14

15 **Abstract**

16 To better understand snow chemistry in different environments across the Antarctic ice sheet, we
17 investigated snow ions on a traverse from coast to Dome A. Results show that the non-sea-salt (nss)
18 fractions of K^+ , Mg^{2+} , and Ca^{2+} are mainly from terrestrial particle mass, and nss Cl^- is associated with
19 HCl. Spatially, the proportions of non-sea-salt fractions of ions to the totals are higher in the interior
20 areas than on the coast, and seasonally, the proportions are higher in summer than in winter. Negative
21 nss SO_4^{2-} on the coast indicates sea salts from the sea ice, and marine biogenic emissions dominate
22 snow SO_4^{2-} in interior areas throughout the year.

23

24 **1 Introduction**

25 Snow chemistry has been broadly investigated along traverses during the International
26 Trans-Antarctic Scientific Expedition (ITASE), e.g., DDU to Dome C, coast-interior traverse in Terre
27 Adelie, Syowa to Dome F, Terra Nova Bay to Dome C, 1990 ITASE, and US ITASE in West Antarctica
28 (Legrand and Delmas, 1985; Qin et al., 1992; Mulvaney and Wolff, 1994; Proposito et al., 2002;
29 Suzuki et al., 2002; Dixon et al., 2013), and Bertler et al. (2005) has comprehensively summarized the
30 glaciochemical data across the ice sheet, most of which are for surface snow. Among the major ions,
31 sea salt related ions (e.g., Na^+ and Cl^-), in general, are the most abundant species, and typically exhibit
32 a clear spatial trend, with concentrations falling off sharply with distance from the coast.

33 Temporally, with varied sources and lifetimes, ions in snow often exhibit different seasonal
34 variations, e.g., sea salt related ions show high concentrations in winter, while elevated concentrations
35 of SO_4^{2-} and NO_3^- are frequently observed in summer (Neubauer and Heumann, 1988; Gragnani et al.,
36 1998; Traversi et al., 2004; Shi et al., 2015). On annual to decadal time scales, ion concentrations in
37 snow and ice tend to be associated with changes in transport from year to year (Severi et al., 2009;
38 Weller et al., 2011), and thus large scale atmospheric and oceanic circulation in the Southern
39 Hemisphere could potentially influence variations snow and ice chemistry (Russell and McGregor,
40 2010; Weller et al., 2011; Mayewski et al., 2017).

41 Although investigations of snow chemistry have been carried out along several overland traverses,
42 the investigation of snow chemistry under different environmental conditions and over time is needed,
43 given that the Antarctic ice sheet itself, and precipitation and deposition patterns and trends are
44 changing. The China inland Antarctic traverse from coastal Zhongshan Station to the ice sheet summit
45 (Dome A) covers a range of environments (~1250 km), e.g., high snow accumulation rate is present on
46 the coast and in some interior areas, and low accumulation rate is observed on the Dome A plateau.
47 Several investigations have been carried out to determine the concentrations of a few ionic species and
48 trace elements on the traverse (e.g., Li et al., 2016; Du et al., 2019), but limited snow chemistry data
49 were previously available. Therefore, we used surface snow and snow pit samples collected during five
50 China inland Antarctic scientific expedition campaigns, to determine the spatial and temporal variations
51 in a comprehensive set of ions (Na^+ , NH_4^+ , K^+ , Mg^{2+} , Ca^{2+} , Cl^- , NO_3^- , and SO_4^{2-}) and their controlling
52 factors.

