15 **Abstract.** We report the first ground-based observations of a subglacial lake in Greenland, confirming previous work based on airborne radar data. Here, we perform an active source seismology and ground penetrating radar survey in northwest Greenland where Palmer et al. (2013) first proposed the presence of a subglacial lake. From reflections of both the lake top and lake bottom, we observe a subglacial lake underlying approximately 845 m of ice, and constrain its depth to be between 10 – 15 m. Additionally, using previously reported estimates of the lake’s lateral extent, we estimate the total volume of liquid 20 water to be 0.15 km³ (0.15 Gt of water). Thermal and hydropotential modeling both suggest that the lake should not exist unless it either sits over a localized geothermal flux high or has high salinity due to significant evaporite source in the bedrock. Our study indicates that this field site in northwestern Greenland is a good candidate for future investigations aimed at understanding lake properties and origins or for direct lake sampling via drilling.

1 Introduction

25 There is mounting evidence that subglacial lake systems below the Antarctic and Greenland ice sheet play an important role in glacier dynamics and ice-sheet mass balance considerations. In Antarctica, the presence of subglacial lakes is suspected to promote ice flow by reducing basal shear stress (e.g., Bell et al., 2007), and periodic drainage events have been linked to accelerated ice flow in outlet glaciers and ice streams (e.g., Stearns et al., 2008; Siegfried et al., 2016). Similarly, in Greenland subglacial lake systems also provide a reservoir for the storage of surface or basal melt water, and hence may be an important, 30 but largely unknown, factor in global sea level change. Additionally, subglacial lakes are of interest due to their ability to harbor complex microorganisms adapted to extreme environments (Achberger et al., 2016; Campen et al., 2019; Vick-Majors et al., 2016) and for paleoenvironmental information contained in subglacial lake sediments (Bentley et al., 2011).

While the presence and nature of subglacial lakes underlying the Antarctic ice sheet has been studied for more than 50 years, the existence of subglacial lakes below the Greenland ice sheet (GrIS) is a relatively recent discovery and comparatively little is known about their properties and origin. Detection of subglacial lakes has relied on a variety of methods, including airborne radio-echo sounding (RES) (Robin et al., 1970; Siegert et al., 1996; Langley et al., 2011; Palmer et al., 2013; Young et al., 2016; Bowling et al., 2019) satellite altimetry measurements (Fricker et al., 2007; Palmer et al., 2015; Siegfried & Fricker, 2018; Willis et al., 2015), and active source seismic experiments (Horgan et al., 2012; Peters et al., 2008). Using these techniques, approximately 400 subglacial lakes have been detected in Antarctica (Wright & Siegert, 2012), of which 124 are considered “active” (Smith et al., 2009). In Greenland, subglacial lakes were first detected in RES data by Palmer et al. (2013), who identified two small (roughly 10 km²) flat regions of anomalously high basal reflectivity below the northwestern GrIS. These features, named “L1” and “L2”, were discovered below 757 m and 809 m of ice respectively. Recently, Bowling et al. (2019) greatly expanded the inventory of subglacial lakes in Greenland to approximately 54 candidates based on a combination of RES and satellite altimetry data. The new inventory shows that, in contrast to subglacial lakes in Antarctica which tend to form under thick (> 4 km) warm-based ice in the continental interior, the majority of subglacial lakes in Greenland are found under relatively thin (1 - 2 km) ice near the margins of the GrIS. Bowling et al. (2019) find that most subglacial lakes in Greenland appear to be stable features, showing temporally consistent RES signatures and an absence of vertical surface deformation over the decadal time scales of observation. Of the 54 candidate lakes, only 2 showed signs of vertical surface deformation indicative of active draining or recharge. While evidence of active subglacial lake dynamics in Greenland has been sparse (Palmer et al., 2015; Willis et al., 2015), approximately 40% of Antarctic subglacial lakes appear to be active features (Bowling et al., 2019).

