Abstract. The pathways and timing of drainage from inundated ice-wedge polygon centers in a warming climate have important implications for carbon flushing, advective heat transport, and transitions from carbon dioxide to methane dominated emissions. This research provides intuition on this process by presenting the first in-depth analysis of drainage from a single polygon based on fundamental hydrogeological principles. We use a recently developed analytical solution to provide a baseline for the effects of polygon aspect ratios (radius to thawed depth) and hydraulic conductivity anisotropy (horizontal to vertical hydraulic conductivity) on drainage pathways and temporal depletion of ponded water heights of inundated ice-wedge polygon centers. By varying the polygon aspect ratio, we evaluate the effect of polygon size (width), inter-annual increases in active layer thickness, and seasonal increases in thaw depth on drainage. One of the primary insights from the model is that most inundated ice-wedge polygon drainage occurs along an annular region of the polygon center near the rims. This implies that inundated polygons are most intensely flushed by drainage in an annular region along their horizontal periphery, with implications for transport of nutrients (such as dissolved organic carbon) and advection of heat towards ice-wedge tops. The model indicates that polygons with large aspect ratios and high anisotropy will have the most distributed drainage. Polygons with large aspect ratios and low anisotropy will have their drainage most focused near their periphery and will drain most slowly. Polygons with small aspect ratios and high anisotropy will drain most quickly. Our results, based on idealized scenarios, provide a baseline for further research considering geometric and hydraulic complexities of ice-wedge polygons.

1 Introduction

Polygonal tundra occurs in continuous permafrost landscapes lacking exposed bedrock or active sedimentation (Brown et al., 1997; Mackay, 2000) and is estimated to occupy around 250,000 km², or around 3% of the Arctic landmass predominantly along the north coasts of Alaska and Siberia (Minke et al., 2007). It is rich in organic carbon (Tarnocai et al., 2009; Hugelius et al., 2014) which is poised to release to the atmosphere as carbon dioxide or methane under a warming climate causing a potential feedback to climate change (Schuur et al., 2008). The microtopography of polygonal tundra collects precipitation

Figure 1. Pie-wedge schematic diagram of 3D-axisymmetric analytical model of inundated low-centered polygon drainage. The diagram represents an idealized *pie wedge* slice of a low-centered polygon including a wedge of the ponded center, rim, and trough. Equipotential hydraulic head lines are denoted as $h(r,z)$ and streamlines as $\Psi(r,z)$. L is the depth of the thawed soil layer and R is the radius of the polygon center. The ponded water height ($H_c(t)$) and trough water level (H_t) are noted.

and snowmelt events resulting in a slow-release from the landscape through the thawed subsurface to surface water drainage networks. This process has important implications for the release of dissolved organic matter from polygon tundra landscapes
25 flushed from the subsurface to surface waters and transport of heat through the subsurface. The role that polygonal tundra regions play in global terrestrial biogeochemical feedbacks as the Arctic warms necessitates understanding their hydrologic flow regimes, including carbon fluxes from the landscape.

Polygonal tundra forms in cold environments by the cyclic process of vertical cracking of frozen ground due to thermal contraction, water infiltration into these cracks, freezing of this infiltrated water, and subsequent re-cracking. Over many cycles,
30 this process leads to the growth of subsurface ice-wedges connected in polygonal patterns known as ice-wedge polygons (Liljedahl et al., 2016). Ice-wedge polygons vary in size from several meters to a few tens of meters in diameter and develop over time frames of hundreds to thousands of years (Leffingwell, 1915; Lachenbruch, 1962; Mackay, 2000; Abolt et al., 2018). Thermal expansion of the ice and soil during summer months often results in warping the soil strata forming parallel rims on both sides of the ice-wedge and a trough directly above the ice-wedge (refer to Figure 1). Ice-wedge polygons with well-
35 formed rims and troughs with a distinct, central topographic depression are referred to as low-centered polygons. Ponding occurs frequently in the centers because the rims can trap water during snowmelt or precipitation events. This ponded water subsequently drains through the subsurface to the troughs (Helbig et al., 2013; Koch et al., 2018; Wales et al., 2020).

Recent observational studies have shaped our current conceptualization of low-centered polygonal tundra hydrology (Boike et al., 2008; Helbig et al., 2013; Koch et al., 2014; Liljedahl et al., 2016; Koch, 2016; Koch et al., 2018) indicating a system
40 of inundated polygonal centers surrounded by elevated rims that prevent surface water from flowing overland into surrounding

trough ponds. This land formation results in standing water over the polygon centers, reduces immediate landscape runoff from precipitation events, and increases evaporation (Liljedahl et al., 2016). Additionally, the elevated ponded water in polygon centers produces hydrological gradients that result in sustained outward flow through the subsurface under the rims, a process that has been observed at multiple field sites (Helbig et al., 2013; Liljedahl and Wilson, 2016; Koch, 2016; Wales et al., 2020). This lateral flow controls landscape redistribution of water during the summer months (Helbig et al., 2013), governs ponded water budgets (Koch et al., 2014; Koch, 2016), and makes up a notable portion of regional river discharge (King et al., 2020). The manner and timing with which polygonal tundra landscapes transition from inundated to drained has important implications for (1) transitions from atmospheric emissions of methane to carbon dioxide (Conway and Steele, 1989; Moore and Dalva, 1997; Zona et al., 2011; Zhu et al., 2013; O'Shea et al., 2014; Throckmorton et al., 2015; Wainwright et al., 2015; Lara et al., 2015; Vaughn et al., 2016), (2) dissolved organic carbon emissions to surface waters (Zona et al., 2011; Abnizova et al., 2012; Laurion and Mladenov, 2013; Larouche et al., 2015; Plaza et al., 2019), (3) biological succession (Billings and Peterson, 1980; Jorgenson et al., 2015; Wolter et al., 2016), and (4) ground surface deformation (Mackay, 1990, 2000; Reynolds et al., 2014; Nitzbon et al., 2019).

The microtopographic features of polygonal tundra result in sharply contrasting spatial thermal and hydrologic conditions (Boike et al., 2008; Zona et al., 2011; Helbig et al., 2013) leading to sharply contrasting spatial biogeochemical conditions (Newman et al., 2015; Norby et al., 2019). Standing water in polygonal centers shows distinctly different chemistry compared to surface water in troughs and ponds (Zona et al., 2011; Koch et al., 2014, 2018) which has been attributed to shallow subsurface flow from centers to troughs (Koch, 2016). For example, Koch et al. (2014) observed high nutrient concentrations in troughs adjacent to centers with low concentrations, indicating inundated center drainage to troughs. Given that the ice-wedge polygon can be considered the fundamental hydrologic landscape unit that initiates landscape-scale surface/subsurface flow and discharge, understanding their characteristic drainage pathways and residence times then provides a basis to quantify the transport of terrestrially sourced dissolved organic carbon to surface waters, which then can be mineralized and released back to the atmosphere (Raymond et al., 2013).

Although there have been numerous field observations of inundated low-centered polygon drainage to troughs (Helbig et al., 2013; Koch et al., 2014; Wales et al., 2020), the research here is, to our knowledge, the first in-depth investigation into the pathways and timing associated with inundated ice-wedge polygon drainage based on fundamental hydrologic principles. Aside from the field tracer experiments of Wales et al. (2020), previous research has primarily focused on 1D vertical hydrothermal effects within ice-wedge polygons (Atchley et al., 2015; Harp et al., 2015; Atchley et al., 2016) or ice-wedge surface hydrology (Boike et al., 2008; Jan et al., 2018a, b). Other researchers have investigated the hydrology of multiple polygons without investigating the drainage pathways within individual ice-wedge polygons (Cresto-Aleina et al., 2013; Nitzbon et al., 2019). While fundamental hydrology dictates that ice-wedge polygon geometry and heterogeneity will explicitly govern subsurface drainage pathways and duration, to date, a fundamental hydrological investigation of this process has not been presented.

The geometric shape of low-centered polygons along with soil hydraulic properties (for example, hydraulic conductivity) affects the distribution of hydraulic heads that control the pathways and timing of inundated ice-wedge polygon drainage. In this paper, we use fundamental hydrogeological principles (Harr, 1962; Cedergren, 1968; Freeze and Cherry, 1979; Bear,

1979) to understand and gain intuition into the effects of geometry and hydraulic properties on inundated ice-wedge polygon drainage. We investigate the pathways and timing of inundated polygon drainage using a 3D-axisymmetric analytical solution of groundwater heads. This approach idealizes the thawed subsurface of an inundated low-centered polygon as a thin cylinder overlain with an initial height of ponded water that drains through the cylindrical thawed soil layer to the surrounding trough (outer vertical boundary; annular ring defined by a line from $(R,0)$ to (R,L) in Figure 1). The depth (L) and radius (R) of the thawed soil layer of the polygon center and horizontal (radial) and vertical hydraulic conductivity are variable within the solution. It is important to note that we are focusing on the drainage of inundated low-centered polygons here, and that biogeochemical investigations suggest that the drainage of non-inundated low-centered, transition, and high-centered polygons may have different characteristics (Heikoop et al., 2015; Newman et al., 2015; Wainwright et al., 2015; Wales et al., 2020). It is also important to note that we use a Robin boundary condition (a third-type boundary condition allowing both head and flux to be specified) for the outer vertical boundary. This allows the model to represent the resistance of drainage under the rim due to elevated frozen ground and due to the accumulation of fine soil particles at the soil/water interface of the trough.

