Abstract

The Hindu-Kush Himalaya mountain range is characterized by highly glacierized, complex, dynamic topography. The ablation area of these glaciers is often covered a highly heterogeneous debris cover mantle comprising ponds, steep and shallow slopes of various aspects, variable debris thickness and exposed ice cliffs. These surface elements are associated with differing ice ablation rates, and understanding the composition of the glacier surface is essential for a proper understanding of glacier hydrology and glacier-related hazards. Here we use high-resolution Pleiades (2 m) and RapidEye imagery (5 m) combined with Landsat imagery (30 m) to estimate the composition of debris-covered glacier tongues across the Himalaya around the year 2015. We use linear spectral unmixing to map various types of debris, clean ice, supraglacial ponds and vegetation on debris-covered glaciers across the mountain range. We develop the spectral unmixing methods in the Khumbu region of eastern Nepal, and then apply them over the entire Himalaya (a glacier area of 2,254 km²). This allowed us to convert 30 m fractional maps into finer classification maps and to estimate the composition of debris-covered glaciers at various spatial scales. Debris-covered glaciers across the mountain range comprised 2.1 % supraglacial ponds, 12.8 % dark debris, 60.9 % light debris and 4.5 % supra glacial vegetation, with negligible amounts of clean ice and clouds and unclassified areas. Supraglacial ponds were more prevalent in the monsoon-influenced central-eastern Himalaya (up to 4 % of the debris cover area) compared to the monsoon-dry transition zone (only 0.3 %). The automated fractional supraglacial pond maps developed here serve to complement and improve the accuracy of existing regional lake datasets. They also provide a basis for exploring the turbidity of lakes and ponds as indicators of glacier change processes, and to monitor the evolution of ponds in the context of glacial hazards.

30 **Keywords:** Himalaya, debris-cover glaciers, remote sensing, spectral unmixing, lake mapping

1 Introduction

High altitude glacierized environments of the Hindu-Kush Himalaya are characterized by complex, dynamic topography, notably the presence of a mantle of debris cover on the ablation areas of glaciers. This is caused by mass-wasting processes such as rock fall and rockslides from the steep valley sides (Kirkbride, 2011; Shroder et al., 2000). This results in a highly heterogeneous surface, consisting of debris material of various lithologies and grain sizes (sand and silt to boulders), forming debris cones on variable but mostly shallow slopes. Some of the most notable features of such surfaces are the supraglacial ponds and exposed ice cliffs, which have gained interest in recent years for several reasons. First, they influence the surface energy receipts of the supraglacial debris surface and the efficiency with which atmospheric energy can be transferred to the underlying ice and cause glacier ice ablation. Ice cliffs and supraglacial ponds, in particular, are local ‘hot spots’ for glacier downwasting due to enhanced heat absorption at the surface of these features (Ragettli et al., 2016; Miles et al., 2016; Sakai et al., 2000). Understanding their distribution and dynamics on the glacier surface is essential for a proper understanding of glacier hydrology, notably to simulate ablation rates and meltwater production using a variety of ice melt models (Reid and Brock, 2010; Foster et al., 2012; Miles et al., 2020). Second, the current distribution and fluctuation of pro-glacial lakes as well as and supraglacial pond extents is also of interest for assessing glacier-related hazards. Recent studies have reported an increase in pro-and supraglacial lake area and number in the Himalaya and worldwide as a response to climatic changes (Shugar et al., 2020a; Nie et al., 2017; Shukla et al., 2018). Some of the supraglacial ponds have been shown to coalesce and form larger supraglacial lakes, or to evolve into fully-formed pro-glacial ice or moraine-dammed lakes. Moraine breaching can occur following an input of ice mass, rock / ice avalanches, glacier calving into these lakes or the melting of ice cored moraines, resulting in glacier lake outburst flood events (Benn et al., 2012; Komori, 2008; Richardson and Reynolds, 2000; Reynolds, 2014; GAPHAZ, 2017), with possibly catastrophic consequences downstream. Quantifying the properties of the supraglacial debris cover is therefore important in order to monitor the conditions conducive to the formation and evolution of supraglacial ponds, i.e., to predict where such ponds may form in the future and which ones may represent conditioning factors for hazards. Presently, such analyses have only been undertaken at single glaciers or small regions in the Nepal and Bhutan Himalaya, for isolated years only (Sakai and Fujita, 2010; Reynolds, 2000). A comprehensive assessment of the surface geomorphology, pond coverage, moraine characteristics and vegetation have so far not been fully quantified over the entire Himalaya. Intraregional variability in rates of change of debris-covered glaciers and their morphological features is currently still difficult to grasp. Understanding the fluctuations of these surface characteristics is important, as they may indicate the transition from a debris cover glacier to a rock glacier in a context of climate change (Shroder et al., 2000; Jones et al., 2019). Until recently, previous efforts to map debris-covered glaciers focused primarily on their extent rather than the surface characteristics. Debris cover mapping techniques include a combination of digital elevation models (DEMs), spectral band ratios and terrain curvature (Shukla et al., 2010; Bolch et al., 2007; Kamp et al., 2011; Bishop et al., 2001; Paul et al., 2004). Attempts to improve the accuracy of debris cover mapping include the use of thermal data based on the temperature difference

65 between debris underlined by glacier ice and the surrounding non-ice moraines (Taschner and Ranzi, 2002; Bhambri et al.,
2011; Racoviteanu and Williams, 2012; Alifu et al., 2016) or glacier velocity (Smith et al., 2015). Other recent approaches
include various machine learning techniques using optical imagery (Xie et al., 2020a; Xie et al., 2020b; Zhang, 2019). Synthetic
Aperture Radar combined with machine learning or object-oriented image analysis (OBIA) overcomes the limitations of
optical remote sensing in areas with frequent cloud cover (i.e., the eastern Himalaya), and has the potential to automate the
70 mapping of debris cover and its characteristics (Lipl et al., 2018; Frey et al., 2012; Robson et al., 2015; Wangchuk and Bolch,
2020). Although these offer promising results, due to the computationally-intensive processes, these were only tested in a few
regions and have yet to be applied in a systematic manner at larger scales.

Despite the increasing interest in ice cliffs and supraglacial ponds on glaciers, the distribution of these features on debris-
covered glacier tongues remains limited at regional scales. Updated regional glacier lake inventories have only recently
75 emerged (Wang et al., 2020; Wangchuk and Bolch, 2020; Shugar, 2020b), but methods to map these surface features are not
consistent. Furthermore, the most recent, publicly available databases of glacial lakes over the entire Himalaya (Shugar, 2020b;
Chen et al., 2020) focus mainly on proglacial lakes and their decadal changes. A complete database should include supraglacial
ponds at least at several time periods, and this requires developing standardized methodology to monitor their temporal changes
at finer time steps. At local scales, supraglacial features are most often mapped only using a combination of manual digitization
80 on high-resolution multi-spectral imagery (1-3 m), Google Earth (Brun et al., 2018; Watson et al., 2018; Watson et al., 2017a,
2016), thermal imagery (Suzuki et al., 2007; Foster et al., 2012) or on the basis of topographic models generated using structure
from motion techniques (Westoby et al., 2014; Rounce et al., 2015). Only a few recent studies focused on seasonal dynamics
and evolution of supraglacial ponds and ice cliffs, and such studies are limited to a small number of glaciers located in the
well-studied Khumbu and Langtang areas of the Nepal Himalaya (Watson et al., 2016, 2017a; Miles et al., 2017). Estimates
85 of the supraglacial pond coverage exist only for nine glacier tongues in the Khumbu using multi-resolution satellite imagery
for isolated years (Watson et al., 2016, 2017a; Watson et al., 2018). Increasing trends of pond development of 17 to 52 % per
year were reported for the period 2000 to 2015 in the Khumbu region (Watson et al., 2016). A three-fold increase in pond area
over three decades (1989 to 2018) was reported for the same area (Chand and Watanabe, 2019).

The increased availability of high-resolution (0.5 to 5 m) remotely sensed data from Pleiades, Planet and Quickbird satellites
90 amongst others has offered new perspectives for characterizing the surface of debris-covered glaciers, but this is often limited
to local scales. Understanding how the surface composition of the debris-covered tongues upscales in coarser resolution
imagery is currently lacking. This paper is a first step towards achieving this. Medium resolution data from archive Landsat
series (30 m spatial resolution) still constitute valuable data sources for various regional-scale mapping applications due to
their wide footprint, free accessibility and acquisition time spanning five decades. One of the drawbacks of current remote
95 sensing studies for glaciology is that most of them rely on traditional “whole pixel” image classification techniques, which
utilize emitted, reflected or back-scattered radiation at sensor. This approach puts little emphasis on the spatial variation of
pixel values, and on the spatial information present in the neighbourhood of a pixel. Innovative techniques grouped under

“super-resolution mapping” include sub-pixel classification, neural network approaches and pixel swapping. Initially introduced by Atkinson (1997; 2004) and Foody (2004), such techniques allow analysis at sub-pixel scales, and are of interest for investigating the small-scale variability of surface properties of debris-covered glaciers. Spectral unmixing routines have been used in glaciology to some extent, i.e. for retrieval of snow grain size or to derive fractional snow covered areas from MODIS or Landsat (Painter, 2003; Painter et al., 2009; Sirguey et al., 2009; Vezon et al., 2014; Rosenthal and Dozier, 1996), to map clean glacier areas or snow (Painter et al., 2012; Cortés et al., 2014), lakes (Zhang et al., 2004) and vegetation (Ettrich et al., 2018; Song, 2005; Xie et al., 2008). However, their use for mapping the surface of debris-covered glacier tongues has not been thoroughly exploited. A couple of studies used spectral analysis to characterize the mineral composition of debris covered glaciers in the Khumbu region of Nepal Himalaya (Casey and Käb, 2012; Casey et al., 2011) or to characterize lake colour, turbidity and suspended solids in the same area (Matta et al., 2017; Giardino et al., 2010). Scherler et al. (2018b) tested various methods, i.e. a fractional debris cover algorithm and standardized band ratios to produce three versions of a global debris cover map (Scherler et al., 2018a) on the basis of Randolph Glacier Inventory (RGI) version 6.0 (RGI Consortium 2017). Recent studies (i.e. Xie et al., 2020a; Xie et al., 2020b; Wangchuk and Bolch, 2020) demonstrated the potential of innovative machine learning techniques combined with freely available data such as Landsat to quantify the surface features of debris-covered glaciers. Applying such methods at large scales allow gaining a better understanding of the response of debris-covered glaciers to climate variability in terms of water resources and hazards.

In this study, we evaluate and explore the potential of spectral unmixing techniques applied to 30 m Landsat imagery to quantify the surface characteristics and the composition of debris-covered glaciers, with a particular emphasis on supraglacial pond coverage. We use high-resolution multi-spectral Pleiades and RapidEye imagery (2 m and 5 m, respectively) to define the materials of interest and to extract their spectral signatures. We test and validate our methods on Khumbu region in the eastern Himalaya and upscale them to the entire mountain range. Specifically, the objectives of this study are to:

- (1) Test spectral unmixing techniques for mapping of debris-covered glaciers and their surface features;
- (2) Estimate the composition of debris-covered tongues in terms of exposed ice, debris material, supraglacial ponds and vegetation at regional and mountain-range scale;
- (3) Automatically map supraglacial ponds and assess their regional distribution with respect to topographic characteristics and geographic location.

The application of sub-pixel approaches to mapping supraglacial features are rather novel, and may serve to fill the gap in the supraglacial pond coverage in the current global debris cover glacier inventories or to provide data for glacier-scale studies. We aim at developing a robust, standardized method that can be transferred from commercial software to open-source software to upscale these characteristics to mountain-range scale and high-resolution temporal steps.

2 Methods and data sources

2.1 Study area

Our study area comprises two spatial domains (**Fig. 1**). The smaller domain, used as test area, comprises the glacierized Khumbu region of Nepal and glaciers north of the divide in China, both of which are part of the larger trans-boundary Sapta Kosi river basin. For simplicity we refer to this region hereinafter as the “Khumbu domain”. The Khumbu region has been well studied in the last decades in terms of glacier mass balance using the traditional glaciologic method (Wagnon et al., 2013),
135 the geodetic method (Bolch et al., 2008; Nuimura et al., 2012; Brun et al., 2017; Bolch et al., 2011; Rieg et al., 2018), energy balance models (Rounce and McKinney, 2014; Rounce et al., 2015; Kayastha et al., 2000), debris cover characteristics (Iwata et al., 1980; Watanabe et al., 1986; Nakawo et al., 1999; Iwata et al., 2000; Casey et al., 2011; Yukari et al., 2000), surface velocity (Quincey et al., 2009) and more recently mapping of supraglacial lakes and ice cliffs at glacier scale (Watson et al., 2016, 2017a). Rates of change of the debris-covered glacier tongues in this area vary from -0.12 ± 0.05 % per year from 1962
140 to 2005 (Bolch et al., 2008) to -0.27 ± 0.06 % per year from 1962 to 2011 (Thakuri et al., 2014). Watson et al. (2017a) reported a pond coverage area of 1 - 7 % of the glacierized area for some glaciers in the Khumbu based on high resolution Pleiades data. Salerno et al (2012) reported an area of 1.49 km² in the Khumbu in 2008 based on analysis of Landsat imagery, which represents 0.42 % of the mapped glacier area in their study. Ice cliffs are estimated to cover about 7 – 8 % of the glacier area, for example for Changri Nup glacier in the Khumbu (Brun et al., 2018).