The formation and location of the detected subglacial lake features in Greenland remains elusive because many are located in regions where observations and modeling suggest that the base of the ice is frozen to its bed (MacGregor et al., 2016). Complicating our understanding of the nature of subglacial lakes is the fact that uniquely identifying lakes in airborne radar data is challenging since basal reflectivity is sensitive to both the physical properties and the roughness of the material underlying the ice (e.g., Jordan et al., 2017). Amplitude anomalies of radar echoes in the range of +10 to +20 dB are often interpreted as subglacial lakes, although flat regions of saturated sediment may produce similar anomalies. Furthermore, the total volume of water stored in subglacial lake systems is unknown since airborne and space based remote sensing observations are incapable of measuring lake depth (i.e., water column thickness). Seismic investigations provide an independent means of confirming the presence of subglacial lakes and are capable of measuring lake depth and underlying geological structures which can provide valuable clues into their formation and total volume.

In this study, we report results of an active source seismology and ground penetrating radar (GPR) survey performed in northwestern Greenland (Figure 1), at the location where Palmer et al. (2013) first identified subglacial lake signatures in RES

70 data. Our survey was conducted above subglacial lake candidate L2 which is within the accumulation area of the ice sheet. Both seismic and GPR results show a flat reflector approximately 830 - 845 m below the surface, with a seismic reflection coefficient of -0.42 ± 0.15 , which is consistent with the acoustic impedance contrast between a layer of water below glacial ice. Additionally, in the seismic data we observe an intermittent lake bottom reflection arriving between 14 - 20 ms after the lake top reflection, corresponding to a lake depth of approximately 10 - 15 m. Strong coda following the lake top and lake bottom reflections is consistent with a package of lake bottom sediments although its thickness and material properties are uncertain. Finally, we use these results to conduct a first-order assessment of the lake origins using a one-dimensional thermal model and hydropotential modeling based on published surface and bed topography (Morlighem et al., 2017). Because the 75 origins are still unclear, this site provides an intriguing opportunity for the first *in situ* sampling of a subglacial lake in Greenland, which could better constrain mechanisms of subglacial lake formation, evolution, and relative importance to glacial hydrology.

2 Methods

80 2.1 Field experiment

In June 2018, we conducted a geophysical survey in northwestern Greenland above the candidate subglacial lake feature L2 (Palmer et al., 2013). This feature sits within a 980 km² drainage basin and is roughly adjacent (< 10 km) to the nearest drainage divide (Fig. 1A and 1B). The mean annual snow accumulation rate at the field site is ~ 30 cm/yr ice equivalent (determined from RACMO2 model results, Noël et al., 2018). In order to confirm the presence of the subglacial lake and investigate its 85 physical properties, we collected data using both active source seismology and GPR. The active source seismic experiment consisted of a moving line of 24 40 Hz vertical component geophones spaced 5 m apart. For each line, we collected data at 4 shot locations using an 8 kg sledgehammer impacted against a 1.5 cm thick steel plate. At each source location at least 5 hammer shots were stacked into a single shot gather in order to increase the signal to noise ratio. The first shot location of each line was offset 115 m from the first geophone, and subsequent shot locations were moved 115 m along the line. After data was 90 collected for each of the 4 shot locations, the line was moved 230 m east along the traverse and data collection was repeated. The seismic line was moved a total of 10 times, totalling 40 separate shot locations. Using this geometry, we obtained reflection points at the ice bottom spaced every 2.5 m along a traverse totalling 2400 m (Fig. 1C and 1D). The GPR survey was conducted across a ~ 5.5 km transect roughly parallel to the seismic survey (Fig. 1C), using a 10 MHz monopulse radar system.

95 2.2 Seismic and GPR imaging

We created a longitudinal seismic reflection image by bandpass filtering data between 100 - 200 Hz and applying a normal moveout (NMO) correction with a velocity of 3700 m/s, which was found to be the average velocity of the ice column from

