallization temperature observed by
527 Koop et al. (2000a). We lack a direct comparison to the bulk, because the electron yield NEXAFS
528 spectroscopy used in our work is inherently surface sensitive. Cooling sodium chloride solutions of
529 varying concentration, Koop et al. (2000a) found precipitation of hydrohalite at 240 K in the
530 presence of ice for bulk samples. Because precipitation occurred at 20 K higher temperatures
531 compared to emulsion samples of the same concentration, the authors concluded that the presence
532 of surfaces enhance the crystallization rate. In that study, the hydrohalite was identified by the
533 melting temperatures of the ice-hydrohalite mixtures. Malley et al. (2018) observed crystallization
534 of sodium chloride solutions 1 K below the eutectic temperature in the presence of ice. The
535 hydrohalite was clearly identified using bulk sensitive Raman spectroscopy. This difference in
536 crystallization temperature may reflect the stochastic character of freezing, as already noted by
537 Koop et al. (2000a) when discussing the scatter in their data. The precise crystallization
538 temperature is also influenced by freezing rate, concentration, and the availability of surfaces
539 (Bartels-Rausch et al., 2014). It appears thus that the precise occurrence of crystallisation is
540 governed by stochastics ~~both~~ at the surface ~~and as has been shown for in heterogeneous~~ freezing of
541 ~~the bulk samples~~ (Alpert and Knopf, 2016) ~~and by experimental settings.~~ Because of the good
542 agreement between the precipitation temperatures observed in this study and in Koop et al.
543 (2000a), we believe that the deviation from Malley et al. (2018)'s results does not indicate
544 differences in the freezing behaviour at the surface vs. that in the bulk.
545
546 To investigate ~~whether or not~~ the impact of the sample's history on the phase-precipitated sodium
547 ~~chloride is the stable form at the interface at temperatures close to the eutectic temperature~~, the

548 sample at 2410 K (green filled ~~triangle~~diamond, Fig. 4B) was warmed towards the eutectic
549 temperature while staying in the ice stability domain. Acquiring a NEXAFS spectrum 3 K below
550 the eutectic temperature (Fig. 3E) that resembles that of hydrohalite, shows that ~~the solid salt is~~
551 ~~the liquid brine is not the~~ thermodynamically stable form ~~also~~ at temperatures close to the eutectic.
552 We therefore interpret the existence of liquid during the previous cooling of the sample (Fig. 4B,
553 orange circle, Fig. 3C) at the interface as supercooled solution. The sample was kept at this
554 condition for 3 h, ~~and showing~~This shows that liquid can exist for extended times at the air-ice
555 interface below the eutectic temperature and that the temperature alone is not sufficient to predict
556 its presence. Rather the thermal history of the ~~snow-frozen matrix~~ needs to be considered.

557
558 For samples that were cooled to temperatures that triggered efflorescence, the chlorine NEXAFS
559 spectra show that the hydrohalite is the dominating phase at the interface of frozen sodium chloride
560 – water binary mixtures. Cho et al. (2002) have shown that when frozen aqueous solutions were
561 warmed, a liquid fraction was observed below the eutectic temperatures. In their experiments, ice
562 was frozen in NMR tubes lowering the temperature to 228 K in 15 min. which is significantly
563 colder than the efflorescence temperatures observed here and by Koop et al. (2000a). After 10
564 minutes, the samples were warmed and NMR signals were recorded. Interestingly, Cho et al.
565 (2002) have observed the liquid fraction only in experiments where the sodium chloride
566 concentration in the initial aqueous solution was below 0.01 mol l⁻¹. If the initial aqueous solution
567 had a concentration of 0.5 mol l⁻¹ no indication of liquid features below the eutectic were found.
568 Tasaki et al. (2010) has shown a similar concentration dependence for sodium bromide solutions
569 using X-ray absorption reporting solvated bromide in the bulk of the samples below the eutectic
570 temperature only for concentrations below 50 mmol l⁻¹.

571
572
573 We will now detail the concentration of brine in the study presented here to elaborate if differences
574 in concentration might explain the differences in the observed liquid content of sub-eutectic
575 samples. The experiments described here started the freezing process with an aqueous solution that

576 was formed in-situ and was kept in equilibrium with a vapour pressure of roughly 1.9 mbar. The
577 chloride concentration in such solutions is close to the concentration in a solution at 1.8 mbar and
578 at 259 K, where ice nucleation occurred and where the freezing point depression data give a
579 concentration of 3.5 mol l⁻¹. This concentration can be directly compared to the concentration in
580 the initial solutions of Cho et al. (2002), which ranged from below 0.01 mol l⁻¹ to 0.5 mol l⁻¹. This
581 back-of-the-envelope calculation thus suggests that the concentration of the solutions from which
582 ice nucleated in the experiments reported here exceeded those described by Cho et al. (2002) for
583 which no liquid fraction was observed.