53

54 **2 Methods**

55 **2.1 Sample collection**

56 Snow samples were collected along the traverse from the coast to the ice sheet summit during five
57 Chinese National Antarctic Research Expedition (CHINARE) campaigns (Fig. S1). In
58 January-February in the years 1999, 2011, 2013, 2015, and 2016, 107, 120, 125, 117, and 125 surface
59 snow samples were collected on the traverse, respectively. In total, 594 snow samples were collected
60 during the five seasons. For the snow sampling protocols refer to Shi et al. (2018). It is noted that the
61 surface ~3 cm snow represents different lengths of time at different locations, considering the wide
62 range of snow accumulation rates on the traverse (Fig. 1(a)). At locations with high snow accumulation
63 rate on the coast, the upper 3 cm of snow may represent deposition from a few weeks or a single
64 snowfall, while the surface 3 cm of snow could represent deposition over a few months on Dome A
65 plateau. Still, the information contained in the surface snow generally indicates summertime conditions,
66 as the sampling took place during late January and February in each season.

67 In addition to surface snow, snow pits were sampled in three representative areas on the traverse: P1,

68 located on the coast (76.49 °E, 69.79 °S; 46 km from the coast), was sampled in December 2015; P2,
69 located in the interior area (77.03 °E, 76.42 °S; 800 km from the coast), was sampled in January 2016;
70 and P3, located on the Dome A plateau (77.11 °E, 80.42 °S; 1256 km from the coast), was sampled in
71 January 2010. Sites P1 and P2 are characterized with high snow accumulation rate ($>100 \text{ kg m}^{-2} \text{ a}^{-1}$),
72 while snow accumulation rate at P3 is $\sim 25 \text{ kg m}^{-2} \text{ a}^{-1}$. The depths of P1, P2, and P3 are 180, 100, and
73 150 cm, respectively, with the respective sampling resolution of 5, 3, and 1 cm. Details on the snow pit
74 sampling are described in Shi et al. (2015). All snow samples were transported and stored under
75 freezing conditions ($\sim -20 \text{ }^\circ\text{C}$).

76

77 2.2 Sample analysis

78 In the class 100 room, about 5 ml of the melted sample was transferred to the pre-cleaned 8-ml ion
79 chromatography (IC) autosampler vials, and then the lid was tightly screwed on to the vials. The
80 samples were analyzed by an ICS-3000 IC system (Dionex, USA) for the concentrations of ions (Na^+ ,
81 NH_4^+ , K^+ , Mg^{2+} , Ca^{2+} , Cl^- , NO_3^- , and SO_4^{2-}) in a class 1000 clean room. More details on ion
82 determination are described in Shi et al. (2012). During sample analysis, replicate determinations ($n = 5$)
83 were performed, and one relative standard deviation (1σ) for all eight ions was generally $<5 \%$.

84 In Antarctic snow, previous observations suggested that concentrations of H^+ can be reasonably
85 deduced from the ion-balance disequilibrium (Legrand and Delmas, 1985; Legrand, 1987):

$$86 [\text{H}^+] = [\text{SO}_4^{2-}] + [\text{NO}_3^-] + [\text{Cl}^-] - [\text{Na}^+] - [\text{NH}_4^+] - [\text{K}^+] - [\text{Mg}^{2+}] - [\text{Ca}^{2+}] \text{ Eq. (1),}$$

87 where ion concentrations are in $\mu\text{eq L}^{-1}$. In addition, the non-sea-salt fractions of ions (nssX), including
88 nss Cl^- , nss SO_4^{2-} , nss K^+ , nss Mg^{2+} , and nss Ca^{2+} , can be calculated from the following expression,

$$89 [\text{nssX}] = [\text{X}]_{\text{snow}} - ([\text{X}]/[\text{Na}^+]_{\text{seawater}} \times [\text{Na}^+]_{\text{snow}}) \text{ Eq. (2),}$$

90 where [X] is the concentration of ion X, and [X]/[Na^+] ratios in seawater are 1.17 (Cl^-), 0.12 (SO_4^{2-}),
91 0.022 (K^+), 0.23 (Mg^{2+}) and 0.044 (Ca^{2+}) (in $\mu\text{eq L}^{-1}$).