145 **Fig. 1 here**

The larger Himalaya domain is defined here as the region spanning from 76.3 to 92.6° W and 26.3 to 34.2° N, covering most area from Himachal/Jammu and Kashmir border to Bhutan Himalaya (**Fig. 1**). Himalayan glaciers have been in a state of negative mass balance in the last decades, and the negative trends have accelerated in the 2000 to 2010 decade (Bolch et al., 2019; Brun et al., 2017; Kääh et al., 2012). We upscaled our methods over this entire region and then selected three areas for
150 a closer comparison of the composition of debris-covered glacier tongues in three regions from west to east, following climatic patterns. The Lahaul Spiti region in the western Himalaya region (labelled “A” on Figure 1) is situated in the “monsoon-arid” transition zone, which receives monsoon precipitation during the summer and precipitation from the Westerlies in the winter (Thayyen and Gergan, 2010). The central and eastern Himalaya regions (“B” and “C” on Figure 1) are situated under the influence of the Indian Summer Monsoon, which brings large amounts of precipitation during the summer months (June to
155 September) especially in the eastern part (Barros and Lang, 2003; Bookhagen and Burbank, 2006). In the central-eastern regions, ablation and accumulation both occur during the summer season (Thayyen and Gergan, 2010).

2.2 Remote sensing data

We used multi-sensor data at various spatial and spectral resolutions, as listed in **Table 1**: Landsat-8 Operational Land Imager (OLI) (30 m), Pleiades (2 m) and RapidEye (5 m). The Landsat OLI sensor has been acquiring data at 30 m spatial
160 resolution in the visible to short-wave infrared since 2013 (USGS, 2016). Sentinel-2 data were not available in this area for the date/year of the acquisition of the Pleiades data (2015), so we developed our method using Landsat data. The estimated

global geolocation accuracy of Landsat OLI data is estimated at 50 m; its spectral band width, calibration, geometry and radiometric resolution are superior to previous Landsat missions (Irons et al., 2012). We obtained level L1TP -T1 data, which consists of top of atmosphere registered, radiometrically calibrated and orthorectified imagery (Wulder et al., 2019; 165 USGS, 2015). A total of 12 Landsat images were needed to cover the entire Himalaya domain for the year 2015. Cloud-free images were selected to match the acquisition date of Pleiades data as closely as possible. For two regions in the eastern part where cloud cover was present in 2015, we used images around the same time of the year (September to October) in 2014 and 2016 (Table 1). The Landsat scene from Khumbu (September 30, 2015) (**Fig. 1**) was used as reference to develop and test our methods.

170 **Table 1 here**

The Pleiades 1A satellite sensor, launched in 2011, has been acquiring tri-stereo high-resolution data at 0.5 m spatial resolution in the panchromatic band and 2 m in the multispectral bands (blue to near-infrared), with 20 km image swath at nadir. Multiple images per acquisition were needed to cover the extent of the Khumbu area (Rieg et al., 2018) (**Fig. 1**). Three Pleiades scenes from the 2015 fall acquisition (Oct 7, 19 and 20) covered the north, northeast and southeast part of Khumbu 175 and were the closest in date to the Landsat (Sept 30). These scenes were cloud-free and snow-free. They were provided as three sets of triplets of primary data (1A), and were orthorectified in ERDAS Imagine Photogrammetry Suite using the Pleiades Rational Polynomial Coefficient model and the Pleiades DEM (1 m) generated using semi global matching (Rieg et al., 2018). The individual image parts were mosaicked to a single image using ERDAS Imagine using a nearest neighbour resampling method at 2 m spatial resolution. False colour composites of Pleiades bands 4,3 and 2 were used to extract 180 spectral signatures for the surfaces of interest from Khumbu in the spectral unmixing procedure (section 2.5.2). For areas in Khumbu located outside the Pleiades extent, we used a RapidEye scene from the Planet satellite from Oct 9th, 2015, namely a Level 3A analytic ortho tile. This product consists in orthorectified, surface reflectance data at 5 m spatial resolution and five multispectral bands. The RapidEye tiles were mosaicked using nearest neighbour resampling method and were used 185 Khumbu region.

2.3 Elevation data

We obtained and evaluated two DEMs : the Shuttle Radar Topography Mission (SRTM) version 3.0 (1 arc second, ~30 m) (NASA-JPL, 2013) and the ALOS Global Digital Surface Model (AW3D30) version 2.2 (30 m) (JAXA, 2019). Their vertical accuracies in the Himalaya were reported as 23.5 m (Mukul et al., 2017) and 2 m (Tadono et al., 2014), respectively. The 190 ALOS tiles were mosaicked using bilinear interpolation to create a seamless DEM covering the entire Himalaya domain. The ALOS DEM provided better vertical accuracy, better shadow rendering and less artefacts due to data voids compared to SRTM and was therefore chosen for this study. We extracted surface slope, minimum elevation and elevation range over the debris

covered areas using zonal analysis and investigated the possible dependency of supraglacial features on these topographic variables.

195 2.4 Image pre-processing

Atmospheric effects due to scattering or absorption from atmospheric gases, aerosols and clouds result in attenuation, brightness modifications, or altered spatial distribution of the reflected solar radiation at visible wavelengths of interest (0.4 – 2.5 μm) (Kaufman, 1989). Sophisticated atmospheric correction models require climatic inputs such as ground measurements of aerosol or temperature, which are not easily available in high mountains. Furthermore, topographic effects caused by differential solar illumination of the earth's surface in complex terrain result in widely varying spectral responses which affect image processing operations, including sub-pixel routines. Various topographic normalization algorithms exist, including the cosine function and the Minaert correction reviewed previously by others (Richter, 1997), and most recently for the Himalaya (Mishra et al., 2010).

We performed atmospheric and topographic corrections of the Landsat scenes using the open-source Atmospheric and Radiometric Correction of Satellite Imagery (ARCSI) routine (Wilson, 2013). This is based on the 6S algorithm (Vermote et al., 1997) and corrects for the spectral variation of surfaces and illumination effects using physically-based illumination and reflectance corrections (Shepherd and Dymond, 2003), a standard atmospheric profile, an Aerosol Optical Thickness (AOT) value and sensor geometry. The AOT is commonly derived by a numerical inversion the surface reflectance on an image-basis using the simple dark object subtraction technique from the blue band. For our Sept 30, 2015 scene from the Khumbu, this yielded an AOT of 0.05. To validate the performance of this technique for atmospheric profile representation in our area, we compared the estimated AOT with data from AERONET (<https://aeronet.gsfc.nasa.gov/>) and Copernicus Atmospheric Monitoring Service (CAMS) (<https://atmosphere.copernicus.eu/catalogue#/>) for the same date and time as the reference scene. AERONET provides three quality levels (Levels 1.0, 1.5, 2.0) for aerosol size (Giles et al., 2019); we used 1.5 level data for 550 m for the three sites in eastern Nepal located within our study area. The CAMS database provides daily forecast global reanalysis of total optical depth at multiple wavelengths. The AOT values calculated from AERONET versus CAMS (based on the average of the two cells where the Khumbu area is situated) were 0.07 and 0.05, respectively, which was consistent with the value obtained using the dark subtraction method (0.05). Based on this, we performed the atmospheric corrections in automatically for each scene using the method implemented in ARCSI.

2.5 Spectral unmixing

220 2.5.1 Background and set-up

Spectral unmixing techniques rely on the basic idea that any pixel in an image represents an average of the various materials on the ground. These techniques aim at decomposing a given pixel, generally at medium-low spatial resolution (> 30 m) into the constituting materials in order to improve mapping accuracy (Keshava and Mustard, 2002). In the case of debris-covered

glaciers tongues, a “mixed pixel” is typically a combination of debris, ice cliffs, and/or supraglacial ponds and vegetation in
225 various proportions (Rounce et al., 2018). Spectral unmixing yields the percent occurrence (or so-called “fractional
abundance”) of each distinct type of material present in a pixel (Keshava and Mustard, 2002). Materials are selected based on
their characteristic, distinct spectral signatures, and are referred to as “pure” endmembers (Painter et al., 2009; Keshava and
Mustard, 2002). The relationship between the fractional abundance of each material and its spectra can be defined either as
linear or non-linear. *Linear mixing models* assume that the spectra of a given pixel is a linear combination of the spectral
230 reflectance of the distinct constituent materials, and is the most widely used to distinguish vegetation, rock, or different snow
grain sizes (Painter et al., 2009). *Nonlinear mixing models* take into account multiple scattering between surfaces, and are
useful when the different materials are in close association, for example vegetation canopy height, or particulate mineral
mixtures (Keshava and Mustard, 2002). While non-linear models are more realistic, they are also less well developed in
the literature and were not considered here.

235 To yield physically meaningful results, fractions obtained from spectral unmixing routines should comply with two major
constraints: (a) the non-negativity (or positivity) constraint (i.e. fractions should not be negative) and (b) the sum-to-unity (i.e.
for each pixel, fractions should add up to 1) (Keshava and Mustard, 2002). The non-negativity condition is recommended
because negative reflectance values have no physical meaning, or for variable illumination conditions. The sum-to-unity
constraint is recommended when very dark endmembers such as shadows are targeted or for unmixing radiance or thermal IR
240 emissivity. Models which comply with both conditions are called “fully- constrained models” but are difficult to implement
as they require perfect knowledge of the system. Moreover, the constrained models have been shown to produce unrealistic
fractions in poorly defined areas or areas of low illumination (Cortés et al., 2014). In this study, we focused on two
implementations of linear mixing models (denoted hereinafter as ‘LMM’) available in the ENVI software, namely a partial
constraint (sum-to-one) and an unconstrained model, applied over the supraglacial debris cover only. For the Khumbu domain,
245 we also tested the ENVI implementation of the Spectral Angle Mapper (SAM), which is an automated, physically-based
spectral classification that matches each pixel to a reference spectra based on an the spectral angle between them (Kruse et al.,
1993). This method was used in the Alps with good results (Naegeli et al., 2015). The SAM method was relevant here because
it is relatively insensitive to illumination and albedo effects when used on reflectance data (Kruse et al., 1993), as is our case.

250 **2.5.2 Endmember selection and spectral signatures**

The selection of endmembers is crucial for the accuracy and reliability of the spectral unmixing (Song, 2005). Prior to selecting
endmembers, we performed a forward Minimum Noise Fraction Transform on the Khumbu Landsat image to determine the
dimensionality of the data. We extracted six endmembers using the pixel purity index routine in ENVI. These were checked
and refined using the n-D visualizer until they were statistically separable based on the Jeffries-Matusita and Transformed
255 Divergence separability measures (values > 1.9–2.0). We tested these against the automated Sequential Maximum Angle
Convex Cone routine in ENVI, which is an unsupervised, iterative algorithm for defining endmembers from spectral data

(Gruninger et al., 2004). We combined this iterative process with *a-priori* knowledge about types of surfaces on the supraglacial debris. We chose six endmembers, namely clean ice, dry vegetation, clouds, light and dark debris and turbid water, which we considered to be representative of the physical components of the glacier surface (Fig. 2). While previous studies (Painter, 2003; Painter et al., 2009; Rittger et al., 2013) only used three or four endmembers for unmixing Landsat data, we considered it necessary to include the cloud and clean ice endmembers ice in order to minimize model errors. We based this on that fact that images were mostly cloud free, and we would not expect clean ice to occur in large quantities on the debris surface. However, we performed model runs with 3, 4, respectively 5, endmembers to test this assumption. The endmember areas were carefully defined as single Landsat pixels to minimize the occurrence of “mixed pixels”, and their location was checked against colour composites of the Pleiades image (bands 4,3,2).

Fig. 2 here

Spectral signatures of endmembers were extracted from Landsat bands 1 to 7 (Fig. 3a). For the two debris classes, we visually compared the spectral signatures of dark and light debris endmembers with spectra previously acquired in the field on Mer de Glace in the French Alps using an SVC HR-1024 spectrometer (350 nm to 2500 nm) (Racoviteanu and Arnaud, 2013), as well as with supraglacial debris spectra from the Swiss Alps (Naegeli et al., 2015; Naegeli et al., 2017)(Fig. 3b). For the turbid water endmember, the spectra defined here corresponds well with field-based spectra for other turbid lakes in the Khumbu, such as Chola Lake, reported in other studies (Matta et al., 2017).