This model provides fundamental insights that enhance our intuition into the pathways and timing of inundated ice-wedge polygon drainage for polygons with different geometries and degrees of anisotropy. Varying the geometry of the cylinder not only allows us to capture differences in drainage between different sized polygons (in other words, polygons with different radii), but also seasonal and inter-annual variations in polygon thaw-layer depth (in other words, as the thawed soil layer increases during the summer or as the active layer increases from year to year). By allowing for different hydraulic conductivities between the horizontal and vertical directions, we can evaluate the effects of preferential flow directions on drainage. In addition to geologic layering, processes such as frost heave and horizontal ice lens thaw can result in preferential horizontal flow in cold climates (Mackay, 1981; Matsuoka and Moriwaki, 1992; Wales et al., 2020). It has also been observed that high hydraulic conductivity peat layers overlying lower hydraulic conductivity mineral soil results in horizontal watershed drainage (McDonnell et al., 1991; Brown et al., 1999; Quinton and Marsh, 1999). Helbig et al. (2013) found that in polygon tundra, the peat layer quickly redistributed precipitation events across the subsurface topography from the rims to the centers and troughs. Vertical cracks, voids left from decayed roots, and animal burrows can result in preferential vertical flow. The cylindrical geometry and anisotropy are not intended to cover all potential variations in ice-wedge polygons, but rather provide base cases where those variations will cause deviations around the idealizations considered here.

The objective of our analysis is to provide a new perspective on inundated polygon hydrogeology indicating the implications of polygon geometry and hydraulic conductivity anisotropy on drainage pathways and timing. Although the simplifications of the model limit its use as a predictive tool that can be applied across inundated ice-wedge polygon scenarios, they allow general intuitive insights to be drawn which would be obfuscated if the simplifications had not been applied. The findings here initiate and direct further research ideas into the many complex features present in real-world polygonal tundra and provide a basis to quantify and understand deviations from our idealized scenarios. We have neglected the effects of evaporation and precipitation as they will not affect the drainage patterns we present (based on non-dimensional heads) and their effect on drainage timing (based on non-dimensional depletion curves) is straightforward, shifting the non-dimensional exponential

110 drainage curve upwards or downwards. In other words, using non-dimensional variables is a powerful approach to gain intuition into the fundamentals of inundated ice-wedge polygon drainage irrespective of variable magnitude.

Other factors, such as complex polygon geometric shapes and thaw table topography, will have more complicated effects on our results, but will be deviations from our idealized scenarios (i.e., heterogeneities will warp the drainage patterns presented here, but not fundamentally violate them). The intuition gained from the fundamental hydrological investigations presented here provide direction and impetus for additional modeling and observational studies.

2 Methods

2.1 Model overview

We use recently developed 3D-axisymmetric analytical solutions derived and validated in Zlotnik et al. (2020) and described in Appendix A, of hydraulic heads and the stream function in the thawed soil layer below a polygon center (dashed rectangle in Figure 1) to investigate inundated low-centered polygon drainage pathways. To generalize the results concerning polygon center and trough ponded heights, we use non-dimensional forms of the hydraulic head and stream function (refer to equation A7 and A8). The non-dimensional hydraulic heads and stream function are independent of time, representing the relative pattern of hydraulic heads and stream function throughout the drainage process. The dimensional values at different times would indicate the change in the absolute magnitude of these patterns as the drainage process proceeds. To evaluate drainage pathways, we plot flow nets, as illustrated in Figure 1, composed of lines of equal non-dimensional hydraulic head ($h^*(r^*, z^*)$), referred to as equipotentials, and contours of the stream function ($\Psi^*(r^*, z^*)$) as a function of radius and depth. The stream function contours are referred to as *streamlines* and are used here to identify steady drainage pathways.

Non-dimensional hydraulic head lines are drawn from 0.05 to 0.95 by increments of 0.1. Dimensional heads ($h(r, z, t)$) can be obtained from the non-dimensional heads ($h^*(r^*, z^*)$) using the ponded height of water in the polygon center $H_c(t)$ and the height of water in the trough H_t as

$$h(r, z, t) = H_t + (H_c(t) - H_t)h^*(r^*, z^*), \quad r^* = \frac{r}{L} \sqrt{\frac{K_z}{K_r}}, \quad z^* = \frac{z}{L}, \quad (1)$$

where r^* and z^* are non-dimensional radius and depth, respectively, L is the polygon thaw depth, and K_r and K_z are the radial (horizontal) and vertical hydraulic conductivity, respectively (refer to Figure 1).

The resistance to drainage below the polygon rim and across the soil/water interface into the trough is represented by a hydraulic conductance $\kappa = k/l$, where k is the hydraulic conductivity and l is the thickness of the drainage interface (refer to equation A3). This allows the model to account for a difference between hydraulic conductance beneath the rim from that in the polygon center. The soil under the rim may have less hydraulic conductive capacity than the polygon center due to a raised thaw table following the surface topography. The soil/water interface may have a lower conductance due to the accumulation of fine soil particles (Koch et al., 2018).

We normalize the stream function $\Psi(r^*, z^*)$ from 0 to 1, and similar to heads, plot stream function contours (streamlines) from 0.05 to 0.95 by increments of 0.1. The region between any two adjacent streamlines conveys 10% of the drainage,

while the two remaining regions (less than 0.05 and greater than 0.95), convey 5% of the drainage each. To make quantitative comparisons of the spread of drainage between polygons, we calculate the percent of each polygon volume accessed by 95% of the drainage (polygon volume with non-dimensional stream function > 0.05).

145 The change in non-dimensional ponded water height in the polygon center due solely to drainage (the depletion curve) over time can be expressed by a simple exponential decay function as

$$H_c^*(t) = e^{-t/t_L} \quad (2)$$

where t_L is the characteristic time of drainage (refer to equation A11), defined as the time when the ponded height is $1/e$ times, or $\sim 37\%$ of, its original height $H_{c,0}$. The dimensional ponded height $H_c(t)$ can be obtained as

$$150 \quad H_c(t) = H_t + (H_{c,0} - H_t)H_c^*(t). \quad (3)$$

2.2 Model parameterization

We selected aspect ratio and anisotropy scenarios based on existing literature and observations. While a pan-Arctic survey of ice-wedge polygon diameters does not to our knowledge currently exist, researchers have provided general characteristics based on extensive observations. Leffingwell (1915) states that ice-wedge polygons have an estimated average diameter of
155 around 15 m. Liljedahl et al. (2016) indicate that low-centered polygons (including rims) can have diameters from 5-30 m. Abolt et al. (2018) state that polygonal formations in ice-wedge tundra are 10-30 m in diameter. Based on digital elevation models, Abolt et al. (2019) calculate that the mean polygon diameter near Utqiagvik, Alaska is around 15 m with 5th and 95th percentiles of approximately 8 and 33 m, respectively. Using a similar analysis on data from near Prudhoe Bay (Abolt and Young, 2020), the mean polygon diameter is around 13 m with 5th and 95th percentiles of approximately 7 and 30 m,
160 respectively.

Maximum thaw depths are increasing throughout the Arctic (Jorgenson et al., 2006). Deeper thaw depths may ultimately result in low-centered polygon transition to high-centered polygons, at which time center inundation will cease to occur due to rim collapse. Therefore, there is a practical limit to the thaw depth of interest in our analysis. Lewkowicz (1994) reported that active layer thickness varied from 40 to 90 cm within the polygonal tundra of Fosheim Peninsula, Ellesmere Island, Canada
165 in 1994. Shiklomanov et al. (2010) reported that polygonal tundra at several study sites near Utqiagvik, Alaska monitored from 1995 to 2009 had active layer thicknesses from 17 to 47 cm. Based on extensive ground-penetrating radar surveys near Utqiagvik, Alaska in 2013, Jafarov et al. (2017) document that average active layer thickness was 41 cm with a standard deviation of 9 cm. Even for polygons with substantial active layer thickness, it is important to understand the change in drainage throughout the season by evaluating early-season thaw depths, which are captured in our analysis by larger aspect
170 ratios.

Based on these considerations, we evaluate aspect ratios from 2.5 to 20. For example, given a thawed depth of 1 m, an aspect ratio of 2.5 would represent a 2.5 m radius polygon center, while an aspect ratio of 20 would represent a 20 m radius polygon center, more than covering the observed range. To consider cases with thinner thawed soil layers, larger aspect ratios can be used. For example, given a thawed depth of 0.5 m, an aspect ratio of 20 would represent a polygon with a 10 m radius center.