92

93 3 Results

94 3.1 Ion variations in snow pits

95 Clear seasonal cycles of Na^+ and nss SO_4^{2-} are present in P1 and P2, and thus the two pits can be well
96 dated, spanning ~ 3 years (Fig. S2). In addition to SO_4^{2-} and Na^+ , the other species also show seasonal
97 variations, especially in P1, where elevated levels of NO_3^- and NH_4^+ are generally present in summer,
98 and the concentrations of Cl^- , K^+ , Mg^{2+} , and Ca^{2+} are high in winter. As for nss SO_4^{2-} at P3, the very
99 large signal at the depth of ~ 120 cm is most likely the fallout from the massive eruption of Pinatubo in
100 1991 (Fig. S2), based upon previous observations at Dome A (e.g., Hou et al., 2007). It is noted that
101 only elevated SO_4^{2-} concentrations are present during this period, possibly suggesting that Pinatubo
102 volcanic emissions contribute less to the ion budgets other than SO_4^{2-} at Dome A.

103 In terms of the non-sea-salt fractions, nss Cl^- is lower at P1 ($0.25 \pm 0.28 \mu\text{eq L}^{-1}$) than at the inland
104 sites P2 and P3 (0.42 ± 0.18 and $0.58 \pm 0.34 \mu\text{eq L}^{-1}$, respectively), while the concentrations of nss K^+ ,
105 nss Mg^{2+} , and nss Ca^{2+} generally show a similar spatial pattern. In general, nss Cl^- , nss K^+ , nss Mg^{2+} , and
106 nss Ca^{2+} in snow pits do not show clear seasonal cycles.

107

108 3.2 Ion concentrations in surface snow

109 Concentrations of ions in surface snow are shown in Fig. 1, and the values generally fall within the
110 reported ranges of the ITASE program sampling (Bertler et al., 2005). Spatially, Cl^- , Na^+ , K^+ , and Mg^{2+}
111 show very high concentrations within the narrow coastal region, and decrease sharply further inland,

112 with minimum values on the Dome A plateau (>~1000 km from the coast). It is noted that some
113 samples on the coast also show elevated Ca^{2+} concentrations. The high ion concentrations near the
114 coast may be associated with the strong marine air mass intrusions (Hara et al., 2014). NO_3^- shows an
115 opposite spatial trend, with increasing values towards inland. As for SO_4^{2-} (and nssSO_4^{2-}), NH_4^+ , and
116 Ca^{2+} , no clear spatial trend was found.

117 Among the chemical ions in surface snow, the most abundant species is H^+ , accounting for 30-40 %
118 of the total ions, followed by NO_3^- , SO_4^{2-} , and Cl^- . In general, NH_4^+ , K^+ , Mg^{2+} , and Ca^{2+} are the smallest
119 component of the ionic composition, with the four cation summing to (6.0 ± 3.4) % of the total (Fig. S3).

121 4 Discussions

122 4.1 Non-sea-salt fractions of ions in surface snow

123 Correlation plots of ions versus Na^+ in surface snow are shown in Fig. 2. On the coast, most of the
124 Cl^-/Na^+ data are distributed close to the seawater dilution line (Fig. 2(a)), while most of the plots in the
125 interior areas are above the seawater line, suggesting an enrichment of Cl^- . nssCl^- accounted for
126 (39 ± 24) % of Cl^- on the traverse, with higher values in the interior areas. The elevated fractions of
127 nssCl^- are likely associated with the 'secondary' HCl which is produced by the reactions between sea
128 salts and acids (e.g., HNO_3 and H_2SO_4) (Finlayson-Pitts, 2003).