Fig. 3 here

2.5.3 Supraglacial debris cover masking

We used the database of global distribution of supraglacial debris cover (SDC v.1) (Scherler et al., 2018a), referred hereinafter as the “SDC dataset”. These debris cover outlines were derived from either Landsat or Sentinel-2 using three different algorithms, on the basis of the Randolph Glacier Inventory (RGI v.6) (RGI Consortium, 2017), as described in Scherler et al. (2018b). The Landsat-based extents issued from single band ratios agreed best with our previous debris-cover estimates based on manual digitization in terms of debris cover representation (Racoviteanu et al., 2013). We constrained our spectral unmixing analysis over these SDC outlines in order to reduce model complexity. Glaciers in this dataset span the period 1998-2001 for the central-eastern Himalaya, 2002 for the western (monsoon-dry transition zone) and mostly 2010 for China. We assumed that any changes in the debris-covered glacier areas from 1998 to 2015 would have occurred within these older outlines, since surge-type glaciers, and hence apparent glacier “advance” are rare or non-existent in the Himalaya region, contrary to the Karakoram (Sevestre and Benn, 2015). SDC outlines required pre-processing because supraglacial ponds were represented as “holes” in this dataset, and some contained geometry errors due to occurrence of nunataks. Since water was one of our target classes, we “filled” the holes and automatically checked and repaired the geometry of the SDC polygons. For the test Khumbu area, we removed supraglacial debris polygons with area less than 0.01 km², which proved to be erroneous areas upon visual

examination, i.e., sliver polygons or isolated bare land pixels. These are unwanted small polygons that typically result from polygon overlays; they do not represent a physical entity on the ground and can be removed in a semi-automated manner
290 (Delafontaine et al., 2009). The repaired SDC outlines were rasterized and used as a mask in the spectral unmixing process.

2.5.4 Surface classification and composition from fractional maps

SAM routines yield a set of greyscale rule images (one image per class), in which each pixel value represents the spectral angle (in radians) between the reference spectrum and the spectrum of each class. For the SAM routine, we combined the light
295 and dark debris into one class. We tested various thresholds for the maximum spectral angles (0.1 to 0.2), and evaluated the resulting classified image based on the spectral similarity of each class to reference spectra.

The LMM routines result in a multi-band raster containing pixel-by-pixel fractional cover values for each class, which ideally range from 0 to 1. However, negative fractions can occur when endmembers are missing or are poorly defined, although they do not necessarily affect the ability to discriminate between surfaces (Klein and Isacks, 1999). In case of negative values, we
300 inferred the absence of the material in that pixel upon examining the rasters, and we forced these negative values to zero. We then normalized values greater than 1 on a by dividing each endmember fraction by the sum of the endmembers, so that the sum of the fractions of the various materials in each pixel added up to 1. This is a common procedure suggested by previous studies (Rosenthal and Dozier, 1996; Quintano et al., 2012; Cortés et al., 2014). To classify the fractional maps, we applied a
305 threshold α (defined based on visual interpretation of the fractional maps) to produce binary maps for each class. The user-defined minimum threshold used in other studies such as snow mapping was $\alpha = 0.4$ or 0.5 , i.e. a pixel was assigned to the snow class if it contained a fraction of 40 – 50 % to 100 % snow (Hall, 2002; Rittger et al., 2013). Since any pixel contains a mixture of materials in various proportions, the thresholds varied by class and were adjusted carefully based on visual interpretation and validation with the Pleiades image. We also developed and tested an automated binary method in which
each pixel was assigned to the class for which it had the highest fractional cover.

310 We converted these lower - resolution (30 m) fractional maps into a finer classification map to estimate the composition of debris-covered glaciers at various spatial scales. We first estimated the composition for seven debris-covered glaciers from the Khumbu domain, which have been well studied in the past (Casey and Kääh, 2012; Watson et al., 2017). Using the spectra and spectral unmixing parameters from the Khumbu, we upscaled the composition to the entire supraglacial debris cover from the SDC v.1 dataset for the Himalaya spatial domain. This allowed us to compare and contrast the composition
315 of debris-covered tongues in three climatically distinct regions, ranging from west to east: Lahaul Spiti, Khumbu and Bhutan

domains (**Fig. 1** inset). All the post- spectral unmixing geospatial analysis steps were implemented in ArcPython scripting to allow for loop processing of multiple images and various spatial extents.

2.5.5 Accuracy assessment and validation

We first assessed the accuracy of the spectral unmixing routines qualitatively, based on visual interpretation and comparison with the high-resolution Pleiades. A more thorough accuracy analysis was performed using established quantitative measures (root mean square error – RMSE, fraction value abnormalities, residual values and confusion matrix) (Gillespie et al., 1990). Residuals were output from unmixing runs on a pixel-by-pixel basis as a separate band. We used this residual map to identify poorly defined endmembers and optimized the LMM by refining these iteratively until we obtained the lowest model RMSE. To assess the ground accuracy of the final LMM, we digitized 151 test pixels (10 – 38 pixels per class) on false colour composites of Pleiades and RapidEye images. These were well distributed on several debris-covered tongues in the Khumbu, and were taken to represent “ground truth”. These locations were compared to the predicted classes in the confusion matrix for the abundance maps. To further validate the LMM performance for water detection, we mapped the supraglacial ponds on seven debris-covered glacier tongues in the Khumbu from the October 2015 Pleiades scene using OBIA methods implemented in the ENVI Feature Extraction module (namely a combination of spectral mean and edge detection). The resulting ponds were manually inspected and corrected in shaded areas beneath ice cliffs following similar procedures as those described in Watson et al. (2017a). We also visually and quantitatively compared the “pond” pixels resulting from the LMM against Pleiades colour composites (bands 4,3,2). The date of the Pleiades pond reference dataset for the Khumbu glacier is one week apart from to the date of the Landsat scene but we assume minimal lateral expansion might have occurred between the two dates, as discussed by Watson et al (2018).

3 Results

3.1 SAM classification results in the Khumbu domain for the entire scene

Here we present the classification map for the five surfaces obtained with a maximum spectral angle of 0.15 (i.e. pixels with spectral angle > 0.15 were not classified) (**Fig. 4**). On Figure 4, we note that SAM classifier performed well for mapping snow and ice and identifying clouds. The debris-covered tongues were also identified roughly, although they contained some extra bare terrain and some water pixels were confused with debris. Supraglacial vegetation was detected at the edges and termini of debris-covered glaciers especially in the eastern part of the domain. This represented mostly dry vegetation (with higher reflectance in the visible and NIR bands compared to green vegetation). Healthy green vegetation present outside the glacier outlines at lower altitudes was not detected by the SAM, due to its distinct spectral signature (i.e., low reflectance in the blue and red bands due to absorption by chlorophyll and high reflectance in the green bands). Some turbid pro-glacial ice-contact lakes (e.g., Imja Lake) were well classified, but others such as the darker blue, less turbid, Gokyo Lakes and most of the supraglacial lakes were not detected. Some lakes are mostly composed of turbid water, with a higher reflectance in the

red bands due to the presence of suspended sediments, and hence a higher reflectance overall than that of clear water. The SAM results were useful here to test the endmember choices and fine tune them for the LMM routines. For example, some of the missing parts in the centre of debris-covered tongues in the northern part of the area (China) as well as Ngozumpa Glacier indicate the need for two debris endmembers to capture the variability in the surface reflectance of debris with varying lithology. Another advantage of the SAM is that it also provides unclassified pixels separately, as well as masked (shadow) pixels as separate classes. The SAM method is presented here only as an additional verification on the endmembers chosen for the subsequent LMM runs.

Fig. 4 here

3.2 Linear mixing model results for the Khumbu domain

In this study, we attempted both an unconstrained and partially constrained (sum-to-one) LMM implementations in ENVI. Despite the non-negativity constraint in the latter, both models yielded negative abundances for all classes, with larger positive values (> 3), especially for the vegetation class as discussed below. While a model is considered “valid” when class abundance < 1.01 (strict constraint rules) or < 2.01 (looser rules) and $RMS < 2.5\%$ (Painter et al., 2009), larger positive values for some classes are to be expected when using limited spectral resolution data (Landsat, 7 bands for unmixing) compared to hyperspectral data (for example AVIRIS, 224 bands) used more commonly (Painter et al., 1998). In terms of model performance, the unconstrained model run had a lower average root mean square error (RMS of 0.6 %) compared to the partially constrained model run (RMS of 1.5 %), so the unconstrained model results were presented in this paper. Here we present results for the unconstrained model, which had a lower average RMSE (0.6 %) than the partially constrained model (1.5 %) (section 4.4).

Examples of the normalized fractional maps for each of the six material types in the test Khumbu domain are presented in Figure 5. Light and dark debris had fractional pixel coverage as low as 0.25 and 0.40 based on comparison with Pleiades. Dry vegetation exhibited pixel fractions > 0.5 , for example as patches on the lateral moraine of Ngozumpa Glacier, and larger patches at the terminus of glaciers in China (**Fig. 5**). Pixels with abnormally high positive fractional vegetation values were found in areas of healthy green vegetation and/or bare terrain, which should not be part of the debris-covered tongues, as will be discussed later (section 3.4). Supraglacial ponds were mapped by thresholding the fractional water raster (fractional water > 0.5), which automatically mapped most ponds. These are well visible for example at the termini of Ngozumpa and Khumbu Glaciers (**Fig. 5**). Clouds were mapped using a threshold of 0.45, but these were often mixed with light or dark debris. For clean ice, fractional values mostly ranged from 0 (areas which might have some degree of dirty, dark ice with a lower albedo) to 1 (clean ice). A fractional ice threshold of 0.20 was useful to classify these ice surfaces.

Fig. 5 here

3.3 Accuracy of the fractional cover maps

380 The overall accuracy of the LMM-based classification was 0.75, with a Kappa coefficient of 0.69 (Table 2). The confusion
matrix presented in Table 2 shows that dark debris was 100 % classified with respect to the reference pixels. Dry vegetation
and water were also classified with a high accuracy (> 83 %), and light debris was classified at 70 %, as some light debris
pixels were confounded with vegetation. Clouds were only classified with 50 % overall accuracy, and these were only
present over small areas. Clean ice was the most poorly classified with an accuracy of 7.1 %. Considering its distinct spectral
385 signature from other classes (Fig. 3), we attribute this to the poor representation of the clean ice class on the debris-covered
tongues, because, in addition to there being only a very small horizontal surface area of exposed ice, it tends to also be
heavily dusted with fine debris.

In Table 2 we also present accuracy measures for each class as omission errors / producer's accuracy (i.e., percentage of pixels
that were omitted from each class) and commission errors/ user's accuracy (i.e., percentage pixels that belong to a category
390 but are mistakenly assigned to another category). The dark debris class had the highest (100 %) producer's accuracy (all
reference pixels on the ground were correctly classified) but lower (56 %) user's accuracy (Table 2). Water and vegetation
classes had high producer's and user's accuracy (> 83 % and > 93 % respectively), i.e., most reference pixels in these classes
were correctly classified, with a high probability that pixels assigned to these two classes contain some amount of the respective
surfaces on the ground. Similarly, light debris had a producer's and user's accuracy > 70%. Clean ice pixels, on the contrary,
395 were not well classified, as 93 % of the ice pixels were omitted (producer's accuracy = 7 %). Clouds were classified at 50 %
producer's accuracy, as 38 % pixels from other classes were mistakenly assigned to this class. Based on the confusion matrix,
we note that overall, the LMM most accurately classified the water, vegetation, and debris classes.

Table 2 here

3.4 Composition of the debris-cover glacier tongues at multi - scale

400 For the seven debris-covered glacier tongues in the Khumbu (Table 3) the most prevalent material in this subset region, as
expected, is debris (dark and light), with an average of 53.7 % and 43.6 % of the debris-covered tongues, respectively. At
regional scales, debris-cover glacier tongues in the Lahaul Spiti region are composed of 13.1 % dark debris and 74.4 % light
debris, and in the Bhutan domain they are composed of 15.0 % and 64.1 % light debris (Table 4). Overall, light debris is

prevalent over the entire Himalayan domain, comprising almost three times the amount of dark debris (60.9 % vs. 23.8 %, respectively) (Table 4).

Table 3 here

Table 4 here

The dark and light debris areas exhibit variable distribution patterns by glacier (**Fig. 6**). For example, the debris-covered tongue of Nuptse Glacier in Khumku is mostly covered by light debris (> 95 % of its area), while the opposite is true for Lhotse Glacier, which is mostly composed of dark debris (> 91 %) (Table 3). Other glaciers in the eastern part of Khumbu exhibit alternating bands of light and dark debris, with darker bands correctly representing medial moraines (**Fig. 6**). Glaciers in the western part of the Himalaya are mostly composed of supraglacial light debris.