175 Comprehensive measurements of hydraulic conductivity anisotropy are lacking from ice-wedge polygons. Based on tracer
arrival times, Wales et al. (2020) estimated horizontal conductivities of approximately 0.7 to 84 m d^{-1} for a low-centered
polygon and 0.01 to 0.3 m d^{-1} for a high-centered polygon. Wales et al. (2020) stated that these are considered lower bound
estimates of horizontal conductivity since, based solely on breakthrough times, the approach is unable to isolate horizontal
and vertical flow effects on arrival times. Beckwith et al. (2003) performed laboratory measurements of anisotropy on small
180 samples from peat soils where horizontal conductivities were around $6\text{-}7 \text{ m d}^{-1}$ and vertical conductivities were around $0.2\text{-}0.4$
 m d^{-1} indicating preferential horizontal flow. The soil samples used in Beckwith et al. (2003) were from peat bogs in England,
and therefore would not have been subjected to freeze-thaw dynamics that current ice-wedge polygons will have been subjected
to in recent times, which would presumably lead to even greater preferential horizontal flow. Therefore, these estimates may
provide a lower bound estimate for Arctic peat horizontal hydraulic conductivity. Based on the existing literature and above
185 considerations, we considered hydraulic conductivities from $0.005\text{-}5 \text{ m d}^{-1}$, primarily focusing on anisotropic values from 0.1
to 100 . These values allow us to investigate the effects of anisotropy on the drainage pathways and timing using hydraulic
conductivities consistent with currently available measurements.

The hydraulic conductivity of the interface between soil and open water can be half that of the rest of the soil due to
the accumulation of fines (Koch et al., 2018). The hydraulic conductance under the rim may also impede drainage due to a
190 raised thaw table following the surface topography. While the conductance of this interface (defined as κ above) will influence
drainage, preliminary analysis indicated that its effect on drainage was significantly less than that of aspect ratio and anisotropy.
Therefore, we chose to use a default value for κ in all cases (unless otherwise specified) of 5 d^{-1} .

In practice, the water level in troughs (H_t in equations 1 and 3) will vary throughout the thaw season, affecting the magnitude
of heads in the soil of the polygon center and drainage times. As the non-dimensional heads are relative to H_t (refer to
195 equation A7), its value does not affect our comparisons of drainage patterns (which are based on non-dimensional heads that
are normalized from 0 to 1). The value of H_t will affect our comparisons of drainage time, but in a systematic, interpretable
manner. For example, a higher H_t will compress the exponential curve defined by equation 3 upwards, while a lower H_t will
stretch the exponential curve downwards. In cases where H_t is below the polygon center ground surface, the solution is valid
until H_c reaches the ground surface, at which time the ponded center has completely drained. Therefore, to isolate our analysis
200 to aspect ratio and anisotropy, we have set H_t in all cases to the ground surface of the polygon center.

3 Results

Here, we present drainage flow nets for various aspect ratios and anisotropy values, polygon center ponded height depletion
curves, and maps of the percent of the thawed soil accessed by 95% of the drainage flow and depletion characteristic times as a
function of aspect ratio and anisotropy. We compare the effect of aspect ratio on drainage pathways in an isotropic and a highly
205 anisotropic ($K_r/K_z = 100$) polygon. The drainage pathways are also evaluated for various anisotropies holding the aspect ratio
constant. A global perspective of the combined effects of aspect ratio and anisotropy on the focusing/spreading of the drainage
flow is provided by mapping the percent of the polygon thawed soil volume that is accessed by 95% of the drainage flow.

We evaluate the effect of aspect ratio and anisotropy on drainage time by plotting the polygon ponded water height depletion curves. A global perspective on the combined effects of aspect ratio and anisotropy on drainage time is presented by mapping the depletion characteristic time. We illustrate the counteracting effects of aspect ratio and anisotropy on drainage pathways by showing two, although geometrically and hydrologically dissimilar, mathematically equivalent solutions of drainage.

3.1 Drainage pathways

The effect of aspect ratio on drainage pathways when the hydraulic conductivities are isotropic ($K_r/K_z = 1$) is shown in Figure 2. Under isotropic hydraulic conductivities, results show that the drainage pathway for high aspect ratio polygons will be predominantly isolated to an annular region at the periphery of the polygon center. As the aspect ratio decreases (in other words, the thawed region of the polygon subsurface becomes deeper with respect to its width), the portion of the polygon accessed by drainage increases. For an aspect ratio of 20 (Figure 2a), 95% of the drainage is focused within around 5% of the polygon volume, while for an aspect ratio of 2.5 (Figure 2d), the drainage is spread over around 29% of the polygon volume. The spreading (increase in the accessed volume) occurs along the radial direction, where the horizontal extent of the accessed volume moves towards the middle of the polygon center ($r = 0$), while the vertical extent is nearly unchanged. The results in Figure 2 indicate that throughout the thaw season, as the thaw depth increases, the drainage path will spread out towards the middle of the polygon center. Similarly, Figure 2 can be used to evaluate drainage pathways of polygons of different widths but similar thaw depths. In this context, Figure 2 indicates that wider polygons will have more focused drainage, while drainage for smaller polygons will be more dispersed.

The effect of anisotropy on drainage pathways when the aspect ratio is held constant ($R/L = 10$) is shown in Figure 3. As anisotropy increases (in other words, the more that horizontal hydraulic conductivity dominates), the region accessed by drainage flow becomes larger. Similar to a decreasing aspect ratio in Figure 2, increasing anisotropy leads to a larger radial extent of the accessed region, while the vertical extent is nearly unaffected. When the vertical conductivity is ten times the horizontal (Figure 3a), only around 3% of the polygon volume is accessed by 95% of the drainage. If horizontal conductivity is 100 times vertical conductivity (Figure 3d), around 49% is accessed. These results indicate that anisotropy has a significant impact on ice-wedge polygon drainage pathways.

The effect of aspect ratio on drainage pathways when the hydraulic conductivities are highly anisotropic ($K_r/K_z = 100$) is shown in Figure 4. In this case, contrary to the isotropic case in Figure 2, as the aspect ratio decreases, the accessed volume generally decreases. However, the largest accessed volume is for an aspect ratio of 10 (Figure 4b), not 20 (Figure 4a). This nuance in the dependence of accessed volume to aspect ratio with high anisotropy is due to the competing effects of radial extension and vertical contraction of the accessed volume as aspect ratio decreases. By comparing Figures 2 and 4, it is also apparent that the volume accessed by 95% of the drainage is generally larger with higher anisotropy.

To gain a global perspective on the trends in drainage pathways with aspect ratio and anisotropy, Figure 5 maps the percent of the polygon accessed by 95% of the drainage as a function of aspect ratio and anisotropy. This illustrates the overall structure of the combined effect of aspect ratio and anisotropy on accessed volume (focused versus dispersed drainage). As indicated by annotated points, the trend in accessed volume with respect to aspect ratio in Figure 2 is represented along the anisotropy=1