129 Mg^{2+} is irreversibly deposited into the snow, and the fraction of nssMg^{2+} , on average, represents
130 (44 ± 19) % of Mg^{2+} in snow, with lower (higher) values on the coast (plateau) (Fig. 2(d)). The
131 enrichment of Mg^{2+} has not been observed in sea salt particles produced by bubble bursting (Keene et
132 al., 2007), and thus enriched Mg^{2+} in the snow is unlikely associated with sea salt spray. In the
133 atmosphere, sea salt aerosols can be modified at low temperatures via the formation of mirabilite, thus
134 leading to an elevated ratio of $\text{Mg}^{2+}/\text{Na}^+$ if mirabilite precipitates from the aerosols. However, the
135 solid-liquid separation of mirabilite in the aerosol droplet was not observed in the experiments
136 (Wagenbach et al., 1998). Thus, the enrichment of Mg^{2+} in surface snow is unlikely associated with sea
137 salt fractionation. Although it is proposed that Mg^{2+} separation in sea salts can occur in surface snow
138 due to the re-freezing process on surface snow (i.e., the quasi-liquid layers on the crystal surface can
139 act like seawater freezing; Hara et al., 2014), our measurement of Mg^{2+} in bulk snow is unlikely to
140 support this process responsible for Mg^{2+} enrichment. A previous observation conducted near this
141 traverse showed a moderate correlation of Mg^{2+} with element Al in the surface snowpack ($r=0.53$,
142 $p<0.05$), indicating a contribution of continental dust (Khodzher et al., 2014). Thus, the most plausible
143 interpretation of nssMg^{2+} is the contribution of terrestrial aerosols. Similar to Mg^{2+} , most of K^+/Na^+
144 data points are close to the seawater dilution line on the coast, suggesting a primary contribution of sea
145 salt spray (Fig. 2(c)). Enriched K^+ is ubiquitous in interior areas, possibly associated with mineral
146 transport, and combustion emissions in the Southern Hemisphere (Virkkula et al., 2006; Hara et al.,
147 2013). Note that all sampling sites are at least several tens of kilometers away from the coast, the
148 contribution of biological activity to snow K^+ would be rather minor (Rankin and Wolff, 2000). A lack
149 of correlation between K^+ (or nssK^+) and refractory black carbon (rBC, unpublished data; Fig. S4),
150 which mainly represent the biomass burning emissions in the Southern Hemisphere (Sigl et al., 2016),
151 suggests that K^+ in surface snow is unlikely dominated by biomass burning emissions.

152 The fraction of nssCa^{2+} , on average, accounts for (73 ± 26) % of total Ca^{2+} in surface snow, with
153 high percentages in the interior areas. In Antarctica, snow nssCa^{2+} was thought to be mainly associated
154 with terrestrial inputs, possibly from both South America and Australia (Bertler et al., 2005; Wolff et al.,
155 2010; Du et al., 2018). nssSO_4^{2-} represents (94 ± 5) % of total SO_4^{2-} in surface snow, with lower (higher)

156 proportions on the coast (plateau) (Fig. 2(b)), suggesting a dominant role of marine bioactivities.
157 Different from the coarse sea salt aerosols, nssSO_4^{2-} originating from marine biogenic production of
158 DMS can form fine aerosol particles in the atmosphere (Legrand et al., 2017a), resulting in long
159 atmospheric residence time (>10 days to weeks) and consequently efficient transport (Bondietti and
160 Papastefanou, 1993; Hara et al., 2014). This can help explain the elevated deposition flux of nssSO_4^{2-}
161 frequently found at inland Antarctic sites, e.g., site P2 (discussed below).