NMO analysis of the primary bed reflection. High frequency spatial noise with wavenumber greater than 0.05 m^{-1} was removed with f-k filtering. Shot gathers with offsets of -115 m and 230 m from the first geophone contained an air wave arrival that was muted by zeroing a 10 ms window with a moveout of 315 m/s . The seismic reflection profile (Fig. 2A) shows a clear ice bottom reflection across the entire transect arriving with a two-way travel time between $400 - 460 \text{ ms}$. The ice bottom multiple (i.e., a wave that has travelled twice between the surface and ice bottom) is also visible between $800 - 920 \text{ ms}$. From hereon, we refer to the ice bottom reflection as R1 and its multiple as R2. At transect distances between $0 - 1700 \text{ m}$, the R1 reflection is flat and relatively uniform in character, which we interpret to be the signal of the top of the subglacial lake. In this region, R1 arrives at 457 ms , which corresponds to a depth of 845 m , assuming an average V_P of 3700 m/s within the ice. At larger transect distances, the reflections arrive earlier with increasing distance, which likely reflects the bed topography adjacent to the subglacial lake. An additional reflection with opposite polarity of R1 is observed arriving between $14 - 20 \text{ ms}$ after R1, which is consistent with a lake bottom reflection (Fig. 2B). This signal is intermittently observed but is most continuous at transect distances between $660 - 1200 \text{ m}$. The travel time differential between the lake top and lake bottom reflection is used to measure the thickness of the water column across the seismic section. Assuming V_P in the lake of 1498 m/s (Table 1), the lake is between $10 - 15 \text{ m}$ deep (Fig. 2C). An uncertainty of $\pm 50 \text{ m/s}$ on lake velocity would correspond to a lake depth uncertainty of $\pm 0.5 \text{ m}$. A strong coda following the lake bottom reflection is apparent which is likely caused by a thin ($\sim 10 \text{ m}$) sediment package underlying the lake (see Discussion).

To verify our seismic results, we also created a GPR image by converting the radar data to depth using a radar velocity of $172 \text{ m}/\mu\text{s}$ (see Supporting Information). The subglacial lake is apparent as a flat reflector at an elevation of $\sim 510 \text{ m}$ across the majority of the transect (Fig. 3A). The surface topography slopes gently to the west across the transect, hence the lake is slightly deeper towards the east (Fig. 3B). The lake is beneath 840 m of ice at transect distances between 2 to 4.5 km , which roughly corresponds to the location of the seismic survey. The transition from the lake top to the adjacent bed is observed at approximately 4100 m along the transect.

2.3 Basal reflectivity

In order to confirm that the flat region of R1 is consistent with a reflection from liquid water below ice, we calculate the reflection coefficient at the base of the ice by analysing the amplitudes of the first (R1) and second (R2) reflections. When both R1 and R2 are visible, the basal reflection coefficient c_R can be determined as a function of incidence angle θ using Eq. (1) where A_{R1} and A_{R2} are the amplitude of the first and second ice bottom reflections, respectively, a is the absorption coefficient, and L is the raypath length of the R1 reflection (e.g., Peters et al., 2008).

$$c_R(\theta) = 2 \frac{A_{R2}(\theta)}{A_{R1}(\theta)} e^{aL(\theta)} \quad (1)$$

At a given geophone, two factors control the amplitude ratio between R1 and R2. First, R1 and R2 reflect off of the lake with slightly different angles, which changes the relative amount of energy partitioned into each reflection. Second, since R2 travels
130 farther than R1, its amplitude is diminished due to geometrical spreading and attenuation. However, at incidence angles in this study, the difference in reflection coefficients between R1 and R2 is negligible. Additionally, the path lengths of R1 and R2 vary by < 5% between their shortest and farthest offsets. Therefore, to calculate the reflection coefficient c_R we use the normal
135 incidence approximation and compare amplitude ratios A_{R2}/A_{R1} on individual seismograms. In order to minimize the influence of the air wave on A_{R2}/A_{R1} ratio we exclude data from geophones with offsets between 135 – 155 m, where there is potential interference between R1 and the air wave. Measurements of A_{R1} and A_{R2} are made prior to f-k filtering.

The relationship between the absorption coefficient a and the seismic quality factor Q is given by Eq. (2), where c is the seismic velocity, and f is frequency (Bentley & Kohnen, 1976). While in principle, the spectral ratio of the R1 and R2 reflections can be used to determine the attenuation (Q^{-1}) of the glacial ice (Dasgupta & Clark, 1998; Peters et al., 2012) the low signal to
140 noise ratio of the R2 reflection prevents us from making a robust measurement. Here, we estimate the absorption coefficient a based on the study of Peters et al. (2012), who reported $Q = 355 \pm 75$ in the upper 1 km of ice in Jakobshavn Isbrae, western Greenland. Using Eq. (2) with $c = 3.7$ km/s, and assuming a frequency of 100 Hz (the predominant frequency observed in the reflections), this corresponds to an absorption factor $a = 0.23 \pm 0.06$.