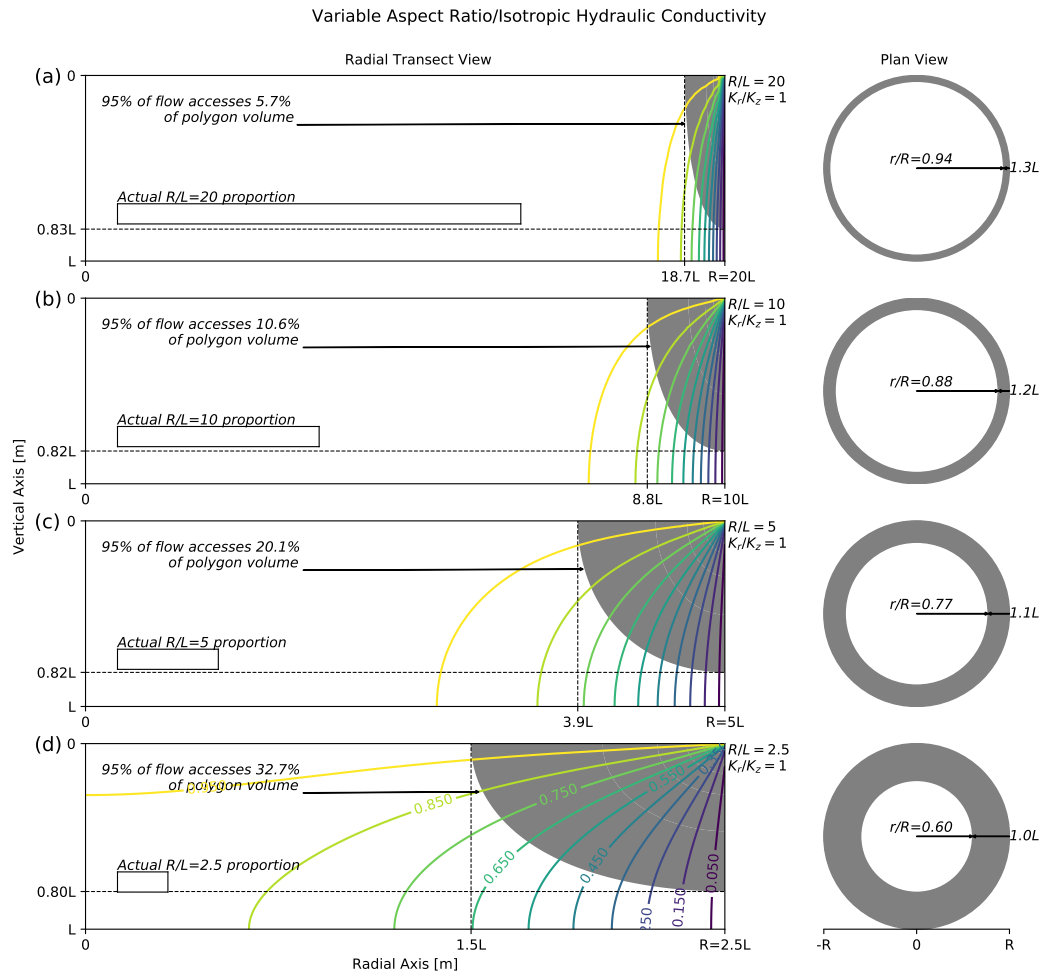

Figure 2. Effect of polygon aspect ratio on polygon drainage with isotropic hydraulic conductivity. Plots along the left contain polygon radial transect head contours (colored lines) and filled stream tubes (grey regions) for several polygon aspect ratios (radius/thickness). The grey shaded region denotes the portion of the transect accessed by 95% of the flow. The plots along the right contain corresponding grey rings indicating the surface area where 95% of the polygon flow infiltrates. Each plot along the left contains a rectangle drawn to the actual proportions for the given polygon aspect ratio. In all cases, the anisotropy (horizontal/vertical conductivity) is fixed at unity.

transect, while the trend in Figure 4 is represented by the anisotropy=100 transect. The trend in accessed volume with respect to anisotropy in Figure 3 along the aspect ratio=10 transect is likewise indicated. There is a spreading ridge-like structure in the accessed volume with increasing aspect ratio and anisotropy with decreasing accessed volume on either side of this curved

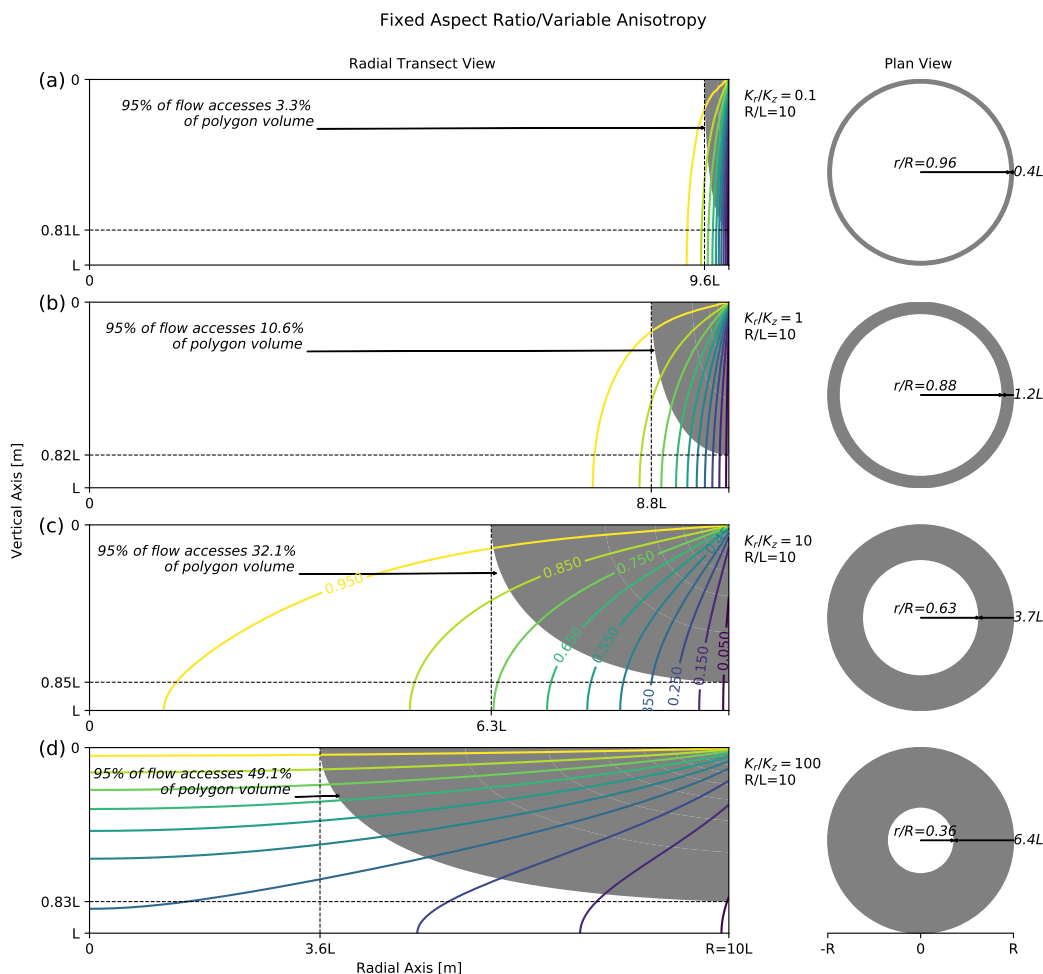

Figure 3. Effect of hydraulic conductivity anisotropy on polygon drainage. Plots along the left contain polygon radial transect head contours (colored lines) and filled stream tubes (grey regions) for several anisotropies (horizontal/vertical conductivity). The grey shaded region denotes the portion of the transect accessed by 95% of the flow. The plots along the right contain corresponding grey rings indicating the surface area where 95% of the polygon flow infiltrates. Each plot along the left contains a rectangle drawn to the actual proportions for the given polygon aspect ratio. In all cases, the polygon aspect ratio (radius/thickness) is fixed at 10.

245 ridgeline. The ridge represents the optimal balance of radial and vertical extension of the accessed volume region, as described in the previous paragraph. This structure explains the increasing accessed volume with decreasing aspect ratio in Figure 2 and the maximum accessed volume at aspect ratio of 10 in Figure 4. The drainage flow is most spread out (largest accessed

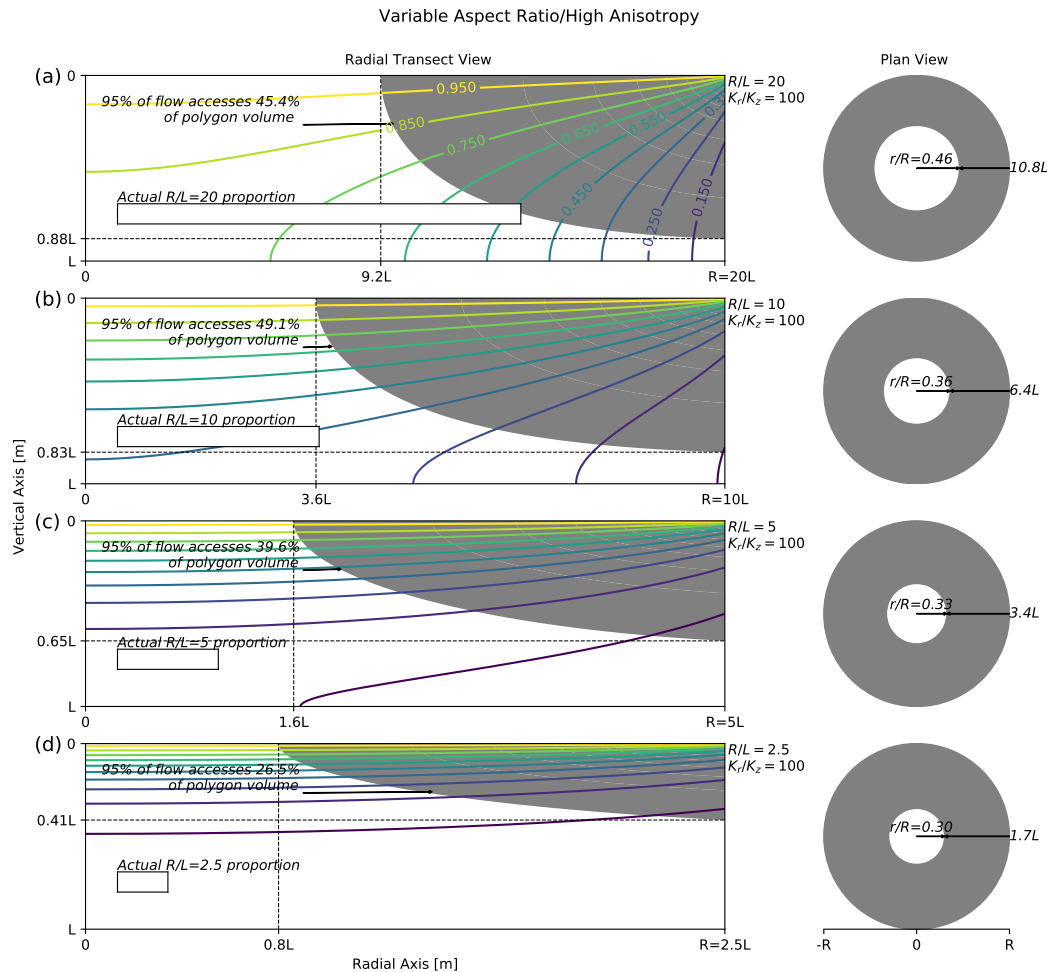

Figure 4. Effect of polygon aspect ratio on polygon drainage with high hydraulic conductivity anisotropy ($K_r/K_z = 100$). Plots along the left contain polygon radial transect head contours (colored lines) and filled stream tubes (grey regions) for several polygon aspect ratios (radius/thickness). The grey shaded region denotes the portion of the transect accessed by 95% of the flow. The plots along the right contain corresponding grey rings indicating the surface area where 95% of the polygon flow infiltrates. Each plot along the left contains a rectangle drawn to the actual proportions for the given polygon aspect ratio. In all cases, the anisotropy (horizontal conductivity/vertical conductivity) is fixed at 100.