584

585 ~~Next, we discuss how higher concentrations of initial solution might impact the location of brine in~~
586 ~~the frozen matrix. The New,~~ the concentration of the initial solution from which ice precipitated,
587 determines the ice to brine ratio after ice formation. This is ~~because as the concentration of the~~
588 ~~brine is a sole function of temperature,~~ the volume of the brine relative to that of ice is given by the
589 water to sodium chloride ratio in the initial solution. ~~The concentration of the brine in the presence~~
590 ~~of ice is a sole function of temperature, and not of the initial concentration of the solution.~~ One
591 might speculate that with large amounts of brine relative to ice, that is concentrations of initial
592 solutions from which ice nucleates > 0.5 mol l⁻¹, patches and inclusions are larger in size than for
593 more dilute solutions. The size of these patches or inclusions is of relevance, as surface forces
594 reduce the melting point only for inclusions in the nanometre range (Nye, 1991; Aristov et al.,
595 1997; Christenson, 2001; Bartels-Rausch et al., 2014). The absence of this ~~so-called~~ inverse Köhler
596 effect in larger ~~partieles-patches or inclusions~~ might explain the lack of liquid features both in the
597 results reported here at the interface of ice and in the high concentration samples of Cho et al.
598 (2002). Support for large patches at the interface when solutions are frozen comes from
599 ~~microseopy-a number of~~ studies (Krausko et al., 2014; Tokumasu et al., 2016; Lieb-Lappen et al.,
600 2017; Malley et al., 2018). ~~Low~~ temperature scanning electron microscopy work suggested the
601 ice surface of frozen 0.05 mol l⁻¹ sodium chloride – water mixtures being covered by µm sized
602 brine features (Blackford, 2007; Blackford et al., 2007). Malley et al. (2018) used Raman
603 microscopy of sodium chloride solutions between 0.02 – 0.6 mol l⁻¹ initial concentration to identify

604 micrometre-sized, partially connected patches of liquid covering 11 % to 85 % of the ice surface at
605 temperatures above the eutectic. Despite the impact of freezing temperature and rate -- that differs
606 among the individual studies -- on the distribution of impurities (Bartels-Rausch et al., 2014;
607 Hullar and Anastasio, 2016), these results clearly show the tendency of μm sized features
608 dominating at the air-ice interface. In the dominant presence of nano-inclusions, we would also
609 expect the deliquescence to occur at a lower temperature. This was not observed in our
610 experiments, suggesting the absence of nano-inclusions in the experiments presented here in the
611 interfacial region. Please note, that the NEXAFS spectroscopy presented here probes an area at the
612 interface of the sample with a diameter of about 500 μm . As the spectroscopy is selective to
613 chlorine, we have no information about the fraction of ice in the probed part of the sample.
614

615 The previous argumentation is based on ~~We have recently reported chloride forming solvation~~
616 ~~shells in the interfacial region of ice upon adsorption of HCl at 253 K (Kong et al., 2017). The~~
617 ~~surface concentration as derived from XPS suggested that it was done in the stability domain of~~
618 ~~ice, i.e., the concentration of HCl was too low to melt the ice. Oxygen K-edge NEXAFS spectra~~
619 ~~showed that a substantial fraction of the water molecules at the air-ice interface is arranged in a~~
620 ~~hydrogen-bonding structure like that of liquid water.~~ The features in the NEXAFS spectrum of
621 sodium chloride – ice mixtures (Fig. 3E) at 249 K shown in Fig. 3 D and E are being
622 indistinguishable dominated from those by the hydrohalite as seen in the NEXAFS spectrum of
623 hydrohalite shown in Fig. 3F. In particular the spectrum in Fig. 3E, acquired 3 K below the eutectic
624 temperature, shows a shoulder starting at 2823 eV. Such a feature is absent in the spectrum of the
625 hydrohalite (Fig. 3 F), but the spectrum of brine (Fig. 3 B) shows an increase in absorption starting
626 at this X-ray energy. This feature might thus indicate small amounts of brine and we can thus not
627 exclude the presence of brine in the samples where the hydrohalite dominates the NEXAFS.
628 Taken the spectra quality and the small difference in the shape of the liquid and of the hydrohalite
629 spectrum, it is beyond the scope of this work to elaborate whether the NEXAFS spectrum in Fig.
630 3E might be understood by deconvoluting it in its hydrohalite and brine components and by this
631 reveal a fraction of the chloride being embedded in a brine-like hydrogen bonding network. Two