Fig. 6 here

Exposed ice was detected in small quantities on the seven debris-covered glacier tongues in the Khumbu, ranging from 0.2 % (Lhotse) to a 1.4 % (Changri Nup) with an average of 0.6 % of the debris-covered part. A total of 126.5 km² of ice (5.6 % of the debris area) was detected over the entire Himalaya (Table 4). Some ice pixels were detected at ice cliffs (**Fig. 7**), but since these are covered with a fine layer of darker particles, they have a lower albedo and lower spectra than that of clean ice (Naegeli et al., 2015), they cannot be properly identified using this endmember.

Fig. 7 here

Clouds were not present over the seven tongues in the Khumbu. While some isolated pixels were classified as clouds, this part of the image is cloud free, and some cloud pixels were confounded with other types of surfaces, notably debris (Table 2). Over the entire range, we mapped 45 km² of cloud coverage, corresponding to 2.0 % of the supraglacial debris cover, with less coverage in Lahaul Spiti and Khumbu (1.6 % and 0.6 % of the supraglacial debris cover, respectively) compared to the Bhutan domain (6%). While these patterns may be explained by climatic patterns, i.e. more frequent cover in the eastern Himalaya in September where glaciers in the eastern Himalaya continue to experience precipitation and more frequent cloud cover until late fall months (Thayyen and Gergan, 2010), we are less confident in the actual estimations of the cloud cover areas.

Patches of supraglacial vegetation were detected over debris-covered tongues, ranging from ~0 % (Lhotse Nup Glacier) to 1.6 % (Ganara Glacier), with an average of 0.5 % over the seven tongues. The higher percentage for the latter is most likely due to some debris and ice pixels mistakenly assigned to the vegetation class (Table 2). At the scale of the Khumbu domain, a closer look at these highly “vegetated” pixels revealed some interesting findings. Some glaciers, for example Khazenpu Glacier in China, exhibit supraglacial vegetation which was correctly mapped using the spectral unmixing (**Fig. 8a**). On other glaciers,

for example Labeilong Glacier in the same area, besides correctly mapped supraglacial vegetation, we also detected large patches of vegetation which actually represent non-glacierized bare land and/or healthy vegetation outside the debris-covered glacier outlines, but these were included in the SDC v.1 dataset (**Fig. 8b**). Such spurious vegetated areas present within the debris cover outlines may have affected to some extent the quality of the spectral unmixing, particularly the non-negativity condition, because it produced large negative and positive fractional vegetation values. The most obvious areas were corrected manually for Khumbu, but no corrections were applied when applying the unmixing over the entire Himalaya domain. Overall, supraglacial vegetation covered 4.5 % of the debris-covered glacier surface in the Himalaya, with less supraglacial vegetation in the western part (Lahaul Spiti, 1.6 % of the debris cover) compared to the central and eastern Himalaya (Khumbu and Bhutan domains, ~3 %).

Fig. 8 here

The fractional supraglacial pond area in the Khumbu in 2015 ranged from 0.9 % (Lhotse and Nuptse Glaciers) to ~ 3 % of the debris-covered glacier area (Ngozumpa and Khumbu Glaciers), with an average of 1.6 % over the seven debris-covered glacier tongues (Table 3). The larger fractional water coverage for the latter two may be explained by the presence of large supraglacial ponds at the terminus of these two glaciers (**Fig. 6**). We obtained a supraglacial pond area of 47 km² over the entire Himalaya (2.1 % of the total supraglacial debris cover area), with regional variability from west to east (Table 4).

3.5 Supraglacial pond validation

To validate the subpixel supraglacial pond classification, we mapped pond extents from the high-resolution Pleiades image using OBIA image segmentation for the seven reference glacier tongues in the Khumbu region. We compared outputs of various manual thresholds, and a binary automated method for classifying supraglacial ponds from the fractional maps (as described in section 2.5.4) against the Pleiades-derived pond areas. A threshold of 0.5 applied to the water class (fractional water > 0.5 = supraglacial ponds) yielded the best agreement with the lake areas obtained from the high-resolution Pleiades image (1.0 km² compared to 1.1 km² for the total coverage, respectively) (Table 5). This is in agreement with other spectral unmixing studies (Hall, 2002; Rittger et al., 2013), which suggested using a threshold of 0.5 for the fractional maps to map seasonal snow.

Table 5 here

In Table 6 we compare the pond coverage obtained using a threshold of 0.5 and an automated binary classification method (i.e., based on the maximum fractional values) against the Pleiades pond areas. When using the automated approach, the total supraglacial pond coverage was over-estimated by 64 % compared to the Pleiades pond area. For the Khumbu glacier, for example, Landsat spectral unmixing yielded a total binary pond area of 0.20 km², in agreement with the area estimated from OBIA analysis using Pleiades (0.23 km²). This is also consistent with the area estimated by Watson et al. (2017b)(0.24 km²)

based on similar methods using the same Pleiades image (Oct 7, 2015) (Table 6). The automated maximum fraction method yielded 0.27 km² for the pond area. For the pond area, the area difference between the thresholded and the manual method is small (0.07 km²), but this has to be however considered when upscaling such results to larger areas.

465 **Table 6 here**

Figure 9 shows the supraglacial pond maps for three glacier termini in the Khumbu domain, compared to the OBIA Pleiades ponds. There is good agreement for the pond coverage for the Ngozumpa and Khumbu Glaciers. For Lhotse Glacier, the supraglacial pond area is slightly under-estimated compared to Pleiades, as noted in Table 6. This may perhaps be due to the predominant darker debris of this glacier, some of which was confused with water, as shown in the confusion matrix (Table

470 **2).**

Fig. 9 here

4 Discussion

4.1 Variability in the composition of debris-covered tongues across the Himalaya

4.1.1 Debris type

475 The composition of debris-covered tongues presented in this study shows that the light debris is prevalent over the entire Himalayan domain, comprising almost three times the amount of dark debris (60.9 % vs. 23.8 % of the debris cover area, respectively). Overall, light debris material tends to dominate particularly in the western parts of the range, which presumably reflects the nature of the underlying bedrock geology (Searle et al., 1987). Sub pixel routines tested here capture the variability in the geological material present on the surface of the debris-covered glaciers in the Himalaya. With regards to the on-the
480 ground spectral characteristics of the debris material in the Khumbu region, Casey et al. (2011) showed that these vary due to the presence of various of minerals, notably distinct granitic (lighter) vs. schistic (darker) debris types. These findings supported our choice of separating the debris material into two different classes: light and dark debris, corresponding to the principal types of material composition found across the mountain range.

485 4.1.2 Exposed ice

The percentage coverage of clean ice within the debris covered area for the entire range (5.6 %) is considerably higher than that for the reference glaciers in the Khumbu region (0.6 % on average) (Table 3). At the date of analysis, chosen based on the Pleiades image (Sept 30th, 2015), we suspect that debris-covered glaciers in some parts of the range may have supraglacial snow because of the differences in timing of the end of ablation season across the mountain range. In terms of spectral
490 unmixing, the algorithm was able to detect snow and ice on the surface of the debris-covered glaciers, corresponding to clean

ice patches at the upper limit between supraglacial debris and clean ice due to either inaccuracies in the input data (inclusion of clean ice) or the presence of snow from avalanches. Given the spectral limitations of the Landsat imagery, we used a “clean ice” endmember and thus we did not expect the algorithm to fully detect dirty ice at the ice cliffs, which have a lower albedo. In terms of ice cliff coverage, we could not extract the accurate percent of ice coverage unless the images are completely free of clean ice and snow. However, we did detect the presence of ice pixels around some supraglacial ponds, indicating the presence of ice cliffs, but this was not the main focus of this study. Targeting exposed but dusted ice features within the debris cover in addition to clean ice would need some refinement of the algorithms we used to optimally detect supraglacial ponds, and better spectral resolution of the imagery.

500 4.1.3 Supraglacial pond occurrence

The coverage of supraglacial ponds over the entire range (2.1 %) is within the range of glacier-by-glacier variability noted in the Khumbu reference area (Table 3). However, this varies across the Himalaya, from a low coverage of in the drier areas in the monsoon transition zone of Lahaul Spiti (0.3 % of the debris-covered area) to 1.6 % in the central Himalaya (Khumbu region) and it is almost seven-fold (4.9 % of the debris-covered area) in the eastern, monsoon influenced parts of Himalaya (Bhutan). We speculate that the lower abundance of supraglacial ponds in the western part of the range is due to a combination of debris cover characteristics and climatic conditions. Climatic conditions and glacier characteristics in the western part of the Himalaya are more similar to the ones in the Karakoram, which have undergone less glacier shrinkage (Brun et al., 2017; Käab et al., 2012; Gardelle et al., 2013) while the eastern, monsoon-influenced Himalaya experience higher temperatures, and lower glacier termini elevations. Supraglacial ponds have been shown to form in on stagnating areas on the ablation areas of glaciers, with surface angles lower than 2° (Sakai and Fujita, 2010; Reynolds, 2000). Pond formation has been shown to relate to the amount of downwasting a glacier surface has undergone and to the related reduction of the downglacier slope angle. In this sense, the degree of pond coverage could be considered an indicator of the degree of glacier decay.

4.1.4 Supraglacial vegetation

515 Although we estimate that some of the classified vegetation also includes healthy vegetation and bright non-glacierized bare terrain (section 3.4), we found that supraglacial vegetation is less prevalent in the west (Lahaul Spiti) than in central and eastern Himalaya (Khumbu and Bhutan domains). Glacier tongues here descend to lower elevations (~3,700 m to 4,400 m compared to ~ 4,700 to 4,900 m in the western part) which, in conjunction with the more humid, monsoon-influenced climate might favour vegetation growth. Development of vegetation (mostly shrubs) has been noted on stagnant, thick debris-covered tongues in other areas of the world (Xie et al., 2020a; Tampucci et al., 2016), and was found to be increasing in certain glacierized areas such as the Alps as a consequence to climatic change and declining glaciation (Vezzola et al., 2016). As vegetation typically will only develop on stagnant surfaces that are no longer undergoing substantial gravitational reworking, its presence is also an indication of glacier inactivity and later stages of decay.

4.2 Controls on supraglacial pond and vegetation coverage

525 Supraglacial ponds and vegetation may reveal information in terms of understanding the evolution of debris-covered
glaciers. For example, the expansion of supraglacial lakes at the terminus of a glacier is a precursor to the transition to a
proglacial lake which may present an enhanced potential for glacial hazard such as glacier lake outburst floods, and
supraglacial vegetation growth may indicate the transition of a debris-covered glacier to an inactive glacier tongue or a rock
glacier. To investigate this further, we explored the possible dependency of supraglacial pond and vegetation cover on
530 topographic variables (elevation, slope, extent of supraglacial debris cover and geographic location). We only performed this
analysis on debris cover glacier tongues $> 1 \text{ km}^2$ in order to remove spurious small bare land patches or isolated debris
pixels. This threshold was also chosen considering that these tend to have higher turbidity (i.e. grey colours) (Matta et al.,
2017) and larger water volumes, which is of concern for outburst flood potential. After the area filtering, the resulting dataset
comprised 408 debris-covered glacier tongues, most of which (90 % of the total number) had a surface area less than 5 km^2
535 and had a mean slope of 12.7° , with a minimum of 7° . The average slope is consistent with values used in previous studies to
delineate debris covered glaciers (10 to 15°) (Bolch et al., 2007; Racoviteanu and Williams, 2012; Lippl et al., 2018; Robson
et al., 2015). While slope thresholds are region-dependent, the minimum slope obtained when filtering the debris covered
glaciers by area is consistent with other areas, for ex. 6.7° in the Hunza (Xie et al., 2020a). Both the area and surface slope
have a skewed distribution (**Fig. 10**). Slope angles $> 30^\circ$ were associated with bare steep terrain outside the glaciers, which
540 was mistakenly classified as supraglacial debris in the SDC v.1 dataset (cf. **Fig. 8**).

Fig. 10 here

We did not find a significant correlation between supraglacial pond coverage and average debris cover slope angles or
elevation. Supraglacial ponds are expected to occur predominantly on parts of the debris cover with slopes less than 2°
(Sakai et al., 2000; Reynolds, 2000) and negative glacier mass balance. From the analysis of supraglacial pond area coverage
545 with respect to average debris cover slope (**Fig. 11a**), we can only say that the debris covered tongues with slopes $< 10^\circ$
comprise on average 1.3 % supraglacial ponds, and for average slopes $> 20^\circ$, this drops to an average of 0.07 %, which is to
be expected because at steeper slopes, meltwater can drain away (Reynolds, 2000).