$$Q^{-1} = \frac{ca}{\pi f} \quad (2)$$

Assuming an absorption factor of $a = 0.23$, the average reflection coefficient of the lake bottom across the transect is -0.42 ± 0.15 (Fig. 4A). In Fig. 4B, we plot c_R calculated for each shot gather above the lake as a function distance along the transect. For comparison we show the expected reflection coefficients of several different geologic materials underlying glacial ice. The reflection coefficients were modeled using the two-term approximation of the Zoeppritz equations (e.g., Aki & Richards, 2002; Booth et al., 2015) with the material properties shown in Table 1. In contrast to other likely geological materials at the base of the ice, liquid water is expected to have a strongly negative reflection coefficient. The reflection coefficient modeled for
150 lithified sediments underlying ice is similar in amplitude to liquid water but opposite in sign, thus, without polarity information sedimentary rock strata could be mistaken for a lake signature. Here, we observe an opposite polarity of R1 and the seismic source which is consistent with the negative reflection coefficient expected for a subglacial lake. Thus, liquid water is the only material that is consistent with both the amplitude and sign of the observed reflections.

3 Discussion

155 3.1 Lake geometry and volume

If our interpretation of the observed reflections as signals from the lake top and bottom is correct, it implies that L2 could hold a significant volume of water. Assuming the imaged lake depth of approximately 15 m is representative of average lake depth throughout the roughly 10 km² surface area determined by RES, we estimate the total volume of liquid water to be 0.15 km³ (0.15 Gt of water). While this is only a small fraction of the 217 +/- 32 Gt of ice that Greenland is estimated to lose each year to glacier discharge and surface melting (IMBIE Team Report, 2019), the net storage capacity of all of Greenland's subglacial lakes could be appreciable. To verify our interpretation of the lake top and bottom reflections, we modeled synthetic seismic waveforms of shot gather 12, which contained some of the clearest reflections. This shot gather corresponds to transect distances between 660 - 720 m in the seismic reflection image. Synthetic seismograms were computed using Specfem2D (Tromp et al., 2008) for two simple layered models of a 12 m thick lake underlying 850 m of glacial ice. In the first model the lake is underlain by a thick layer of sediments that extends to the bottom of the model domain. In the second model there is 10 m of sediments overlying a discontinuity with the bedrock below. The seismic velocity profiles for the two cases are shown in the insets in Fig. 5B and 5C. The source used in the simulations was a Ricker wavelet with a dominant frequency of 100 Hz. Fig. 5 shows a comparison between the observations and synthetics. In both the observed (Fig. 5A) and synthetic (Fig. 5B and 5C) shot gathers, the lake top and lake bottom reflections are separated by ~ 20 ms, and show a clear polarity reversal, which reflects the opposite sign of the acoustic impedance contrast between an ice-water and a water-lake bed transition. The observed shot gather contains a coda following the lake bottom reflection that is absent in the synthetics that do not include a discontinuity at the base of the sediment package (Fig. 5B). When a discontinuity between the sediment and underlying bedrock is included a strong sediment bottom reflection is introduced which more closely matches the observations (Fig. 5C). In the observed data it is difficult to clearly identify a sediment bottom reflection since the complex coda could be caused by reverberations within a thin sediment sequence, or many superposed reflections from individual discontinuities. However, if the first positive peak following the lake bottom reflection represents the base of the sediment, we can estimate a sediment thickness of 8.5 m assuming a sediment V_P of 1700 m/s (Table 1).

3.2 Lake origin

While our results confirm that L2 is indeed a subglacial lake, its presence is perplexing given its location with a mean annual surface temperature of -22° C, and its position beneath a relatively thin column of glacial ice. In contrast to many well studied subglacial lakes below Antarctica such as Lake Vostok that lie below ~ 4 km of ice, the basal temperature at our field site is expected to be well below the pressure dependent melting point of ice. Distinguishing between the different hypotheses of subglacial lake formation has implications for the stability and dynamics of the GrIS since they predict different basal thermal and hydrological conditions. Thus, constraining the temperature of L2 is an important goal. We determine the range of possible basal temperatures using a 1D steady state advection-diffusion heat transfer model solved using the control volume method

(Patankar, 1980). The modeling assumes an ice density $\rho = 920 \text{ kg/m}^3$, a heat capacity $c_p = 2000 \text{ J/kg/K}$, and a thermal conductivity $k = 2.3 \text{ W/m/K}$. The basal geothermal heat flux q is varied between $50 - 60 \text{ mW/m}^2$, which is consistent with estimates derived from magnetic data (Martos et al., 2018) and thermal isostasy modeling (Artemieva, 2019). Fig. 6 shows results for surface temperatures T_s of -20° C and -22° C and accumulation rate w ranging from 0 to 0.3 m/yr ice equivalent.