volume) when the aspect ratio is large and the anisotropy is high (upper right of Figure 5). The drainage is the most focused (least accessed volume) when the aspect ratio is large and the anisotropy is low (lower right of Figure 5).

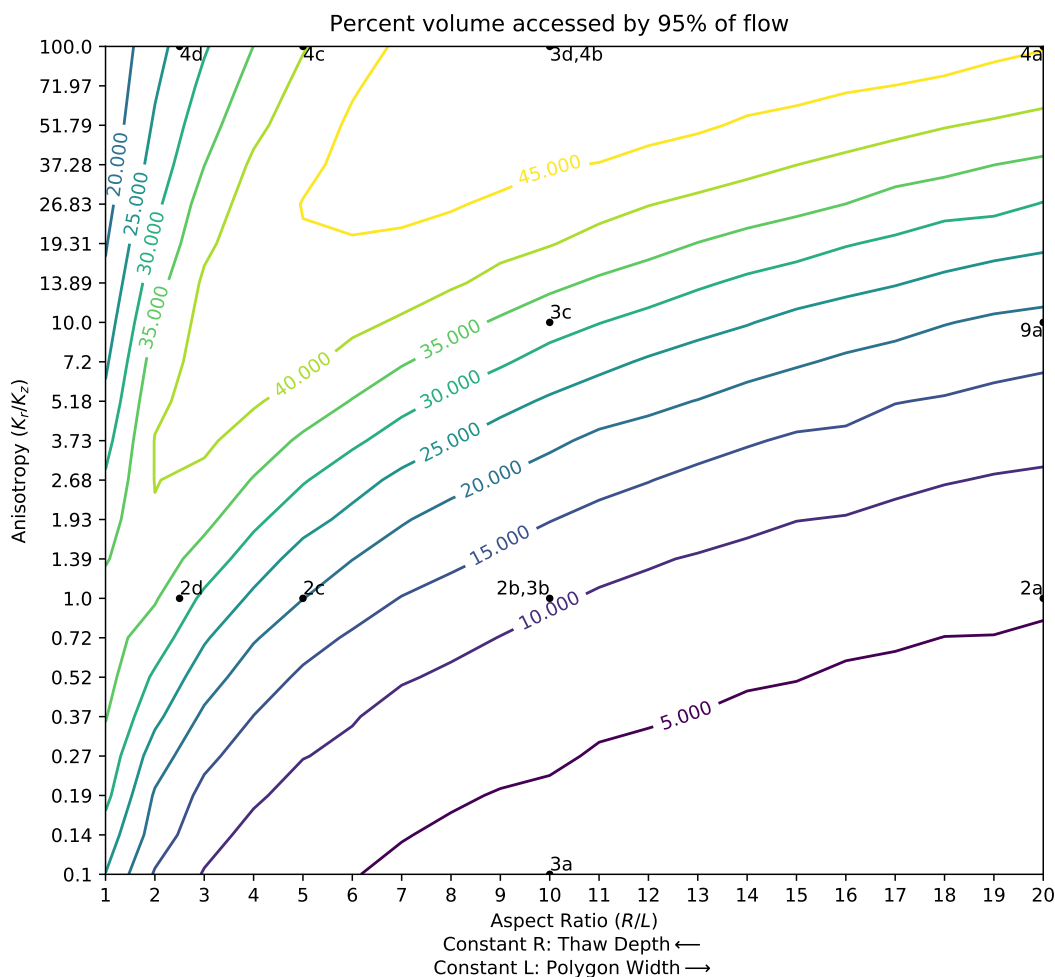

Figure 5. Contour map of the percent of the polygon access by 95% of the flow as a function of polygon aspect ratio and anisotropy. Locations associated with other figures are indicated by labeled points. By choosing a constant value for R ($L = R/x$), horizontal transects parallel to the x-axis represent the effect of thaw depth increasing from right to left, while they represent increasing polygon width from left to right for constant values of L ($R = Lx$). Note that $\kappa = 5 \text{ day}^{-1}$ in these calculations, and therefore, the location associated with Figure 9b cannot be indicated.

250 3.2 Ponded water depletion

Depletion curves for the non-dimensional ponded water height in the polygon center for various aspect ratios (at fixed high and low anisotropy) and anisotropies are shown in Figures 6a, b, and c, respectively. Note that since the depletion of the volume of ponded water is directly related to the ponded water height, the plots in Figure 6 can be used to obtain either, as indicated by

Figure 6. Depletion of ponded water height over time ($H_c(t)$) for (a,b) alternative polygon aspect ratios (radius/depth (R/L)) and (c) anisotropy (K_r/K_z). Plots (a) and (b) have anisotropy fixed at unity with plot (a) having high conductivity ($K_r = K_z = 0.5$ m/s) and plot (b) low conductivity ($K_r = K_z = 0.05$ m/s). The aspect ratio is fixed at 10 in plot (c). The curves also describe the depletion of ponded water volume over time ($V(t)$). Dashed lines indicate the characteristic times (t_L) in each case. Note that the orange line in (b) and (c) are identical, $R/L = 10$ and $K_r/K_z = 1$.

the y-axis labels. As a point of reference between depletion curves, the characteristic time (the time when the height or volume
 255 of ponded water reaches $1/e \approx 0.37$ its initial height or volume) is indicated.

It is apparent from these plots that small, deeply thawed (lower aspect ratio) polygons will drain faster than wide, shallowly thawed (high aspect ratio) polygons, while polygons with higher anisotropy will drain faster than those with low anisotropy. It is also apparent that the increase in drainage time with aspect ratio is nearly linear, while for anisotropy, it is exponential. This is further illustrated in Figure 7, where we plot the trend in characteristic times as a function of aspect ratio for various

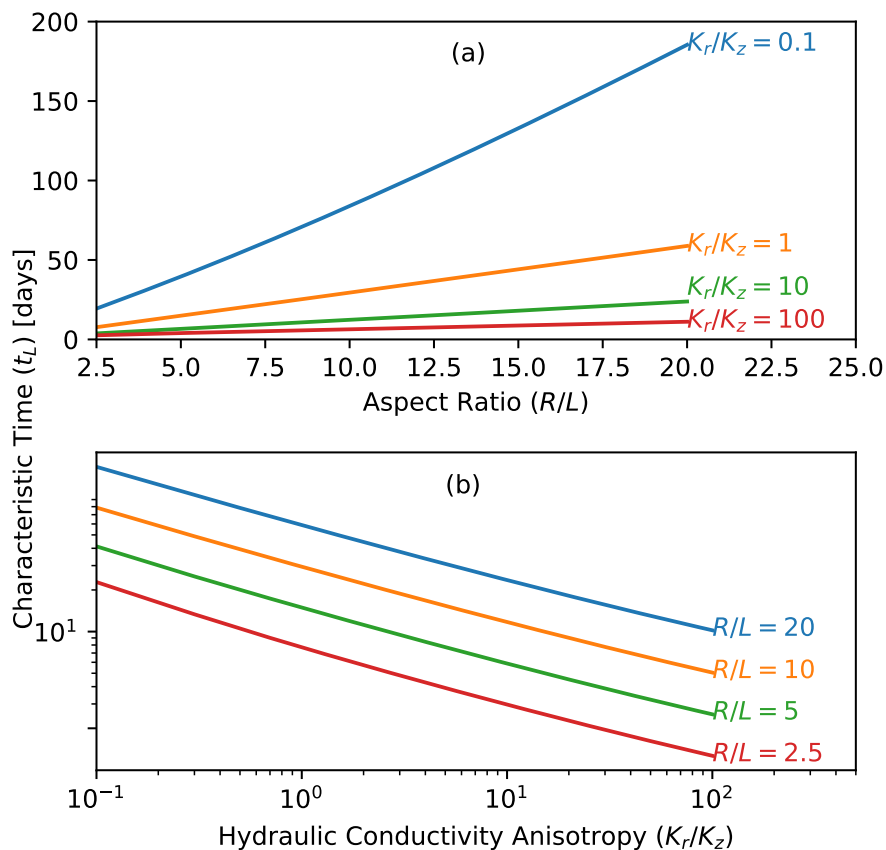

Figure 7. Characteristic time as a function of (a) polygon aspect ratio and (b) anisotropy. The $K_r/K_z = 1$ line in plot (a) corresponds to characteristic times in Figure 6b. Note that the trends in (a) are nearly linear and on natural scaled axes while the trends in (b) are also nearly linear on log transformed axes.