632 reasons might explain the presence of liquid-like feature in the NEXAFS spectra at sub-eutectic
633 temperatures. First, one might expect a certain distribution in the size of micropockets and a
634 fraction of the pockets might thus be small enough to stabilize liquid at these temperatures.
635 Secondly, some of the chloride might form solvation shells with water molecules from the ice
636 matrix as proposed for trace gases adsorbed to ice (Krepelova et al., 2010b; Krepelova et al., 2013;
637 Bartels-Rausch et al., 2017). In particular, Krepelova et al. (2010a)'s oxygen K-edge spectra of
638 sodium chloride—ice did not reveal water molecules being coordinated like in the liquid. We
639 have recently reported chloride forming solvation shells in the interfacial region of ice upon
640 adsorption of HCl at 253 K (Kong et al., 2017). The surface concentration as derived from XPS
641 suggested that it was done in the stability domain of ice, i.e., the concentration of HCl was too low
642 to melt the ice. Oxygen K-edge NEXAFS spectra showed that a substantial fraction of the water
643 molecules at the air-ice interface is arranged in a hydrogen-bonding structure like that of liquid
644 water. We like to note, that Krepelova et al. (2010a)'s oxygen K-edge spectra of sodium chloride --
645 ice did not reveal water molecules being coordinated like in the liquid. Taken together it seems
646 likely that the chloride at the hydrohalite—air interface does not engage in forming solvation shells
647 similar to those in aqueous solutions and that the signal from the hydrohalite by far exceeds the
648 signal from a chloride that in brine or in an liquid-like environment at the molecular level might
649 migrate to the ice surfaces in intensity.

650 **Nucleation in absence of ice**

651 Hydrohalite can also precipitate in absence of ice by evaporating water from a solution at
652 temperatures below 273 K (Craig et al., 1975; Yang et al., 2017). Such a trajectory, that is the
653 temperature and water vapor pressure the sample experienced, is shown in Fig. 4C (green solid
654 line). In this set of experiments, water was evaporated by decreasing the relative humidity to about
655 70 % at 252 K from a brine sample in absence of ice, followed by -lowering the temperature to
656 247 K at constant partial pressure of water (so that the relative humidity increased to about 80 %).
657 When the ice stability line in the phase diagram was crossed, ice nucleation was not observed as
658 the oversaturation was not sufficient to trigger ice nucleation. This procedure was repeated to

659 further lower the temperature to 244 K at 59 % relative humidity. Then, Two NEXAFS spectra
660 were recorded (Fig. 4, green diamonds), both of which were identified as hydrohalite (Fig. 3F).
661 The first one NEXAFS was recorded at 244 K and 59 % RH (Fig. 4, green diamond), where in
662 absence of ice nucleation was visually observed. The location in the phase diagram is in
663 agreement with Wagner et al. (2012)'s observation of salt deposits in aerosol droplets in an aerosol
664 chamber (AIDA) in absence of ice. The second NEXAFS spectra resembling that of the
665 hydrohalite and in absence of ice was recorded at a slightly higher relative humidity of 72-73 %
666 (Fig. 4, green diamond). Both NEXAFS spectra (Fig. 4, green diamonds) were identified as
667 hydrohalite (Fig. 3F).

668
669 The sample at 44 % RH (Fig. 4C, blue line 3A) has been exposed to 0 % RH prior to acquiring the
670 NEXAFS spectrum (Fig. 4C, blue square and blue line), which removes the crystal water (Light et
671 al., 2009; Wise et al., 2012). This NEXAFS spectrum recorded at 248 K and 44 % RH shows that
672 no deliquescence occurred and thus serves as reference for a halite spectrum (Fig. 4A3A). We note
673 that we misinterpreted this spectrum as that of hydrohalite in our previous technical paper
674 introducing the NAPP end station (Orlando et al., 2016).