190 When advection is ignored (i.e., no ice accumulation), most scenarios predict frozen bed conditions with the exception of the relatively warm surface condition ($T_s = -20^\circ \text{ C}$) and high heat flow ($q = 60 \text{ mW/m}^2$) scenario (Fig. 6A). When ice accumulation is considered, all scenarios predict frozen bed conditions (Fig. 6B). For an ice accumulation rate of 0.3 m/yr , which most closely matches the conditions of the field site, the basal temperature is expected to be between approximately -12° C and -14° C .

195

There are several possible explanations for the existence of liquid water in L2, including hypersalinity, recharge by surface meltwater, high geothermal flux, and latent heat from freezing.

(1) Hypersalinity: If the lake is hypersaline it would depress the freezing temperature. Because the ice surrounding the lake would be frozen to the bed, it would form a closed hydrologic system that could remain isolated on geologic timescales. In this scenario, the lake could represent a body of ancient marine water that was trapped as glacial ice advanced over the area and potentially further enriched in salt through cryogenic concentration processes (Lyons et al., 2005, 2019). Similar hypersaline lakes with salt concentrations several times higher than sea water are known to exist below the McMurdo Dry Valleys in Antarctica (Hubbard et al., 2004; Lyons et al., 2005, 2019; Mikucki et al., 2009) and in the Devon Ice Cap, Canada
205 (Rutishauser et al., 2018). However, because the current elevation of the lake is more than 500 m above sea level, it is unlikely to be trapped sea water as in the McMurdo Dry Valleys; however, we cannot rule out an ancient evaporite deposit as is proposed for the Devon Ice Cap (Rutishauser et al., 2018). However, the geologic map of Greenland does not indicate likely evaporites in this area (Dawes, 2004).

210 (2) Surface meltwater: The lake may be part of an open hydrological system that is continually recharged by surface meltwater. This lake, however, is in the accumulation area of the ice sheet, near the ice divide (Fig. 1B) and there are no obvious sources for significant surface recharge. To determine possible pathways for surface recharge, we estimate the local hydraulic head based on surface and bed elevations (Fig. S4) and find no pathways given the present resolution of bed and surface topography. It is possible that a subglacial pathway exists that is smaller than the resolution of BedMachine (Morlighem et al., 2017). If
215 the hydrological system is connected and the rate of recharge matches or exceeds the rate of freezing, a lake could persist despite sub-freezing temperatures in the lower part of the ice. At other locations in Greenland, observations of vertical surface deformation and collapse features have suggested that surface meltwater plays a prominent role in subglacial lake formation and dynamics (Palmer et al., 2015; Willis et al., 2015). Thus, subglacial lakes in Greenland could become more widespread as the GrIS responds to a warming polar climate.

220

(3) High geothermal flux. Anomalously high basal heat flux may promote melting of the GrIS from below (Fahnestock et al. 2001; Rogozhina et al., 2016). If this is the case, the local geothermal heat flux must greatly exceed regional estimates of the geothermal heat flux beneath the northwestern GrIS, which are typically in the range of 50 – 60 mW/m² (Artemieva, 2019; Martos et al., 2018; Rogozhina et al., 2016). Based on the one-dimensional model shown in Fig. 6, a geothermal flux on the order of 100 mW/m² would be necessary to sustain the lake. While high heat flux in this region would be unexpected based on the cratonic bedrock geology and lack of recent volcanism, a local region of high heat flux could be promoted by the presence of upper crustal granitoids rich in radiogenic heat producing elements or hydrothermal fluid migration through pre-existing fault systems (e.g., Jordan et al., 2018).