260 anisotropies (Figure 7a) and as a function of anisotropies for various aspect ratios (Figure 7b). Drainage time (represented by characteristic time) increases in a nearly linear fashion, particularly for high anisotropies, with slight upward curvature increasing for low anisotropies. The drainage time decreases in a nearly log-log fashion (exponentially) with increasing anisotropy with an identical trend for different aspect ratios.

A global perspective on drainage timing trends, where characteristic time is mapped as a function of aspect ratio and
 265 anisotropy, is shown in Figure 8. The fastest (shortest) drainage times are achieved with a low aspect ratio and a high anisotropy, while the slowest (longest) drainage times are achieved with high aspect ratio and low anisotropy. These trends indicate that given the same thawed soil layer thickness, wider polygons will drain more slowly than small polygons. Or, for polygons with similar aspect ratios, those with preferential horizontal flow will drain most quickly, while those with preferential vertical flow will drain most slowly.

Figure 8. Contour map of the characteristic time of polygon drainage as a function of polygon aspect ratio and anisotropy. Locations associated with other figures are indicated by labeled points. By choosing a constant value for R ($L = R/x$), horizontal transects parallel to the x-axis represent the effect of thaw depth increasing from right to left, while they represent increasing polygon width from left to right for constant values of L ($R = Lx$). Note that $\kappa = 5 \text{ day}^{-1}$ in these calculations, and therefore, the location associated with Figure 9b cannot be indicated.

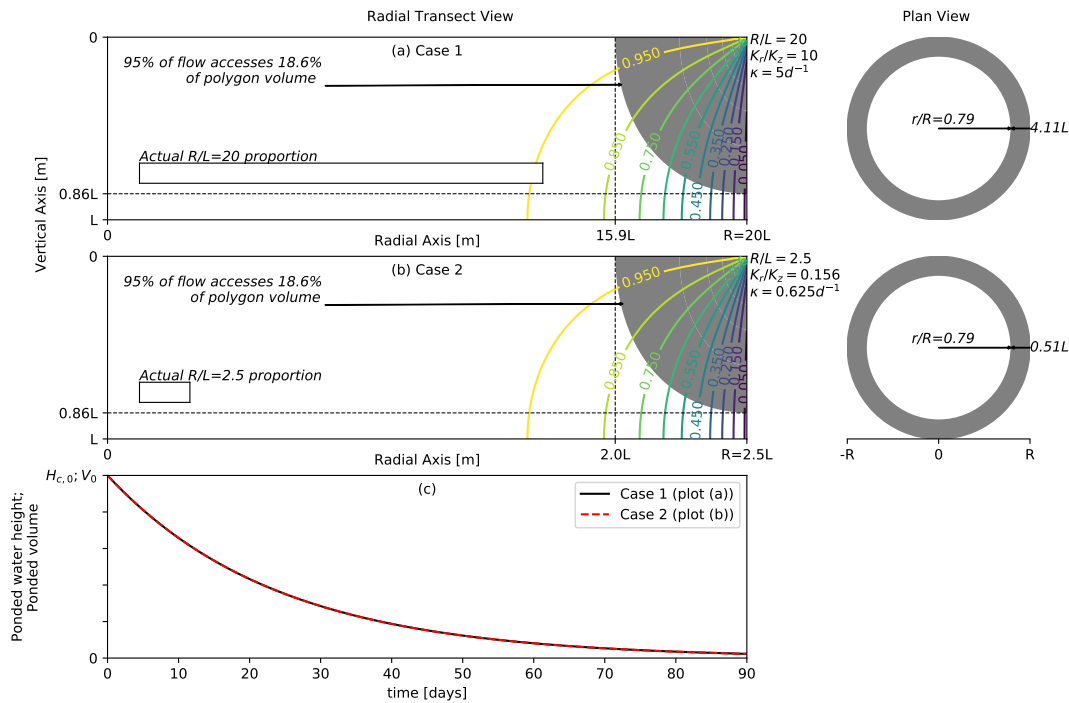

Figure 9. Attaining the same mathematical solution by modifying polygon aspect ratio (R/L), anisotropy (K_r/K_z), and rim conductance (κ). The left plots of (a) and (b) contain polygon radial transect head contours (colored lines) and filled stream tubes (grey regions) for several polygon aspect ratios (radius/thickness). The grey shaded region denotes the portion of the transect accessed by 95% of the flow. The right plots of (a) and (b) contain corresponding grey rings indicating the surface area where 95% of the polygon flow infiltrates. Plots (a) and (b) contain a rectangle drawn to the actual proportions for the given polygon aspect ratio. The pondered water height/volume depletion curves for both cases are presented in (c).

270 3.3 Counteracting effect of aspect ratio and anisotropy

It is important to note that aspect ratio and anisotropy have similar effects on drainage. Within the model used here, in a similar fashion to aspect ratio, anisotropy stretches the domain by multiplying the non-dimensional radius by $\sqrt{(K_z/K_r)}$ (refer to definition of r^* in equation 1). As a result, the effect of increasing anisotropy in the analytical solution is mathematically equivalent to a decrease in aspect ratio. In the end, the equipotential heads and streamlines computed on stretched or compressed radial coordinates (r^*) are assigned back to non-modified radial coordinates (r). This would lead one to believe that it should be possible to obtain two scenarios with different aspect ratios and anisotropies that produce the same mathematical solution. For example, doubling the aspect ratio should produce the mathematically identical effect as dividing the anisotropy by four. However, this is not the case because the solution involves a Biot parameter (Bi) which defines the ratio of the ability for fluid

to conduct across the drainage interface (the vertical outer boundary) relative to the internal hydraulic conductivity as

$$280 \quad \text{Bi} = \frac{\kappa L}{\sqrt{K_r K_z}}, \quad (4)$$

where κ characterizes the hydraulic conductance across the outer vertical boundary of the model (refer to Appendix A for more details). A large Bi indicates that the outlet boundary interface of the model will not limit the drainage, while a small Bi will result in outlet boundary interface limited drainage. Therefore, to obtain an identical mathematical drainage solution using

285 However, given two solutions, this requires satisfying the conflicting conditions that $K_{z1}/K_{r1} = K_{z2}/K_{r2}$ and $K_{r1}K_{z1} = K_{r2}K_{z2}$ (refer to equations 1 and 4), where subscripts 1 and 2 refer to the two solutions. Since these two constraints cannot be simultaneously met, κ or L must also be modified along with aspect ratio and anisotropy to achieve an identical mathematical solution of drainage. An example where identical mathematical solutions for drainage are obtained is provided in Figure 9, where the bottom plot is obtained by taking the properties of the top plot and dividing the aspect ratio by 8, dividing the
290 anisotropy by 8^2 , and dividing κ by 8. While the solutions are mathematically identical, note that the axes in both plots are not to scale (actual proportions are provided as insets to the plots) and that there are differences in some relative dimensions indicated in the figure (for example, the relative width of the polygon volume accessed by 95% of the drainage flow is around
295 $4L$ in the top case and around $0.5L$ in the bottom case).

In the bottom plot in Figure 9, we demonstrate that despite these differences, the depletion curves are identical for both cases.
295 This result is due to our choice to modify R to change the aspect ratio and modify K_r to change the anisotropy. If either L or K_z are chosen to modify the aspect ratio or anisotropy, respectively, the depletion curves would not necessarily be identical. For example, if L is multiplied by 8, K_z multiplied by 8^2 , and κ divided by 8 (equivalent modifications to aspect ratio and anisotropy as above), the drainage flow net would still be mathematical equivalent, but the characteristic time would be 8 times shorter than in the original case (refer to equation A11). Therefore, while it is possible to obtain mathematically equivalent
300 drainage patterns with counteracting modifications to aspect ratio, anisotropy, and outflow conductance, the temporal depletion will only be equivalent if R and K_r are used to modify the aspect ratio and anisotropy, respectively.

4 Discussion

Our analysis provides new insights into how geometry and anisotropy affect how inundated ice-wedge polygons retain and slowly release water from their centers to their troughs, which form the drainage network of polygonal tundra landscapes.

305 Using a mathematical representation of inundated ice-wedge polygon drainage (Zlotnik et al., 2020) based on extensive field observations (Helbig et al., 2013; Koch et al., 2014; Liljedahl and Wilson, 2016; Wales et al., 2020), we quantify the sensitivity of inundated ice-wedge polygon drainage to representative polygon sizes, inter- and intra-annual changes in thaw depth, and preferential flow (hydraulic conductivity anisotropy).