675
676 The halite spectrum (Fig. 3A, Fig. 4C blue square) was recorded at 44 % RH, a humidity where
677 water readily adsorbs on surfaces (Bluhm, 2010), and the presence of water at the sodium chloride
678 - air interface at elevated RH has been demonstrated previously (Ewing, 2005; Wise et al., 2008).
679 A further reason for the presence of water at lower RH than the deliquescence might be sodium
680 chloride's high solubility. Kong et al. (2020) has recently suggested that sodium ions from sodium
681 acetate are dissolved in adsorbed water prior to deliquescence. Indications for solvation of halide
682 ions on single crystals below deliquescence relative humidity were also reported previously (Luna
683 et al., 1998). An analogue investigation was beyond the scope of this work. The fact that we find
684 no indication for a dominant liquid feature in the upper 6 nm of the sodium chloride – air interface
685 based on the chlorine X-ray absorption spectrum might be due to probing deeper into the
686 interfacial region in this work as compared to Kong et al. (2020).

hat formatiert: Tiefgestellt

687 NaCl or NaCl·2H₂O

688 We have shown that in the presence of ice, hydrohalite precipitates; halite was not observed in this
689 study except when crystal water was removed in vacuum. This ~~is in agreement~~ agrees with Koop et
690 al. (2000a) who found precipitation of hydrohalite in the presence of ice and suggested that
691 heterogenous nucleation at ice surfaces favours nucleation of hydrohalite. Studies with liquid
692 droplets in absence of ice found both halite and hydrohalite precipitating in the thermodynamic
693 stability domain of the hydrohalite (Wagner et al., 2011; Wise et al., 2012; Peckhaus et al., 2016).
694 The transition between crystallization of halite and hydrohalite at between 253 K to 241 K was
695 explained based on nucleation theory and the deviating trend of nucleation rate of both species
696 with temperature (Peckhaus et al., 2016). That hydrohalite crystallizes in absence of ice in our
697 study shows that also gold surfaces, of the sample holder, serve as good nucleation support for
698 hydrohalite. It appears that any specific properties of the ice surface, as compared to gold, are of
699 minor importance. In agreement, Wagner et al. (2015) showed efficient nucleation of hydrohalite
700 in droplets containing solid oxalic acid and halite precipitated in absence of oxalic acid at the same
701 temperature and relative humidity.

702 1 Summary and Atmospheric Implication

703 The upper few nanometre (~~mean electron escape depth of 6 nm~~) of the interfacial region of a
704 sodium chloride – ice binary system was investigated in this study at various positions in the phase
705 diagram. The sample was always in equilibrium with gas-phase water which makes cooling
706 conditions ~~and concentrations of the brine~~ identical ~~and concentration of brine similar to that of~~
707 aerosol particles embedded in snow or in the troposphere. ~~The~~The inherent sensitivity to the
708 interfacial region comes from using partial Auger-Meitner electron yield NEXAFS and the limited
709 pathlength of electrons travelling in matter. With a ~~mean electron escape depth of 6 nm probing~~
710 ~~depth of a few nanometre~~, the interfacial region is probed spanning from the upper molecular
711 layers somewhat into the bulk (Ammann et al., 2018). In this work, we describe the NEXAFS
712 spectrum of hydrohalite for the first time.

713
714 The results emphasise that the nucleation of hydrohalite is a function of both the temperature and
715 the relative humidity. While we show that the nucleation of hydrohalite at the interface is favoured
716 by surfaces, we find supercooled solution of sodium chloride in the interfacial region of ice. The
717 supercooled solutions have been observed to be metastable for hours in these experiments. This has
718 direct implications for heterogeneous chemistry in cold parts of Earth's environment. Multiphase
719 reactions may proceed at accelerated rates in these highly concentrated brines at temperatures ~10
720 degrees below the eutectic compared to reactions on solid hydrohalite. This temperature range of
721 ~241 K is frequently observed in polar coastal sites during spring and in the free troposphere. In
722 this respect, there is no difference in the interfacial region to liquid embedded in the bulk of snow
723 and ice samples. This implies that when chemical reactivity of ice and snow is discussed,
724 knowledge of its thermal history is essential. From temperature and relative humidity alone,
725 nucleation or efflorescence cannot be predicted at the interface as in the bulk. We suggest that
726 further studies focus on samples with more complex chemical composition to enhance our
727 knowledge of environmental multiphase chemistry. For example, organic compounds are a
728 common constituent of sea-salt aerosol (O'Dowd et al., 2004) Kirpes et al. (2019) and Edebeli et al.
729 (2019) have shown how the presence of organics impacts the microphysics and thus reactivity of
730 salt particles towards ozone (Edebeli et al., 2019). Further, Chakraborty and Kahan (2020) have
731 shown a depression in hydrohalite precipitation temperature in humic acid – sodium chloride
732 mixtures.
733
734 We suggest that the brine observed by Cho et al. (2002) is a consequence of the presence of very
735 small micro-pockets holding the brine. Because ~~these~~ pockets only tend to be small enough to
736 establish a significant depression in freezing point when solutions with are only observed at low
737 concentration of the solution before freezing of ice are freezing, but and because aerosol at typical
738 relative humidity that prevail in cold parts of the atmosphere are highly concentrated, we suggest
739 that ~~such micro~~ nanometer ~~pockets in the interfacial region small enough to establish a significant~~
740 depression in freezing point at the air-ice interface are of small relevance to the environment.