230

(4) Latent heat from freezing. For either the isolated lake of actively freezing brine (as in Hypothesis 1) or the hydrologically connected continuous flow (Hypothesis 2), or if the lake is a relic of a larger freshwater body that is slowly freezing, the thermal profile of the ice would show a curvature change at depth due to a latent heat source at the bottom boundary. Given a latent heat of freezing of 334 J/g, freezing a layer 1 m thick to the bottom of the ice over one year is roughly equivalent to increasing the geothermal flux by 10 mW/m². Sustaining a freezing rate of several m/yr to generate the latent heat necessary to maintain warm basal ice is less likely than locally elevated geothermal anomaly. We, therefore, rule out cryoconcentration and narrow the lake origin hypotheses to either anomalously high geothermal flux or hypersalinity due to local ancient evaporite. Measuring the thermal profile above this lake would provide important information to assess these hypotheses as the basal ice temperature would be near 0° C for the freshwater lake created by high geothermal flux hypothesis and substantially below zero for the hypersaline lake created by evaporite.

240

A freshwater lake and a hypersaline lake have different physical properties and thus may have different signatures that could be detected in geophysical surveys. Radar reflections from an ice/brine boundary undergoing freezing and cryoconcentration of the brine is known to cause scattering and decrease the reflectivity (Badgeley et al., 2017) which we do not see in our data; this provides a second justification to rule out cryoconcentration. Further, because the seismic velocity and density of water depends on temperature and salinity, we would expect that lakes formed by different mechanisms would have slightly different basal reflection coefficients c_R . To estimate the difference in c_R for different lake conditions, we calculate the basal reflectivity as described in Section 2.2 for low and high salinity end member scenarios. The V_P in water is calculated as a function of pressure, temperature, and salinity using Equation (7) from Coppens (1981). At 0° C, the difference between c_R of a freshwater lake and a saline lake with 100 ppt (approximately three times the salinity of ocean water) is 0.06 at normal incidence. While a hypersaline lake could remain liquid at temperatures below 0° C, reducing temperature and increasing salinity have the opposite effect on seismic velocities thus reducing temperature below 0° C would decrease the contrast in c_R . Because the difference in reflection coefficient calculated for end member scenarios of 0.06 is smaller than the uncertainty on our measurements (approximately 0.15) we are unable to distinguish between different models of lake salinity and temperature

250

255 from our basal reflectivity analysis. On the other hand, because the electrical resistivity of water is strongly dependent on
salinity, magnetic sounding could provide useful constraints on lake composition. Future active source seismic experiments
focused on measuring Q within the overlying glacial ice could help us constrain the thermal profile above the lake (Peters et
al., 2012). Additionally, repeated seismic reflection or GPR surveys calculated along the same transect could provide clues
into whether or not lake levels are changing over time (e.g., Church et al., 2020). Direct sampling with drilling would provide
the best measurements on subglacial lake properties and could also yield useful biological and paleoenvironmental information.

260

4 Conclusions

We conducted an active source seismic reflection and GPR survey in northwestern Greenland above a site that was previously
identified as a possible subglacial lake. We observed a horizontal reflector at the base of the ice across the majority survey
with a seismic reflection coefficient of -0.42 ± 0.15 , confirming the presence of a subglacial lake. Additionally, we observed
265 a lake bottom reflection near the center of our seismic profile consistent with a lake depth of approximately 15 m. From
previous observations of the lateral extent of the lake based on RES (Peters et al. 2013), we estimate the subglacial lake holds
a total of 0.15 Gt of water. Strong coda arriving after the lake-bottom reflection suggests that the lake is underlain by a
sedimentary package but its thickness and material properties are uncertain. To the authors knowledge, this is the first time a
ground based geophysical survey has confirmed the existence of a subglacial lake in Greenland and provided constraints on
270 its depth. Understanding the nature and origins of recently detected subglacial lakes in Greenland is important since wet basal
conditions enable glacial ice to flow more easily which can further promote ice loss. Our analysis of the seismic, radar, as well
as thermal and hydropotential modeling narrow the lake origins to either locally high geothermal flux or an ancient evaporite
deposit. Future work, such as additional geophysical investigations or drilling expeditions, should focus on constraining the
temperature and salinity of the lake which will provide clues to its origin. Additionally, monitoring the vertical motion of the
275 ice surface above the subglacial lake system with satellite altimetry could provide further insight into the subglacial hydrology
(e.g., Siegfried & Fricker, 2018).