4.1 Analysis implications

310 A key result of this study is that the geometry and anisotropy of the polygon subsurface have a significant effect on the region
of the polygon subsurface predominantly accessed by drainage flow and the time to transition from inundated to drained. Due
to the geometry of inundated polygons, the primary drainage pathway is restricted to an annular, radially-peripheral region
of the ice-wedge polygon center near the rim. As a result, the middle and lower portions of the polygon center are excluded
from the majority of the drainage to varying degrees depending on the aspect ratio and anisotropy. Also, the majority of the
315 ponded water will flow to an outer ring of the polygon before infiltrating into the subsurface. Field observations have indicated
not only the existence of intra-polygon biogeochemical diversity (Zona et al., 2011; Newman et al., 2015), but that, based
on mineral and nutrient loading, pervasive subsurface flow from centers to troughs exists (Koch et al., 2014). Based on our
analysis, polygon geometry and anisotropy will have important effects on the biogeochemistry of polygons (Heikoop et al.,
2015; Throckmorton et al., 2015; Newman et al., 2015; Wales et al., 2020; Plaza et al., 2019) effecting dissolved organic matter
320 and mineral flushing from the subsurface of polygon centers to the surface waters of troughs. This is important not only simply
concerning the discharge of dissolved organic matter from polygonal tundra landscapes, but also for the biogeochemical effects
due to photolysis of dissolved organic matter newly exposed to sunlight (Laurion and Mladenov, 2013; Cory et al., 2014).

The potential that the annular, radially-peripheral region near the rims will be well flushed of nutrients, while the middle
may not, indicates the need for additional field studies designed to measure the effects of anisotropy and preferential flow paths
325 on thermal-hydrology and biogeochemistry. For isotropic cases, it should also be considered that the drainage will spread out
further towards the middle of the polygon center as the thaw season progresses and the thawed soil layer thickens (in other
words, the aspect ratio decreases; Figures 2 and 4). However, with high anisotropy, the drainage still spreads out towards the
polygon middle as the thaw season progresses (aspect ratio decreases), but the depth of the main drainage pathways contract
towards the ground surface (Figure 4). Ultimately, the effect of this vertical contraction outweighs the lateral spreading, leading
330 to a smaller region being accessed by drainage. Therefore, in the case of low aspect ratio and high anisotropy, the dissolved
organic matter and nutrients closer to the surface will be flushed more than the deeper stores of dissolved organic matter and
nutrients. Deeper nutrients that become available for transport because of recent thaw may still be less accessible to aqueous
transport due to drainage pathways in polygons with high anisotropy. This research reinforces the need for field studies on
anisotropy and preferential flow in polygon landscapes to better understand the hydrologic transitions and feedbacks that will
335 occur in a warming climate.

Ice-wedge polygons with focused, deep annular flow towards their periphery may also direct warmer surface waters towards
the top of ice-wedges, resulting in enhanced ice-wedge degradation (Wright et al., 2009). Based on our calculated drainage
pathways, advective heat transport will be most pronounced in large aspect ratio polygons with low anisotropy (refer to Fig-
ures 2a and 3a). Therefore, drainage events for wide, isotropic (or with preferential vertical flow) polygons may result in
340 enhanced ice-wedge top thawing, which would promote low- to high-centered polygon transition. The more spread out the
drainage is throughout the thawed soil layer, the less pronounced this effect may be (for example, wide polygons with high
anisotropy as in Figures 4a and b). However, small polygons with high anisotropy will restrict the drainage flow near the ground

surface, potentially reducing the advective transport of heat to the ice-wedge top as well (Figure 4d). These results provide an additional perspective on ice-wedge degradation along with previous research which found that ice-wedge degradation will also be controlled by trough geometry (Abolt et al., 2018) and the hydrologic regime below the trough (Nitzbon et al., 2019).

Small polygons with deeply thawed soil layers (low aspect ratios) and high horizontal preferential flow (high anisotropy) have the potential to drain most quickly. Therefore, all other factors being equal, regions of polygonal tundra characterized by small, deeply thawed, anisotropic polygons will drain more quickly and consequently would have a greater potential for nutrient flushing, a transition from methane to carbon dioxide atmospheric emissions, and biological succession than regions with large, shallowly thawed, isotropic polygons. Of course, for a given location, other factors such as regional flow patterns, large-scale topography, etc. will influence the region's overall drainage timing. However, along with these other factors, our analysis indicates that aspect ratio will have a nearly linear positive relationship while anisotropy will have an exponential negative relationship with drainage timing.

4.2 Model limitations

The drainage pathways and timing presented here are based on fundamental hydrogeological principles (Harr, 1962; Cedergren, 1968; Freeze and Cherry, 1979; Bear, 1979) using a generalization of ice-wedge polygon geometry and hydraulic properties that allow fundamental insights of generalized drainage pathways and timing of inundated ice-wedge polygons to be obtained. Our solutions capture the fundamental physical forces that ponded water exerts on a cylindrical porous disc with drainage allowed radially through its sides. While the cylindrical geometry and anisotropy considered here do not cover all potential variations present in ice-wedge polygons, the impact of those variations will cause deviations around the base case, idealized scenarios considered here. For example, heterogeneities will warp the base case hydraulic head equipotentials and streamlines. The cylindrical idealization of ice-wedge polygon geometry will best approximate drainage in nearly symmetrical hexagonal ice-wedge polygons, while non-symmetric, square ice-wedge polygon drainage will deviate most from that shown here. The model assumes uniform radial discharge around the periphery of the polygon center. Low points in the elevated frozen ground under the rim will lead to deviations from our results.

In our analysis, we use idealized conceptualizations and dimensionless variables which allow hydrologic characteristics of drainage to be exposed in their most fundamental form. To clearly and concisely expose these characteristics, we neglect factors such as evaporation, precipitation, and non-idealized polygon geometry. As a result, our analysis is not intended to provide predictive capability across all polygon tundra scenarios, but to provide fundamental hydrologic intuition into inundated ice-wedge polygon drainage and timing.

As the analytical solution applies to ponded conditions, it does not apply to freeze-up at the end of the thaw season after the ponded water in the ice-wedge polygon center freezes. At this time, the active layer freezes simultaneously from the top and bottom and cryosuction draws water towards the freezing front. This redistribution of water affects ice-wedge polygon drainage and Wales et al. (2020) postulate that it may explain some of the observations of their tracer test. More complex models than applied here are required to capture the details of water redistribution during freeze-up (Painter, 2011; Atchley et al., 2016; Schuh et al., 2017).

Since the model is based on the saturated groundwater flow equation, in its current form it cannot be applied to non-inundated low-centered polygons. Since it is based on having a ponded center, the model is also not applicable to high-centered polygons. However, a similar approach to that presented here could be taken with the unsaturated groundwater flow equation to capture these other polygon scenarios and types.

4.3 Relation to other mathematical analyses

As our analysis is the first detailed examination of inundated ice-wedge polygon drainage patterns, our results provide a new perspective to existing mathematical analyses. Much of the existing mathematical analyses investigate drainage from polygonal landscapes. For example, Cresto-Aleina et al. (2013) analyze low-centered polygonal landscape hydrology stochastically using percolation theory, a method this is not designed to investigate drainage pathways of individual polygons. Nitzbon et al. (2020) investigate the hydrology of polygonal tundra using a “tiled” approach, another approach that is not designed to map individual ice-wedge polygon drainage pathways. In these cases, our analysis enhances our understanding by considering details that are glossed over in these analyses for the sake of considering drainage from many polygons. Other research has focused on process-rich 1D analyses that are unable to consider lateral flow. For example, Atchley et al. (2015); Harp et al. (2015) and Atchley et al. (2016) use a process-rich, complex 1D model to calibrate and perform uncertainty and sensitivity analyses of thermal-hydrology models of ice-wedge polygons. Our analysis augments these by providing insights into lateral fluid flow. Abolt et al. (2018) performed a sensitivity analysis of the thermal effects of ice-wedge thaw on individual polygons using a full-physics thermal-hydrology model. Our analysis adds to this research by providing indications of the drainage patterns that would exist along with the thermal effects. Jan et al. (2020) calibrate a full-physics thermal-hydrology model of ice-wedge polygons using field data, but since their focus was on calibration, they did not investigate drainage pathways. As a result, our analysis provides new information that augments existing research, helps the Arctic hydrology research community gain an intuitive understanding of inundated ice-wedge polygon drainage, and provides new modeling and experimental research directions based on the idealized, base cases considered here.

5 Conclusions

Our results indicate that existing conceptualizations of polygon drainage need revisiting. Fundamental hydrological principles indicate that, due to low-centered polygon geometry and hydraulic properties, inundated polygon drainage flux will not be uniform throughout the thawed soil layer. This conclusion indicates that while some portions of the polygon thaw layer will be well flushed, other portions will be poorly flushed. This has important implications for the aqueous transport of carbon and other dissolved nutrients from polygonal tundra. It also indicates the potential for focused advective heat transport from the ponded water towards the ice-wedge tops, which could enhance ice-wedge degradation. Within this context, we provide the following conclusions:

- The majority of drainage from inundated ice-wedge polygon centers occurs along an annular region along their radial periphery; however, polygon aspect ratio and hydraulic conductivity anisotropy significantly impact the drainage pathways.