Fig. 11 here

We note a decreasing pattern in supraglacial pond coverage with debris cover area, with larger glaciers displaying a
550 maximum of ~ 5 % ponds on their surface, but the trend is not statistically significant at 95% confidence interval (Fig. 11b).
Supraglacial ponds covered in general 0 to 2 % of the debris cover area (**Fig. 11b**), with more extreme values (up to 20 % of

the debris area) for higher debris cover termini, some of which we attribute to errors in the input SDC dataset. We did not find a clear trend of pond coverage with respect to minimum elevation (**Fig. 11c**).

Supraglacial vegetation coverage did not display strong dependencies on slope nor minimum elevation of the debris-covered
555 tongues (**Fig. 11a-b**). While we could hypothesize that vegetation tends to develop on stagnant, low slope debris-covered
tongues situated at lower elevations, the trends were not statistically significant. In general, supraglacial vegetation cover
was concentrated on glaciers with an average slope less than 25 % and minimum debris elevation situated from 3,000 m to
5,000 m (**Fig. 11c**), with some extreme fractional vegetation values > 40 % at higher elevations, which we attribute again to
errors such as those noted in Figure 8. The lack of significant dependencies of supraglacial pond coverage and vegetation
560 may imply that their distribution is governed by more complex factors which may include geomorphologic and climatic
patterns, which cannot be examined here in detail.

The distribution of supraglacial pond and vegetation coverage across the entire mountain range (**Fig. 12**) shows that both
supraglacial ponds and vegetation cover a relatively small percent of debris-cover areas in Western Himalaya (0 to 2.5 %),
with clusters of higher percentage in the central-eastern Himalaya (7.5 to 10% and 20 – 40 %, respectively). The high
565 percentage of supraglacial vegetation in some of the eastern parts is partly explained by the errors in the input supraglacial
dataset, as explained earlier, and we are hesitant to over interpret the vegetation analysis.

Fig. 12 here

4.3 Further applications and comparison with regional lake databases

The fractional water maps obtained from the spectral unmixing techniques presented here can be further used to characterize
570 the state of lakes and ponds in terms of their turbidity, i.e., by quantifying the fraction of a pixel covered by water, light and/or
dark debris (Fig. 13). This aspect is not fully explored in this study, but can be further investigated using field measurements
spectra of ponds and lakes with various degrees of turbidity (Matta et al., 2017; Giardino et al., 2010) to characterize the lake
turbidity across the mountain range. In this regard, repeated monitoring of pond turbidity using these combined tools allows
tracking changes in suspended sediment load over time, which are considered direct indicators of glacier wasting processes
575 and glacier–lake interaction (Giardino et al., 2010).

Fig. 13 here

Another important application of this study is the mapping of lakes outside the glacier areas across the mountain range. This
can be achieved by replacing the turbid water with a clear water endmember, and applying the unmixing over the full
Landsat extent rather than just the debris cover. Mapping all the lakes was beyond the purpose of this study, but initial tests
580 provide an illustration of such an output for the terminus of Ngozumpa Glacier (**Fig. 13**). We compared our lakes and pond
extents with two existing glacial lakes databases constructed from the same year (2015 Landsat): the HMA v.1 lake dataset,

585 derived using a normalized difference water index (Shugar, 2020b) and HI-MAG constructed using a modified NDWI and
manual corrections (Chen et al., 2020). A comparison with other global databases such as the Global Surface Water (GSW)
(Pekel et al., 2016) was not undertaken here, as this has already been shown to underestimate the water occurrence over most
of the Himalaya by Chen et al. (2020). With regards to HMA v1 and HI-MAG datasets, Figure 13 shows that the lake
outlines obtained from spectral unmixing in this study are outperforming both of the existing databases. Our lake extents are
consistent with the HMA v.1 lakes extents outside debris cover (**Fig. 13**), and the surface area estimates agree quite well, for
example we calculated a difference of 5 % in the summed pond area over the three Gokyo Lakes (1.15 km² in our estimates
vs. 1.09 km² in HMA v.1). The slight underestimate in the latter is due to simplification of the raster edges in the vector
590 conversion process, visible in the lake extents. With regards to supraglacial ponds, for example Spillway Lakes at the
terminus of Ngozumpa Glacier, our spectral unmixing technique maps most of these lakes, while both HMA v.1 and the HI-
MAG datasets fail to detect all the supraglacial ponds (**Fig. 13**). The HI-MAG detects more of the surface of Spillway Lake
compared to HMA v.1, but the outlines are very much simplified and lack precision with respect to Landsat pixels (**Fig. 13**).
We did not simplify the lake and pond polygons, as this can introduce significant area errors. The examples above show that
595 spectral unmixing can help refine and complement these larger databases at regional and global scales.

4.4 Uncertainties and limitations

While spectral unmixing is a relatively straightforward routine to implement, limitations and main difficulties in correctly
applying this routine arise due to several factors: 1) quality and limitations of the input data; 2) illumination differences and
3) uncertainties in the endmember selection and in the unmixing routine itself.

- 600 (1) With respect to the quality of the input data, our study relied on Landsat-8 OLI. Using the Landsat series has the advantage
of spanning several decades (1972 to present), with the possibility of replicating this study for past decades. While
previous missions such as Landsat 7 missions suffer from saturation at the sensor and data gaps due to Scan Line Corrector
(SLC)-off, these were still useful for snow mapping as noted earlier. Using Landsat data has the advantage that the same
methodology can be applied to previous Landsat missions to investigate changes in supraglacial features. For dates post-
605 2015, Sentinel-2 or the future Landsat-9 may be used to improve the performance of the spectral unmixing.
- (2) Atmospheric and topographic corrections were found to be necessary when applying the spectral unmixing over large
areas. In this study, such corrections helped minimize illumination differences, remove deep shadows etc. so we were
confident that spectra developed for the Khumbu could be used over the entire Himalaya. However, in some areas, some
spectral differences may have remained, leading to confusion between the water and light debris classes and hence some
610 over-estimation of the pond coverage particularly in some areas of the western Himalaya. Such areas require some post-
classification corrections prior to their inclusion in regional datasets, but these will not be very computationally-intensive.

- 615 (3) The endmember selection was a crucial step in the spectral unmixing process, as it is prone to uncertainties and limitations of the satellite imagery used. The impact of the different parameters of the spectral unmixing model on the performance of the subpixel mapping needs to be thoroughly evaluated (Xu et al., 2017). One of the difficulties of applying spectral unmixing lies in capturing the variability of the system while maintaining a low model complexity to ensure a “valid” model. In this study, Pleiades imagery combined with field expertise was essential in fine tuning our choice of materials and extracting “pure” pixels. We used six endmembers, which can be considered large compared to the limited number of Landsat bands ($n = 7$). However, our tests with fewer classes (three or four) resulted in large model errors (RMS) due to missing classes. To minimize the numbers of classes, we made several choices: (a) We combined snow and clean ice
620 into one class (even though their spectral signatures were statistically different), and this potentially reduced the accuracy of the clean ice classification. (b) For the same reasons, we could not define a dirty ice endmember as done in studies using hyperspectral imagery (Naegeli et al., 2015). (c) On the debris surface, we assumed the supraglacial ponds to be mostly of turbid type, with larger quantities of suspended sediments, though some small clear water supraglacial ponds may exist as well (Takeuchi et al., 2012; Giardino et al., 2010). The limited Landsat spectral resolution implied that we
625 could not concomitantly use both a clear and turbid water endmember in the spectral unmixing. However, we used these two endmembers in different model runs, and then combined the results. (d) We defined both a light and dark debris endmember on the basis of spectral differences noted in other studies (Casey et al 2011), but we are aware that these may not cover the wide spectrum of lithology present across the Himalaya. Using a single debris endmember would have resulted in large RMS errors, indicating a missing or poorly defined class. (e) The vegetation endmember was defined as
630 graminoid shrubs or overgrown vegetation with a grass-like appearance, which occur at high altitudes (Wehn et al., 2014). However, we note that some small amounts of healthy vegetation do occur on debris-covered glaciers, and the spectral unmixing was able to detect these healthy vegetation areas as well. (f) A cloud endmember was needed because when omitted, cloudy areas were confused with light debris. However, clouds were accurately mapped using the SAM unmixing method and perhaps removed prior to running the LMM, so these two methods can be combined in order to get a better
635 accuracy. Cloud masking algorithms such as Fmask (Zhu et al., 2015) do not perform well over glacierized areas because of the confusion of snow and ice with clouds.
- 640 (4) Our study revealed some important issues with the input SDC v.1 dataset used to constrain the spectral unmixing, particularly with respect to the inclusion of healthy vegetation and bare, bright steep terrain in the debris cover extents. This affected the accuracy of the LMM to some extent, notably by resulting in large negative and positive values. On the other hand, these abnormal values can be used to identify errors in the existing global supraglacial debris cover maps, and thus a valuable tool to correct and refine these databases.

5 Summary and further work

645 In this study, we estimated the spatial distribution of surface characteristics on the debris-covered glaciers (various types of debris, clean ice, supraglacial ponds and vegetation) at a subpixel scale using 30 m fractional maps obtained from a spectral linear mixing model. We developed the spectral unmixing in the wider Khumbu region of eastern Nepal and China using Landsat combined with Pleiades and RapidEye imagery, and then applied them over the entire Himalaya to test its applicability to a wider domain. Our key findings can be summarised as follows:

- 650 • We have demonstrated that spectral signatures derived from the Landsat image and cross-checked using high-resolution Pleiades from the same date can be successfully applied at the mountain range scale provided that all images are atmospherically and topographically corrected to reduce differences in illumination patterns;
- We successfully used spectral unmixing to map supraglacial ponds at the scale of the entire Himalaya from coarse resolution and freely available Landsat imagery, and this approach can provide more detail, and thus outperform other
655 analyses of automatic lake identification and classification performed on similar Landsat data for the same period but based on normalized difference water indices (Shugar, 2020b; Chen et al., 2020);
- Spectral unmixing thus allows us to produce more accurate supraglacial pond maps from historical coarser satellite imagers that are more comparable to mapping quality from higher resolution, and more recently available imagery, allowing improved analysis of multitemporal change in pond incidence and size;
- 660 • Extreme fractional vegetation pixels identified by the spectral unmixing can be used as a tool to indicate non-glacierized terrain that has been incorrectly included in global debris-covered glacier databases such as the SDC v.1 (Scherler et al., 2018a);
- We are less confident of the utility of spectral unmixing in identifying exposed ice within the debris cover from coarse scale imagery. Because of its limited spectral resolution, we could not effectively optimize our end member selection
665 to identify the steep, dusted ice typically found within the debris cover. This is a pity as such exposed ice is of interest is known to contribute disproportionately to total glacier ablation (Steiner et al., 2015; Brun et al., 2018);
- While the limited Landsat spectral resolution did not allow for a very fine definition of the wide spectrum of all the different debris lithologies and ice types present on debris-covered tongues across the study area, LMM successfully distinguished among broad categories. Overall, we consider the spectral unmixing method presented here a promising
670 approach to add to the suite of tools that are valuable in analyzing the dynamic surfaces of debris covered glaciers.

Future developments include exploring the use of more sophisticated non-linear mixing models, including the ERDAS Subpixel Classifier, which is useful for specific materials that may be spectrally either similar or different to other materials in the scene and overcomes the limitations of LMM in discriminating materials of interest in detail. Furthermore, while we developed this routine in commercial remote sensing software (ENVI), the spectral signatures and the linear unmixing steps
675 can be integrated in other python-based routines. Other improvements envisioned include applying the spectral unmixing

developed here on recent Sentinel-2 imagery, which has a better spectral, spatial and temporal resolution (13 bands in the visible to shortwave infrared, 10 – 20 m, 5-day revisit time) compared to Landsat (7 bands in the visible to shortwave, 30 m, 16-day revisit time), allowing for better definition of endmembers, more accurate and repeated mapping in the future.

680 With continued advances in satellite data in the near future, the methodology developed here provides avenues towards achieving large-scale, repeated mapping of supraglacial features. Ongoing work is undertaken to make the unmixing step approach fully automated by integrating it in python-based routine such as RSGISLIB software (Bunting et al., 2014), so it can be applied to derive supraglacial pond outlines at multi-temporal scales to monitor pond development over time.. Given that these surface ponds are ephemeral and change rapidly, automated multi-temporal scale mapping is highly desirable to track their evolution over time in various regions. Mountain-range mapping of the pro-glacial lakes using the clear water class
685 as an endmember is currently in progress and can help complement existing databases. Thus, this analysis presented here complements and expands the existing lake databases for the year 2015 such as the HI-MAG or the HMA, with a particular emphasis on providing supraglacial debris cover pond extents. Such a mapping effort has not been undertaken at the scale of the Himalaya to our knowledge.

6 Author contributions

690 AR led this work, conceiving the idea, designed the spectral unmixing experiments, obtained and processed the Landsat images and wrote the paper. LN provided Pleiades imagery, discussed the research strategy and helped select endmembers based on field expertise. NG supervised the study and provided geomorphology expertise. All authors contributed to writing the paper.