405 **Figure 1: (A) Map of Greenland showing our field location in the northwest. (B) Composite satellite image from Landsat 8 taken between 2018-5-20 and 2018-5-27. (C) Close up map of field region. The green stars show the active source shot and the orange line shows the track of the GPR survey. Only the first of 4 shot locations for each geophone line is plotted. (D) Geometry of the active source experiment for a single geophone line. Raypaths of R1 are plotted for all 4 shot locations.**

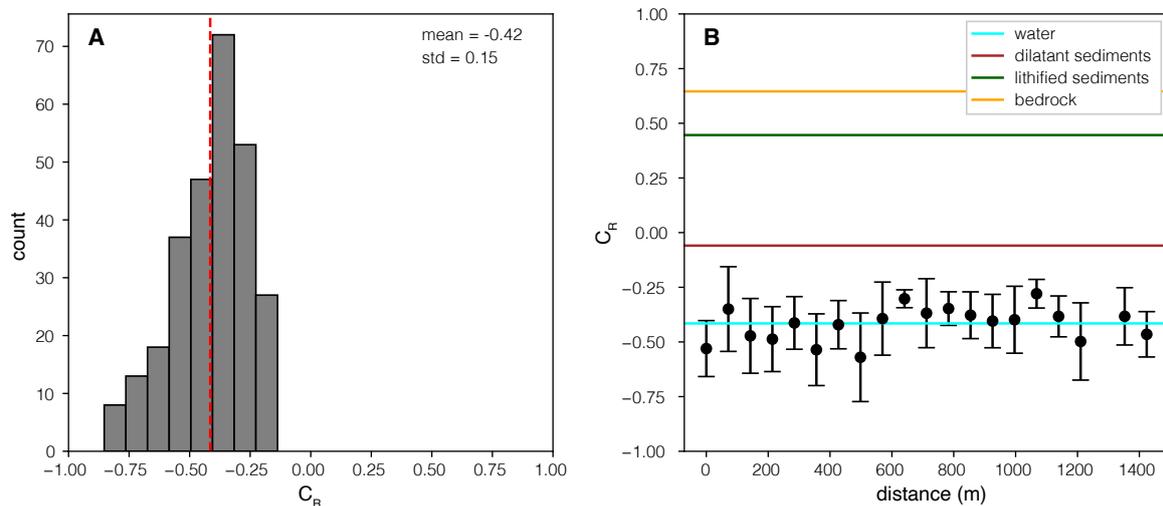

410 Figure 2. (A) shows the seismic reflection profile of the entire traverse. Reflections labeled R1 and R2 correspond to the primary
415 reflection from the lake top and its multiple. A transect distance of 0 m corresponds to the southwestern end of the line. (B) shows a
close up of the R1 reflection window (black rectangle in A), showing reflections from both the lake top and bottom. Travel time picks
of the lake top and lake bottom reflections are drawn with the dashed blue line. The depth of the lake inferred from the picked
reflections assuming a lake V_P of 1498 m/s is shown in (C). Blue shaded regions indicate where the lake bottom reflection is most
clearly identified.

420 **Figure 3.** GPR profile. (A) shows the 10 MHz radar data, unmigrated. The horizons outlined in red are the top and bottom of the ice. The depth from the surface to the base of the ice is shown in (B). Vertical dashed lines mark the approximate endpoints of the seismic survey.