162

163 4.2 Non-sea-salt fractions and fluxes of ions in snow pits

164 At P1, the slope values of the linear regression between Na^+ and the four ions are close to those of
165 seawater (Fig. 3), suggesting a dominant source of sea salt aerosols. The proportions of the non-sea-salt
166 fractions of K^+ , Mg^{2+} , and Ca^{2+} to the ions in snow are much lower in winter than in summer, as a result
167 of the high sea salt inputs in winter. Negative nssCl^- is present in summer snow, indicating the
168 modification to sea salts (i.e., formation of mirabilite in the atmosphere) in summer when the acid
169 levels (e.g., HNO_3) are relatively high (Savarino et al., 2007). Some winter snow samples featured
170 negative nssSO_4^{2-} , i.e., $\text{SO}_4^{2-}/\text{Na}^+$ ratio below the value of seawater (Fig. S2), suggesting sea salt
171 aerosols originating from the sea ice (Marion et al., 1999). In the winter snow, if all SO_4^{2-} is from sea
172 salt aerosols, nssSO_4^{2-} is expected to be lower than or close to zero. However, 13 out of the 17 samples
173 classified as winter snow at P1 were characterized with positive nssSO_4^{2-} , suggesting a significant
174 contribution from marine biogenic emissions. It is interesting that nssSO_4^{2-} has a strong negative
175 correlation with Na^+ in winter ($r=0.82$, $p<0.001$), raising two potential cases: 1) stronger winds
176 transport more sea salt aerosols to P1 featured with depleted SO_4^{2-} from sea ice, thereby resulting in
177 low concentrations of nssSO_4^{2-} and assuming a stable SO_4^{2-} input flux from marine biogenic emissions;
178 and/or 2) with a larger extent of sea ice and strong transport, a large sea salt flux would still result but
179 carry less nssSO_4^{2-} from marine biogenic emissions due to the longer transport distance (Wolff et al.,
180 2006 and references therein). If case 2) dominated nssSO_4^{2-} variations in the winter snow, lower
181 nssSO_4^{2-} would be expected in the end than at the beginning of winter when a sea ice coverage
182 minimum is present. The observation at P1, however, does not support this expected seasonal trend
183 (Fig. S2). It is most likely, then, that sea salt aerosol inputs dominate nssSO_4^{2-} variations in the winter
184 snow instead of the marine biogenic emissions.

185 The patterns of relationships between ions and Na^+ at P2 are similar to those of P1 except for Ca^{2+}
186 (Fig. 3). Non-sea-salt fractions of Ca^{2+} account for $(79\pm 9)\%$ of the total, suggesting a dominant role of
187 the terrestrial source. It is noted that Ca^{2+} remains relatively constant with increasing Na^+ (Fig. 3),
188 possibly suggesting insignificant seasonal variations in terrestrial dust inputs. The fractions of nssSO_4^{2-}
189 to SO_4^{2-} in summer and winter snow are (94 ± 4) and $(88\pm 4)\%$, respectively, suggesting a dominant role
190 of marine biogenic emissions, different from that at P1. Previous investigations proposed that sea salt
191 aerosols emitted from sea ice are an important contribution to the sea salt budget in central Antarctica
192 in winter (Legrand et al., 2016; Legrand et al., 2017b). Here, the high nssSO_4^{2-} concentrations indicate
193 that marine emissions could also be an important source of ions in winter.

194 At P3, Cl^- , K^+ , and Mg^{2+} are also correlated well with Na^+ (Fig. 3). The non-sea-salt fractions of Cl^-
195 make up $(38\pm 24)\%$ of the total, similar to that at P2, indicating the importance of HCl deposition, and
196 consequently results in Cl^- not being a quantitative indicator of sea salts in the interior areas. nssSO_4^{2-}
197 at P3 accounts for $(95\pm 2)\%$ of SO_4^{2-} . Together with the observations at P2, it can be inferred that SO_4^{2-}
198 in the interior areas is dominated by marine biogenic emissions throughout the year, generally in line
199 with the observation at Dome C (Udisti et al., 2012).