7 Code availability

695 Atmospheric and topographic corrections have been performed using the ARCSI routine, which is embedded in the freely available, python-based RSGISLIB software (Bunting et al., 2014). The code for batch processing of the Landsat OLI images for the entire Himalaya can be provided upon request. Post-processing of the spectrally unmixed Landsat OLI maps was done in ArcPython. The steps for loop processing (normalizing the fractional rasters, classifying the surfaces, and extracting the composition of the debris-covered glaciers from the fractional maps) can be provided upon request.

8 Data availability

700 Landsat OLI data used in this study can be obtained at no cost from the USGS Earth Explorer (<https://earthexplorer.usgs.gov/>). All versions of the NASA SRTM Global 1-arc second DEMs are available from the EarthData platform (<https://earthdata.nasa.gov/>). All versions of the ALOS Global Digital Surface Model, including the one used in this paper, are available from <https://www.eorc.jaxa.jp/ALOS/en/aw3d30/index.htm>. Preliminary datasets of supraglacial ponds and vegetation, along with the fractional maps are available via Zenodo data repository (DOI:10.5281/zenodo.4421857) and will
705 be updated regularly after post-classification corrections.

9 Competing interests

The authors declare that they have no conflict of interest.

10 Acknowledgements

- 710 This research received funding from the European Union's Horizon 2020 research and innovation programme under the Marie Skłodowska-Curie grant agreement No 663830. LN was supported by the Austrian Science Fund (FWF) Grant P28521. Access to Pleiades imagery was provided through the Österreichische Forschungsförderungsgesellschaft (FFG) project “High resolution spaceborne studies of mass balance processes on glaciers of the Khumbu Himal, Nepal” (GIHima-Sat). We acknowledge the BritInn Fellowship programme which funded AR’s work visit to Univ. of Innsbruck to develop this research
- 715 with LN in 2018. We are grateful to United States Geological Survey and to Planet API program for providing free access to Landsat and RapidEye imagery. Thanks for Lorenzo Rieg and Christoph Klug of the University of Innsbruck for processing of the Pleiades DEMs.

	147/37		2015-09-15			
147/38	2015-09-15					
1040 Pleiades	-	Level 1A	2015-10-07 2015-10-19 2015-10-20	Blue, green, red, and NIR	2	20
1045 Rapid- Eye		Level3A Analytic	2015-10-09	Blue, green, red, red edge, NIR	5	77

Table 2 Confusion matrix of the spectral unmixing expressed as percentage accuracy (computed as numbers of pixels classified correctly/total number of reference pixels). Diagonal values represent number of pixels that are correctly classified, and off-diagonal are number of pixels that are misclassified. Class accuracy is reported as omission and commission errors and corresponding Producer's and User's accuracy (as percent).

	clean ice	turbid water	debris dark	debris light	clouds	vegetation dry	Commi-ssion	Omi-ssion	Produ-er's	User's
clean ice	7.1	0.0	0.0	0.0	0.0	0.0	0	93	7	100
turbid water	14.3	84.2	0.0	0.0	0.0	0.0	6	16	84	94
debris dark	28.6	15.8	100.0	26.7	50.0	0.0	44	0	100	56
debris light	21.4	0.0	0.0	70.0	0.0	16.7	28	30	70	72
clouds	21.4	0.0	0.0	0.0	50.0	0.0	38	50	50	63
vegetation dry	7.1	0.0	0.0	3.3	0.0	83.3	7	17	83	93

Table 3 Fractional composition of each material for the seven debris-covered tongues in Khumbu, expressed as percent of the debris-covered part of each glacier.

Glacier	Clean ice (%)	Water turbid (%)	Debris dark (%)	Debris light (%)	Cloud (%)	Vegetation dry (%)
Khumbu	0.4	2.8	17.2	79.3	0.0	0.3
Lhotse	0.2	0.9	91.1	7.5	0.0	0.4
Lhotse Nup	0.7	1.0	69.1	29.2	0.0	0.0
Ngozumpa	0.4	2.7	54.2	42.2	0.1	0.5
Nuptse	0.3	0.9	2.7	95.8	0.0	0.3
Changri Nup	1.4	1.3	76.0	20.9	0.0	0.5
Gaunara	0.9	1.4	65.6	30.5	0.0	1.6
Average	0.6	1.6	53.7	43.6	0.0	0.5

Table 4 Composition of the debris-covered glaciers over the entire Himalaya and three selected domains listed from west to east. Debris cover surface areas are based on the SDC v.1 dataset (Scherler et al., 2018a).

	Lahaul Spiti		Khumbu		Bhutan		Entire Himalaya	
	Area (km²)	%	Area (km²)	%	Area (km²)	%	Area (km²)	%
Clean ice	10.2	5.0	2.7	0.9	10.1	7.8	126.5	5.6
Clouds	3.3	1.6	0.6	0.2	7.8	6.0	45.0	2.0
Debris (dark)	26.6	13.1	148.1	48.9	19.5	15.0	535.4	23.8
Debris (light)	151.4	74.4	130.2	43.0	83.1	64.1	1371.0	60.9
Turbid water	0.6	0.3	4.9	1.6	5.2	4.0	47.0	2.1
Vegetation (dry)	3.3	1.6	9.6	3.2	4.1	3.1	101.7	4.5
Unclassified	8.0	4.0	6.9	6	0.0	0.0	26.0	1.2

Table 5 Differences in the supraglacial pond area for seven glaciers in the Khumbu for various thresholds applied to the fractional water maps.

Glacier	Surface area (km²)		
	Fractional water > 0.4	Fractional water > 0.45	Fractional water > 0.5
Khumbu	0.45	0.32	0.20
Lhotse	0.07	0.06	0.05
Lhotse Nup	0.03	0.03	0.02
Ngozumpa	0.79	0.66	0.50
Nuptse	0.09	0.05	0.03
Changri Nup	0.25	0.19	0.09
Gaunara	0.16	0.12	0.07
Total pond coverage	1.8	1.4	1.0

1075

Table 6 Area comparison between Landsat spectral unmixing pond areas (this study) and OBIA mapping results for the seven reference glaciers based on Pleiades scene.

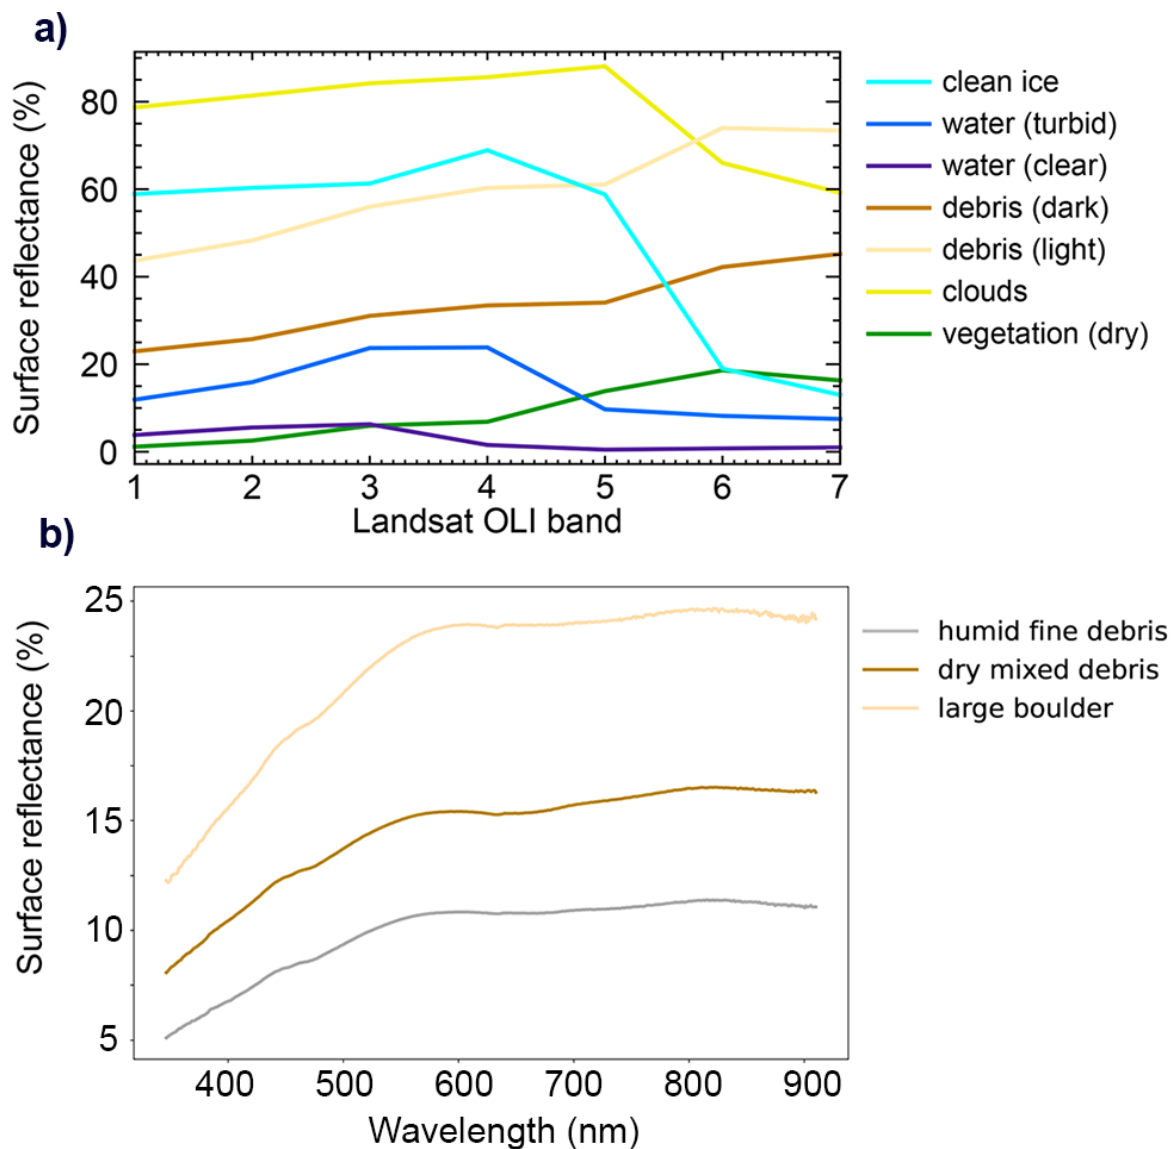

Glacier	Debris area (km ²)	Landsat spectral unmixing				Image date	Pleiades OBIA		
		Automated		Manual			Pond area (km ²)	% coverage	Image date
		Pond area (km ²)	% coverage	Pond area (km ²)	% coverage				
Khumbu	7.5	0.27	3.6	0.20	2.8	0.21	2.7		
Lhotse	5.2	0.08	1.5	0.05	0.9	0.08	1.7		
Lhotse Nup	1.5	0.04	2.6	0.02	1.0	0.02	1.6		
Ngozumpa	19.4	0.83	4.3	0.50	2.7	0.59	3.0		
Nuptse	2.9	0.06	2.0	0.03	0.9	30/09/2015	0.03	1.0	07/10/2015
Changri Nup & Shar	7.3	0.18	2.5	0.09	1.3	0.11	1.5		
Gaunara	5.2	0.22	4.2	0.07	1.4	0.09	1.7		
Total	49.0	1.7		1.0			1.1		