741

742

743

744 The appearance of hydrohalite at air-ice interfaces might also be of interest to sea ice research,
745 because precipitation of hydrohalite increases the albedo of sea ice. During the Snowball Earth
746 period, 700 million years before present, climatic conditions may have favoured the existence of
747 hydrohalite with its climatic feedback (Light et al., 2009). For modern Earth, precipitation of brine
748 constituents in sea ice is relevant for ion mobility and might result in ion fractionation during wash
749 out events (Maus et al., 2008; Obbard et al., 2009; Maus et al., 2011) and possibly brine migration
750 upwards through the snow (Dominé et al., 2004).-

751

752 Precipitation of sodium chloride in sea spray aerosol in the troposphere, not embedded in snow or
753 sea ice, is further of ongoing interest. Again, the Arctic coastal areas are of high relevance here,
754 because temperature and relative humidity frequently favour precipitation of hydrohalite. Other
755 studies have focus on the temperature range of 230 K to 260 K at a relative humidity of 30 % to
756 70 % (see Fig. 4 and references therein) to explore the precipitation in the dryer free troposphere.
757 ~~The Research focused focus is placed~~ on whether anhydrous sodium chloride (halite) or hydrohalite
758 precipitates. In regions of the phase diagram, where the hydrohalite is the thermodynamic stable
759 form, precipitation of the halite was observed with impacts on stability of the solid phase upon
760 warming and or humidification, since the deliquesce relative humidity of the two compounds
761 differs by 6 percentage points (Wagner et al., 2012; Wise et al., 2012; Peckhaus et al., 2016).

 991

992 Appendix A

993

994 **Figure A1:** It shows the photo emission intensities as acquired before (blue line) and after (red
995 line) each NEXAFS spectrum. The PE spectra of sodium (Na1s) are shown in column 1, of oxygen
996 (O1s) in column 2, of chlorine (Cl2p) in column 3, and of carbon (C1s) in column 4. All spectra
997 were acquired at the Phoenix beam line of SLS of PSI with a photon energy of 2200 eV. Pass
998 energy was set to 100 eV and dwell time to 100 ms. Beam line slits were 2 x 2 mm. The C-H
999 feature at 285 eV of the C1s photoemission spectra served as binding energy reference and all
1000 spectra were shifted by 4-5.5 eV to account for charging effects.

1001

1002 The spectra in Fig. A1 can be described as follows:

- 1003 • The Na1s region shows one gauss-shaped feature at 1072 eV as expected for sodium.
- 1004 • The O1s region shows one dominant feature at 535 eV in line with oxygen in ice and a smaller feature at higher
1005 binding energy which might be attributed to gas-phase water.
- 1006 • The Cl2p region shows the typical doublet of the p-orbital spin-orbit splitting (p(3/2) and p(1/2)), 1.6 eV apart
1007 at 200 eV binding energy. Additionally, in some spectra a small feature at 203 eV binding energy is evident
1008 which might be attributed to the Cl2p(1/2) of organic carbon species.
- 1009 • The C1s region shows a broad spectrum with the main feature at 285 eV binding energy, typical for the C-H of
1010 adventitious carbon. The overlapping features at higher binding energy can be attributed to C-OH, C=O,
1011 C(O)=O and C-Cl.
- 1012 • The spectra of all species acquired before and after the sample in Figure A are significantly wider compared to
1013 the other samples. Additionally, the Cl2p features are shifted by 2 eV to lower binding energy. This sample is,
1014 unlike the others, is characterised by a large variation in sample thickness (Figure 3A of manuscript) which
1015 leads to differential charging and might explain the wider peak shapes and shift in the Cl2p features.
- 1016 • In sample A, the photoemission intensities of the Na1s and Cl2p show a higher intensity after the NEXAFS
1017 spectrum was acquired compared to before. During that time, the photoemission intensity of O1s increased.
1018 This suggests that water kept adsorbing to the sample and masked the signal intensity of the underlying sodium
1019 chloride.
- 1020 • In sample B, all photoemission intensities decreased during the time it took to acquire the NEXAFS spectra.
1021 This suggests that the working distances changed which impacts the sensitivity of all sample components.
- 1022