200 Ion fluxes in the 3 snow pits can be determined by multiplying the concentrations by snow
201 accumulation rate, and the highest fluxes of ions except for NO_3^- were generally present at P1, followed
202 by P2 and P3 (Fig. S5). It is noted that nssSO_4^{2-} fluxes at P1 ($99.4 \pm 46.7 \mu\text{eq m}^{-2} \text{a}^{-1}$) and P2
203 ($109.2 \pm 21.6 \mu\text{eq m}^{-2} \text{a}^{-1}$) are comparable, although P1 is located on the coast and P2 located further
204 inland (~ 800 km from the coast). In addition, the ratio of nssSO_4^{2-} flux at P1 over that at P3 is 2.2, the
205 lowest among the ratios for the observed ions (17.2, 7.5, 26.7, 8.5, 17.4, 17.0, and 10.0 for Cl^- , NO_3^- ,
206 Na^+ , NH_4^+ , K^+ , Mg^{2+} , and Ca^{2+} , respectively), suggesting more efficient transport of nssSO_4^{2-} . In other
207 words, atmospheric nssSO_4^{2-} from the open ocean can be efficiently transported to at least as far inland
208 as ~ 800 km from the coast (~ 2800 m above sea level; site P2).

209

210 5 Conclusions

211 Snow chemistry on a traverse from coastal Zhongshan Station to Dome A was investigated. It is
212 shown that the non-sea-salt fractions of K^+ , Mg^{2+} , and Ca^{2+} are mainly associated with terrestrial
213 particle mass, while nssCl^- is linked to the deposition of HCl. Spatially, the proportions of non-sea-salt
214 fractions of ions to the totals are higher in the interior areas than on the coast, and seasonally, the
215 proportions are generally higher in summer than in winter, due to the high sea salt inputs during
216 wintertime. Negative nssSO_4^{2-} observed on the coast indicates sea salts mainly originating from the sea
217 ice in winter, while positive nssSO_4^{2-} is present throughout the year in the interior areas, suggesting the
218 dominated role of marine biogenic emissions. The nssSO_4^{2-} can be transported efficiently to at least as
219 far inland as the ~ 2800 m contour line.

220

221 **Data availability.** This dataset, chemical data on ion concentrations in snow on the traverse from coast
222 (Zhongshan Station) to Dome A, is in the process of being hosted on a public server by the Chinese
223 National Arctic and Antarctic Data Center (<https://www.chinare.org.cn/>).

224

225 **Author contributions.** GS, ZC, YL and BS designed the experiments and GS, HM, ZH, CA, SJ, TM,
226 JY, DW and SL carried them out. GS and MH prepared the manuscript with contributions from all
227 co-authors.

228

229 **Competing interests.** The authors declare that they have no conflict of interest.