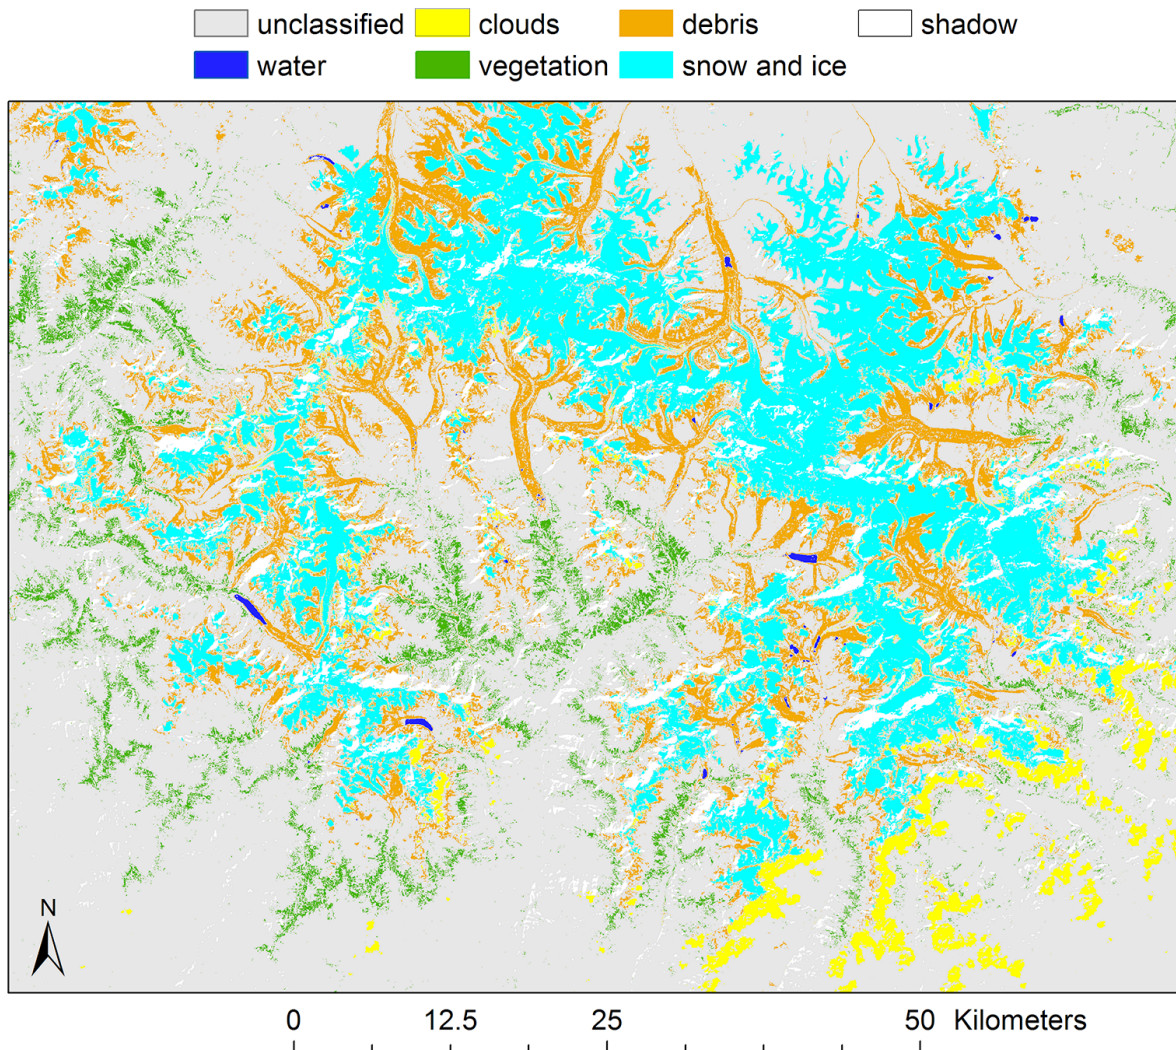

1080 **Fig. 1** Study area showing the test subset Khumbu area in Nepal. The map shows a color composite of Landsat OLI bands 5,4,3 of the Sept 30, 2015 image. Labels point to the regions discussed in the text: A – Lahaul Spiti in the “monsoon-arid” transition zone; B – Khumbu domain and parts of eastern Tibet; C – Bhutan. The yellow dotted shape shows the extent of the Pleiades image of Oct 9, 2015 (color composite of bands 4, 3, 2).

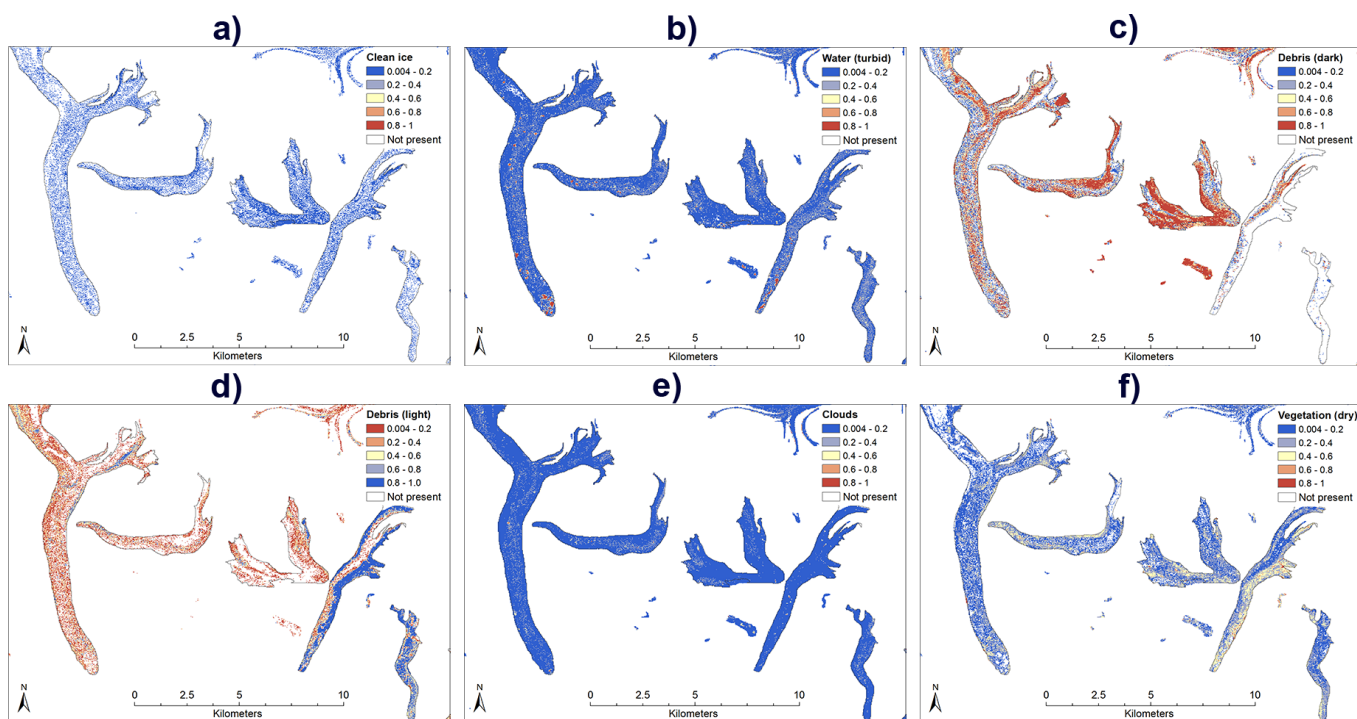

1085 **Fig. 2** Types of surfaces present in the study area: a) light debris cover (quartz, feldspar); b) darker schistic debris with ice cliff; c) clean ice with crevasses in the glacier ablation area; d) graminoid shrub type vegetation (dry); e) supraglacial lakes of different turbidity; f) valley clouds. All photos were taken in the Khumbu region. Photo credit: A. Racoviteanu

1105 **Fig. 3** a) Spectral signatures of endmembers extracted from Landsat OLI bands 1 to 7 (Sept 30, 2015 image) after the atmospheric and topographic corrections; b) field spectra from the debris-cover part of Mer de Glace Glacier (France) shown for comparison purposes only.

1110 **Fig. 4** Classification maps of surfaces in the Khumbu domain based on the SAM method. For this routine, the two types of debris were combined into one class and the algorithm was applied over the entire scene.

115 **Fig. 5** Fractional maps obtained from the LMM routine for a subset of the Khumbu area (Ngozumpa, Khumbu, Changri Nup and part of Nuptse Glaciers). Colour bars show the percentage covered by each type of material on a pixel-by pixel basis: a) clean ice; b) turbid water; c) dark debris; d) light debris; e) clouds; f) dry vegetation.

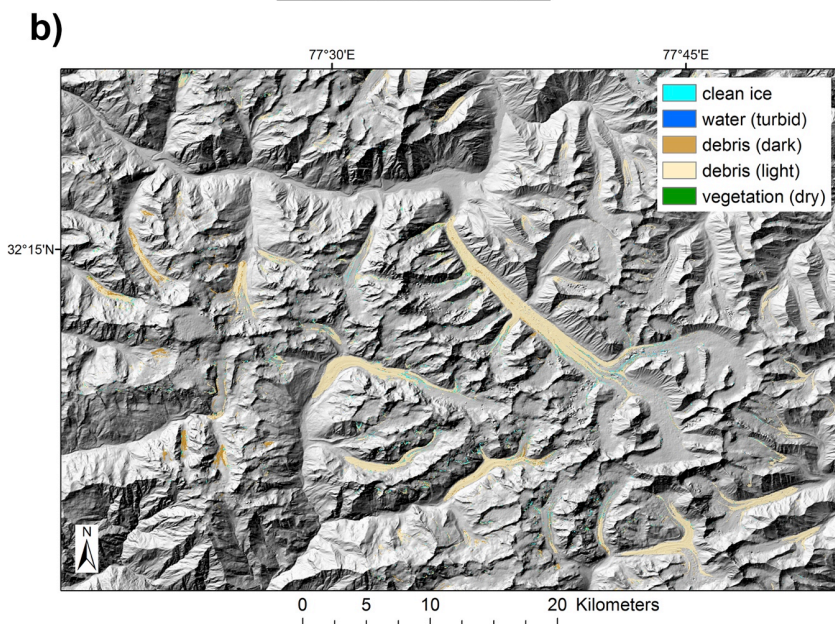

Fig. 6 Composition of debris-covered glacier tongues: a) subset of the Khumbu area (A- Ngozumpa, B- Changri Nup, C- Khumbu, D- Rongbuk, E- Nuptse, F- Lhotse Nup, G- Lhotse, H- Lhotse Shar, I- Ama Dablam) and b) subset of the Lahaul Spiti area. Debris-covered outlines are adapted from SDC v.1 (Scherler et al. 2018a). Note that the extent of Changri Nup incorrectly includes the inactive part of the glacier in this global dataset.