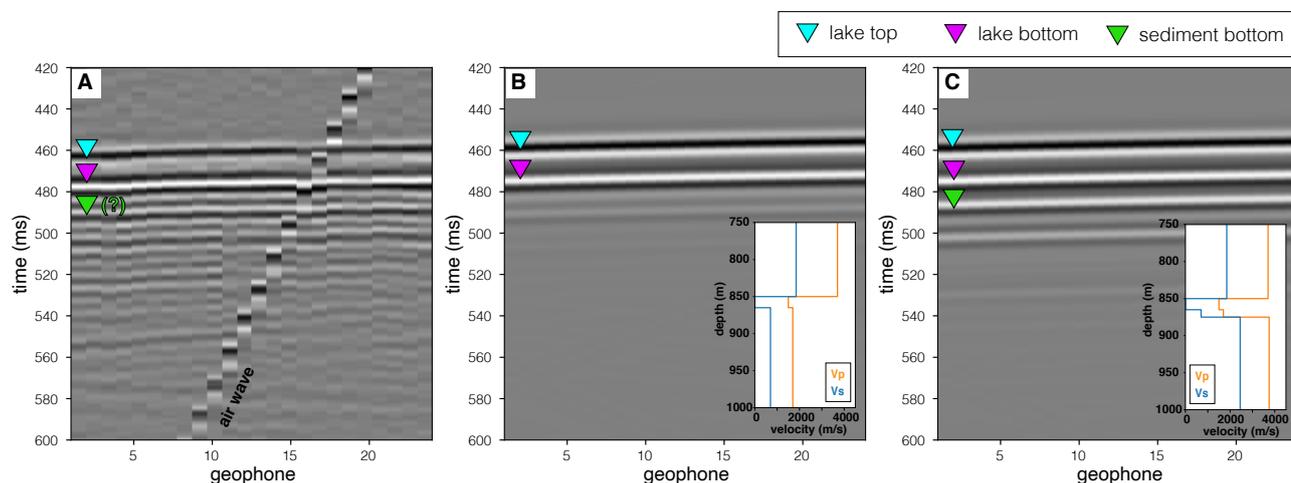

425

430 **Figure 4. (A) Distribution of reflection coefficients C_R for locations where both R1 and R2 are observed. Only data collected over the subglacial lake is included. (B) Observed (black points) and expected (colored lines) reflection coefficients for shot gathers, shown as a function of distance along the transect.**

435

440

445 **Figure 5.** Observed (A) and synthetic (B and C) seismic data for shot gather 12 bandpass filtered between 50 – 200 Hz. The offset from the source to geophone 1 is 230 m. The colored triangles indicate reflections from the lake top (blue), lake bottom (purple), and sediment bottom (green). The insets in panels B and C show the Vp and Vs models that were used to compute the synthetics. Both models include a 12 m thick lake below 850 m of ice. The model used in (C) includes an additional discontinuity 10 m below the lake, which represents the boundary between the lake bottom sediments and underlying bedrock.

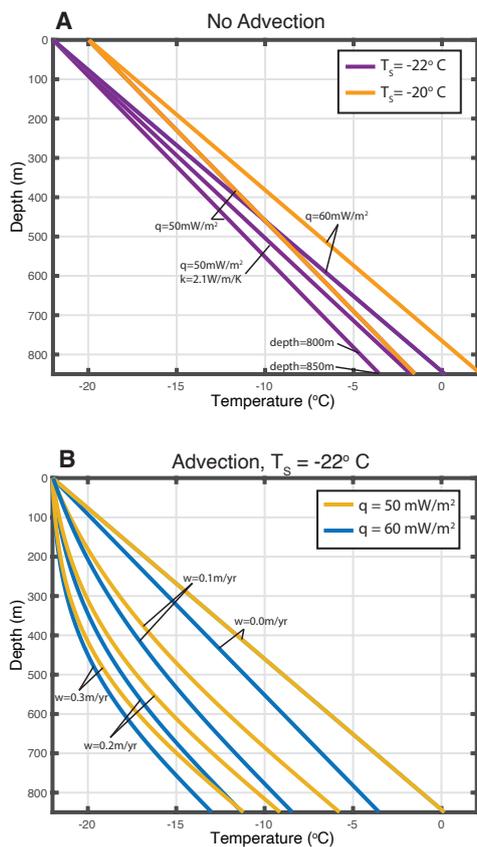

Figure 6. Modeling of ice sheet thermal structure. Panel A shows thermal profiles neglecting advection for surface temperatures $T_s = -22^\circ\text{C}$ and $T_s = -20^\circ\text{C}$. Panel B shows thermal profiles including advection for surface temperatures of $T_s = -22^\circ\text{C}$ and $T_s = -20^\circ\text{C}$, respectively. The basal heat flux q is varied between $50 - 60\text{ mW/m}^2$ and the accumulation rate w is varied between 0 m/yr and 0.3 m/yr .

Material	V_P (m/s)	V_S (m/s)	Density (kg/m^3)
Glacial ice	3810	1860	920
Water	1498	0	1000
Dilatant sediment	1700	200	1800
Lithified sediment	3750	2450	2450
Bedrock	5200	2700	2700

Table 1. Description of material properties used in reflection coefficient modeling. Values are from Peters et al. (2008).