363
364

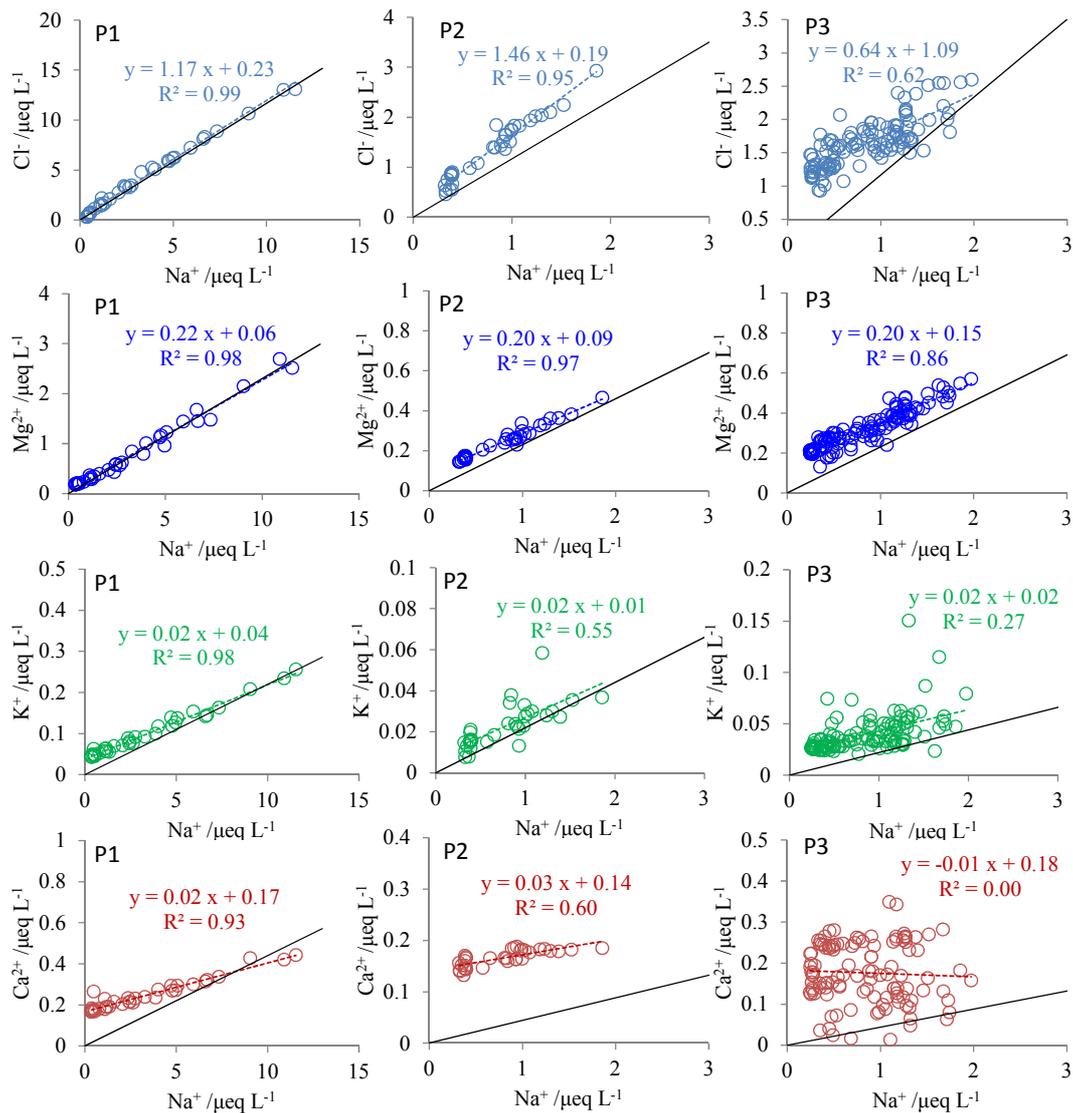

368 **Figure 1.** Annual snow accumulation rate, elevation (a) and ion concentrations in surface snow
 369 collected during five seasons (b-i). Annual snow accumulation rate is obtained from field bamboo stick
 370 measurements, updated to 2016 from Ding et al. (2011). The closed diamond, open circle, closed
 371 triangle, cross and closed circle denote ion concentrations in the years 1999, 2011, 2013, 2015, and
 372 2016, respectively. Note that a base-10 log scale is used for the y-axis of Cl^- (b), Na^+ (e), and Mg^{2+} (h).

373

374 **Figure 2.** Correlation plots of Cl^- , SO_4^{2-} , K^+ , Mg^{2+} , Ca^{2+} , and NO_3^- versus Na^+ in surface snow. The
 375 black solid line represents the seawater dilution line, with slopes of typical ions versus Na^+ ratios in
 376 seawater (in μeq L⁻¹). The concentration of NO_3^- in seawater is too variable among the seas, and a
 377 representative ratio of $\text{NO}_3^-/\text{Na}^+$ cannot be presented. Note that a base-10 log scale is used for ion
 378 concentrations.

379

381

382 **Figure 3.** Relationships between Na⁺ and Cl⁻, K⁺, Mg²⁺, Ca²⁺ in the three snow pits (P1, P2, and P3).

383 Also shown are the linear regressions between them (dashed line), with all of the linear correlation

384 significant at p<0.001 except Ca²⁺/Na⁺ at P3. The black solid line represents seawater dilution line.

385 Note that the data of the bottom ~30 cm layer of P3 was excluded in the plots, since it represents a

386 snow layer clearly impacted by volcanic (Pinatubo) eruption emissions.

387