410 This implies that nutrient flushing and the advective thermal transfer will be focused along polygon edges, neglecting the polygon center.

– A combination of high aspect ratios and high anisotropy results in the greatest spreading of drainage flow towards the middle of the polygon center and the largest fraction of the polygon volume being accessed by drainage flow. In these cases, the nutrient flushing will be more uniform than other cases and advective heat transport towards the ice-wedge top will be less focused and therefore its ability to thaw the ice-wedge top diminished.

415 – A combination of high aspect ratios (wide, shallow polygons) and low anisotropy (preferential vertical flow) result in the greatest focusing of drainage flow and the smallest fraction of the polygon volume being accessed by drainage flow. In these cases, nutrient flushing will be more localized along the outer edge of the polygon (non-uniform) and the advective heat transport towards the ice-wedge tops most focused, likely resulting in greater degradation of ice-wedges than in other cases.

420 – Combinations of aspect ratio and anisotropy have counteracting effects of radial versus vertical extension/contraction of drainage pathways, producing non-monotonic relationships between aspect ratio/anisotropy and accessed volume (ridgeline in accessed volume response surface in Figure 5). Therefore, the combined, non-linear effects of geometry and anisotropy on drainage patterns must be considered when evaluating nutrient flushing and advective heat transport.

425 – The characteristic time for a polygon to drain has an approximately positive linear relationship with aspect ratio; in other words, wide, shallow polygons drain slowly while small, deep polygons drain quickly. This implies that polygonal tundra with larger polygons may drain more slowly than tundra composed of smaller polygons.

– The characteristic time for a polygon to drain has a negative exponential relationship with anisotropy. In other words, preferential horizontal flow leads to exponentially faster drainage. Therefore, polygonal tundra with greater preferential
430 horizontal flow, due to more pronounced horizontal stratigraphy or ice lens development, will drain faster, while less horizontally stratified tundra, due to cryoturbation, for example, will drain more slowly.

Code availability. Matlab code of the analytical solution is available via Zlotnik et al. (2020) at <http://www.mdpi.com/2073-4441/12/12/3376/s1>.

Video supplement. A video illustrating the validation of the analytical solution to an inundated ice-wedge polygon drainage event in 2012 near Utqiagvik is available via Zlotnik et al. (2020) at <http://www.mdpi.com/2073-4441/12/12/3376/s1>.

435 Appendix A

Here, we present the analytical solutions for hydraulic heads and stream function under the center of an inundated ice-wedge polygon and the depletion curve of the ponded water height due to drainage to the surrounding trough. For details on the derivations and validation of the model, refer to Zlotnik et al. (2020).

A1 Hydraulic head and stream function analytical solutions

440 We idealize the subsurface below the center region of a low-centered polygon as a thin cylinder with radius in the horizontal direction and length in the vertical direction (refer to Figure 1). Based on this approximation, the hydraulic heads ($h(r, z, t)$) in an inundated polygon will satisfy the following equation:

$$\frac{K_r}{r} \frac{\partial}{\partial r} \left(r \frac{\partial h}{\partial r} \right) + K_z \frac{\partial^2 h}{\partial z^2} = S_s \frac{\partial h}{\partial t}. \quad (\text{A1})$$

445 However, considering that storativity is negligible given the vertical and horizontal scale of the domain, the right-hand term can be neglected as

$$\frac{K_r}{r} \frac{\partial}{\partial r} \left(r \frac{\partial h}{\partial r} \right) + K_z \frac{\partial^2 h}{\partial z^2} = 0, \quad (\text{A2})$$

where h is the hydraulic head, r is the radial coordinate, z is the depth coordinate (positive in the downward vertical direction), K_r is the horizontal (radial) hydraulic conductivity, K_z is the vertical hydraulic conductivity, t is time, and S_s is specific storage. The system is fully specified by ensuring that (BC1) the heads along the central vertical axis ($h(0, z, t)$) are finite, (BC2) the heads along the ground surface are equal to the height of ponded water in the polygon center ($h(r, 0, t) = H_c(t)$), (BC3) the change in heads along the outer vertical boundary is governed by the change in heads along the boundary and the height of water in the trough (H_t)

$$-K_r \frac{\partial h(R, z, t)}{\partial r} = \kappa(h(R, z, t) - H_t), \quad (\text{A3})$$

(BC4) the bottom of the model has a zero head gradient

$$455 \frac{\partial h(r, L, t)}{\partial z} = 0, \quad 0 < r < R, \quad (\text{A4})$$

and (BC5) the change in volume of ponded water in the polygon center is related to the vertical head gradients along the ground surface,

$$\pi R^2 \frac{dH_c(t)}{dt} = 2\pi K_z \int_0^R \frac{\partial h(r, 0, t)}{\partial z} r dr, \quad H_c(0) = H_{c,0}, \quad (\text{A5})$$

460 where R is the radius of the polygon, L is the depth of the thawed subsurface of the polygon, $H_c(t)$ is the ponded water height in the center of the polygon at time t , H_t is the height of water in the trough, and κ characterizes the conductance to flow across the drainage interface to the trough (in our case, the hydraulic conductance of the soil layer under the rim).

Using dimensionless coordinates and parameters defined as

$$r^* = \frac{r}{L} \sqrt{\frac{K_z}{K_r}}, \quad z^* = \frac{z}{L}, \quad R^* = \frac{R}{L} \sqrt{\frac{K_z}{K_r}}, \quad \text{Bi} = \frac{\kappa L}{\sqrt{K_r K_z}}, \quad (\text{A6})$$

dimensionless solutions for hydraulic heads and the stream function can be obtained as

$$465 \quad h^*(r^*, z^*) = \frac{h(r, z, t) - H_t}{H_c(t) - H_t} = 2 \sum_{n=1}^{\infty} \frac{J_1(\lambda_n R^*)}{\lambda_n R^* [J_0^2(\lambda_n R^*) + J_1^2(\lambda_n R^*)]} \frac{\cosh(\lambda_n(1 - z^*))}{\cosh(\lambda_n)} J_0(\lambda_n r^*) \quad (\text{A7})$$

and

$$\Psi^*(r^*, z^*) = \frac{\psi(r^*, z^*)}{\psi(R^*, 0)} = 2 \sum_{n=1}^{\infty} \frac{J_1(\lambda_n R^*) J_1(\lambda_n r^*) r^*}{\lambda_n R^* [J_0^2(\lambda_n R^*) + J_1^2(\lambda_n R^*)]} \frac{\sinh(\lambda_n(1 - z^*))}{\cosh(\lambda_n)}, \quad (\text{A8})$$

respectively, where J_m , with $m=0$ or 1 , is the Bessel function of the first kind of m th order and λ_n is the n th root of the equation

$$470 \quad \lambda_n J_1(\lambda_n R^*) = \text{Bi} J_0(\lambda_n R^*), \quad n = 1, 2, \dots \quad (\text{A9})$$

The solutions can be verified by direct substitution of equations A7 and A8 into the boundary value problem defined by equations A2 to A6.

A2 Poned height depletion curve analytical solution

The ponded height depletion curve can be defined as

$$475 \quad H_c(t) = H_t + [H_{c,0} - H_t] e^{-t/t_L}, \quad (\text{A10})$$

where t_L is the characteristic depletion time defined as

$$t_L = \frac{R^2}{2K_r L F(\text{Bi}, R^*)}, \quad (\text{A11})$$

which is the time when $H_c(t)/H_{c,0} = 1/e$; in other words, when the ponded height is approximately 37% of its initial. The function $F(\text{Bi}, R^*)$ can be evaluated as

$$480 \quad F(\text{Bi}, R^*) = \int_0^{R^*} \frac{\partial h^*(r^*, 0)}{\partial z^*} r^* dr^* = 2 \sum_{n=1}^{\infty} \frac{\tanh(\lambda_n)}{\lambda_n [(\lambda_n/\text{Bi})^2 + 1]}. \quad (\text{A12})$$

The depletion curve can be expressed in non-dimensional terms as

$$H^*(t^*) = \frac{H_c(t) - H_t}{H_{c,0} - H_t} e^{-t^*}, \quad (\text{A13})$$

where non-dimensional time $t^* = t/t_L$. The solution can be verified by direct substitution of equation A10 into equation A5.

485 *Author contributions.* DH and VZ developed the conceptual model of inundated polygonal tundra hydrology. VZ derived the analytical solutions. VZ and DH encoded the analytical solutions. CA created Figure 1. DH created Figures 2-9. AA provided text for the Introduction and Discussion sections. EJ provided text for the discussion section. AA, BN, EJ, and CW provided critical reviews of the manuscript. CW secured funding.

Competing interests. The authors declare no competing interests.