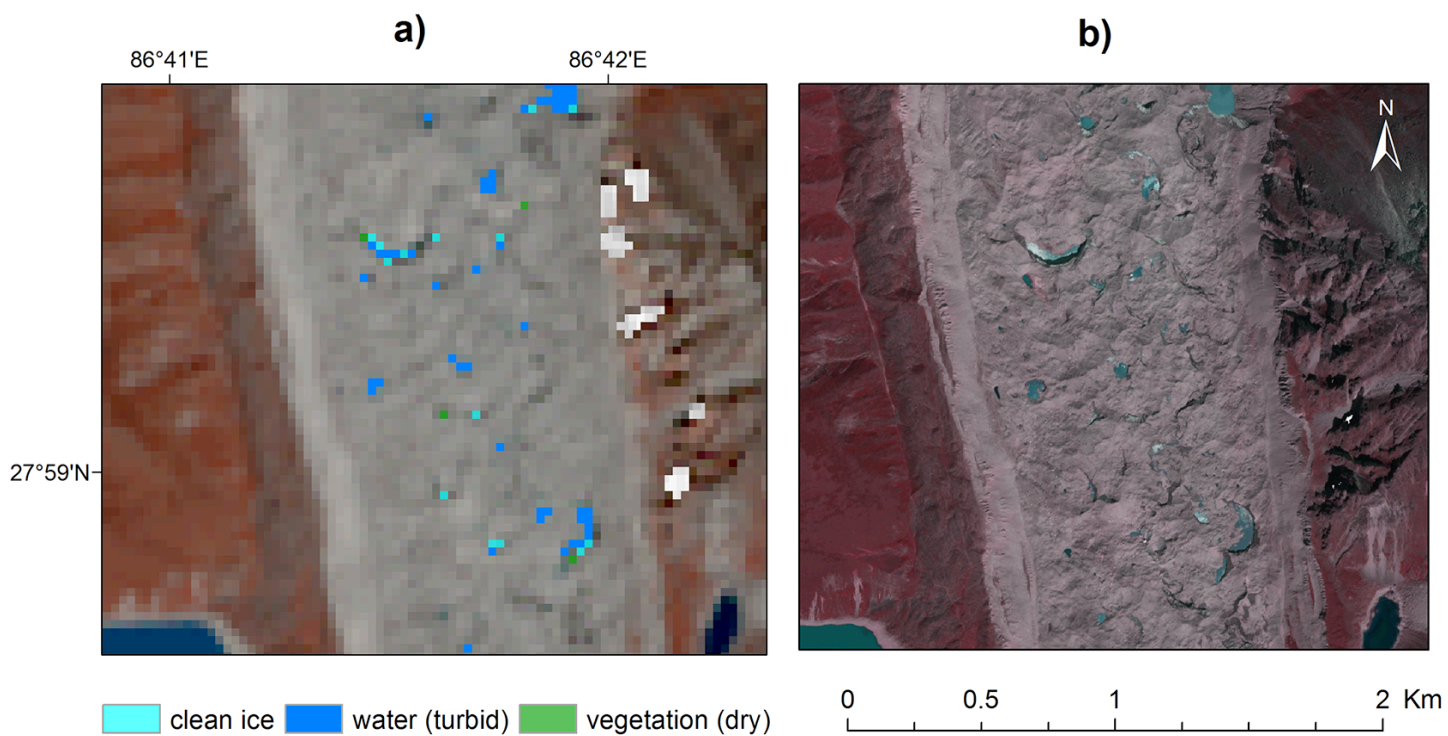

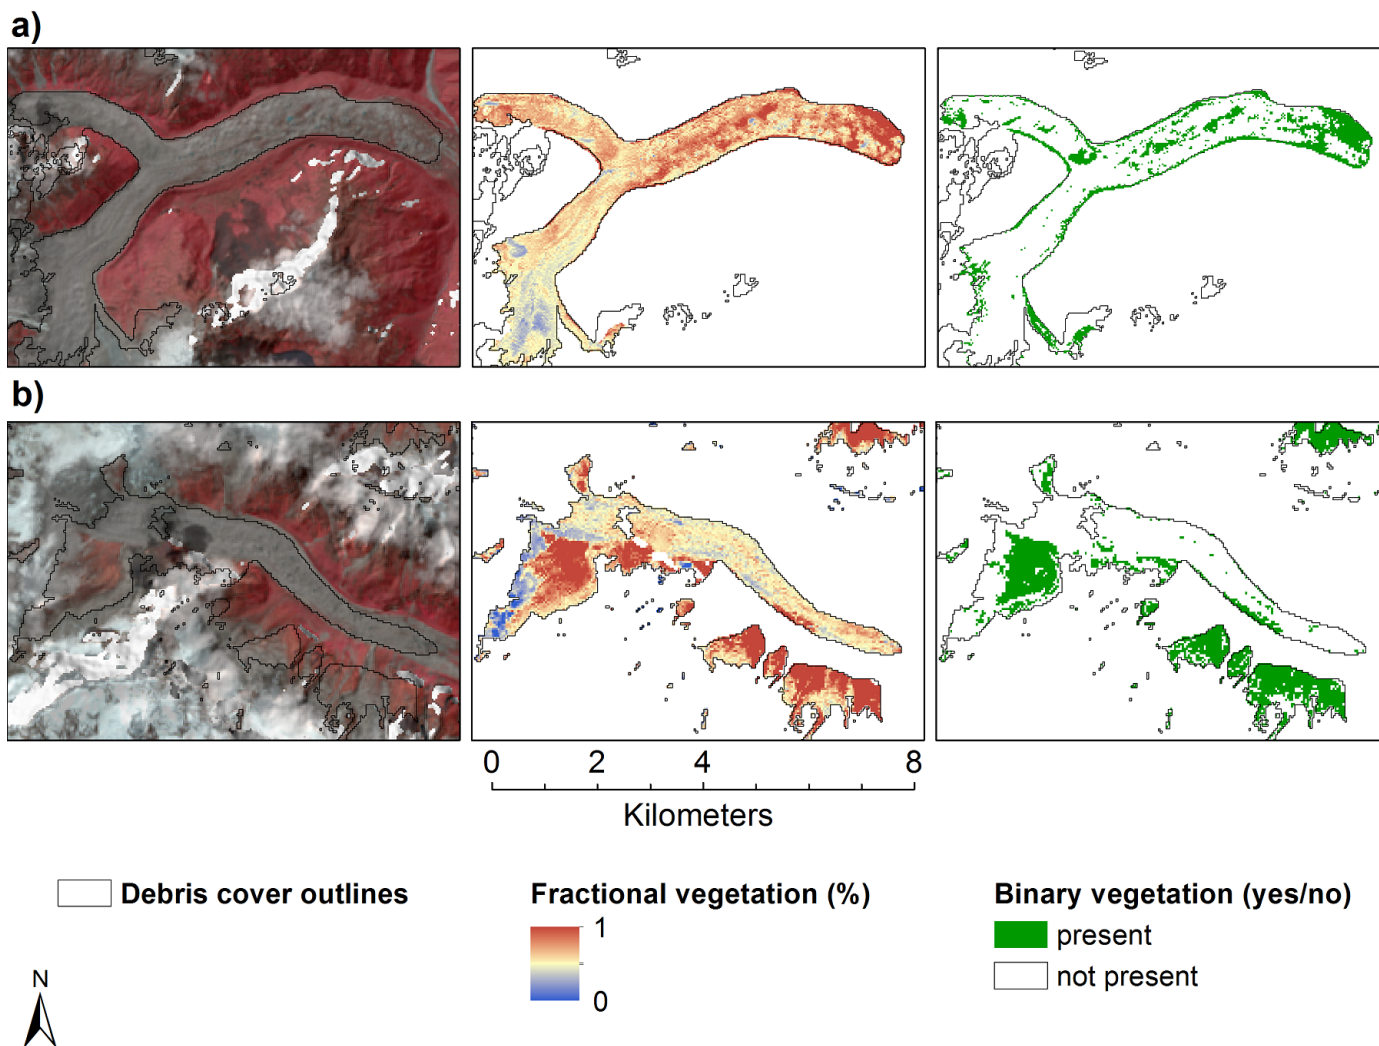

Fig. 7 Ice pixels detected by the LMM at the surface of Ngozumpa Glacier in the Khumbu region. a) Landsat OLI colour composite bands 5,4,3 and unmixing results for ice, water and vegetation classes only; b) Pleiades colour composite bands 4,3,2 for comparison. Supraglacial lakes and ice cliffs have a typical crescent moon shape.

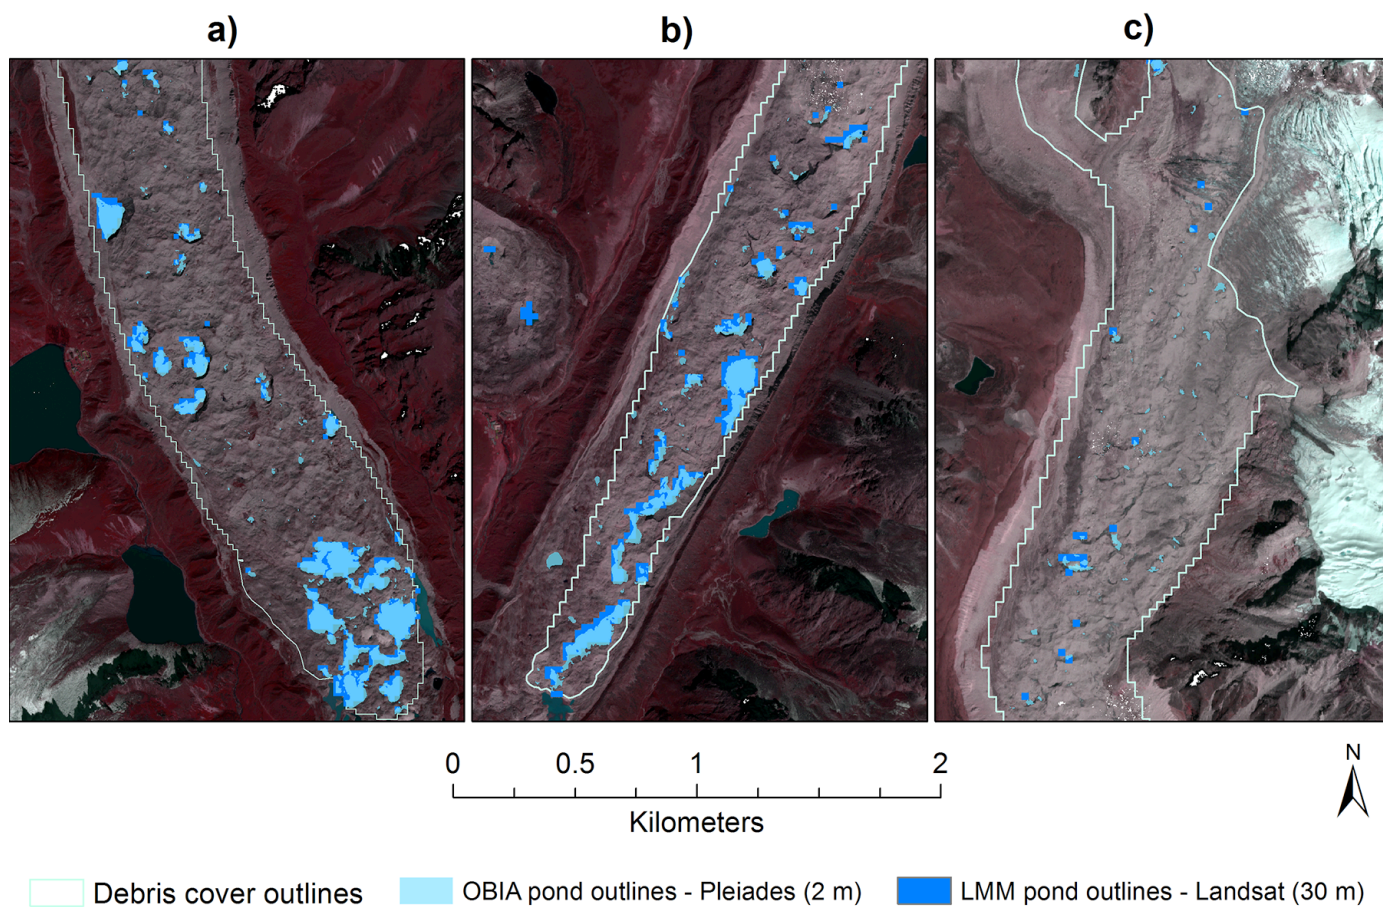

1155

1160 **Fig. 8** Examples of the supraglacial vegetation maps for two glaciers in eastern Himalaya: a) Kazhenpu Glacier; b) Labeilong Glacier. Left panels show the Landsat OLI colour composite (bands 5,4,3) draped onto a shaded relief map from the ALOS DEM. Middle panels show fractional vegetation and black arrows point to identified errors (bare land or healthy vegetation) in the supraglacial debris dataset. Right panels show the pixels containing more than 65 % fractional vegetation.

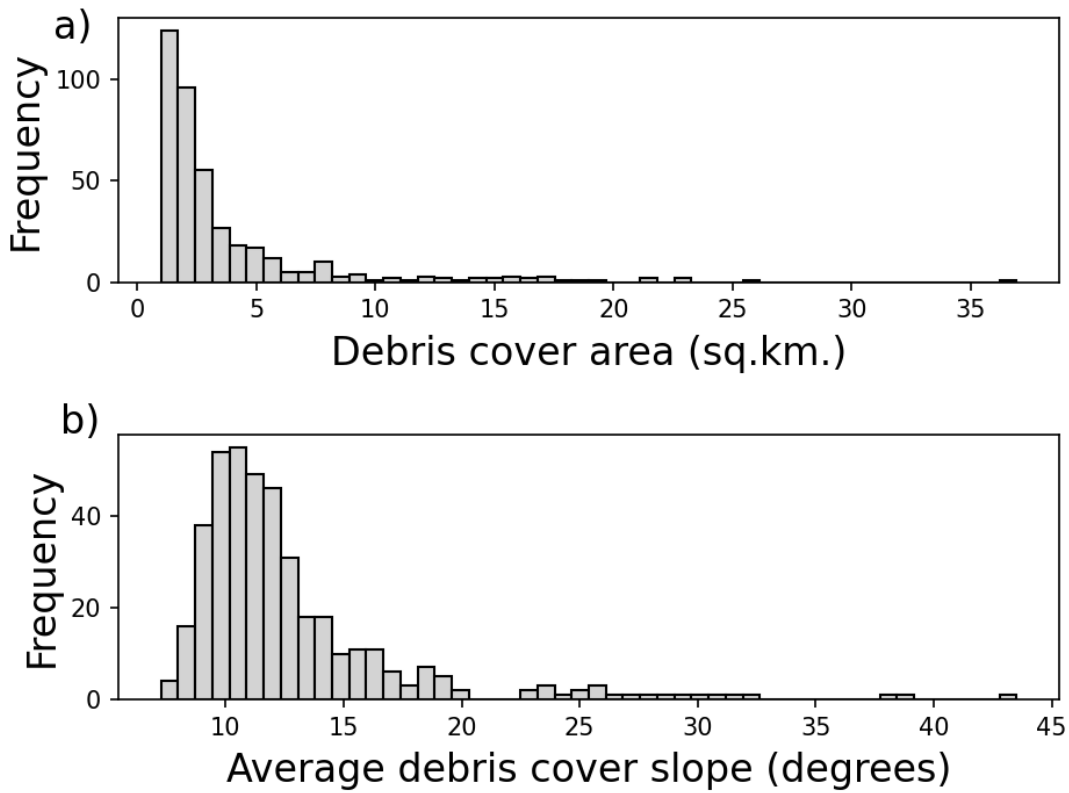

1165

1170

Fig. 9 Comparison of the Landsat sub pixel binary maps (dark blue) for the supraglacial ponds with Pleiades-based pond outlines (shown as transparent light blue) for subsets of three glaciers: a) Ngozumpa Glacier terminus; b) Khumbu Glacier terminus and c) Nuptse Glacier accumulation area. The spectrally unmixed pond pixels correspond well with the validation dataset, with a notable difference in spatial resolution (30 m Landsat vs. 2 m Pleiades).

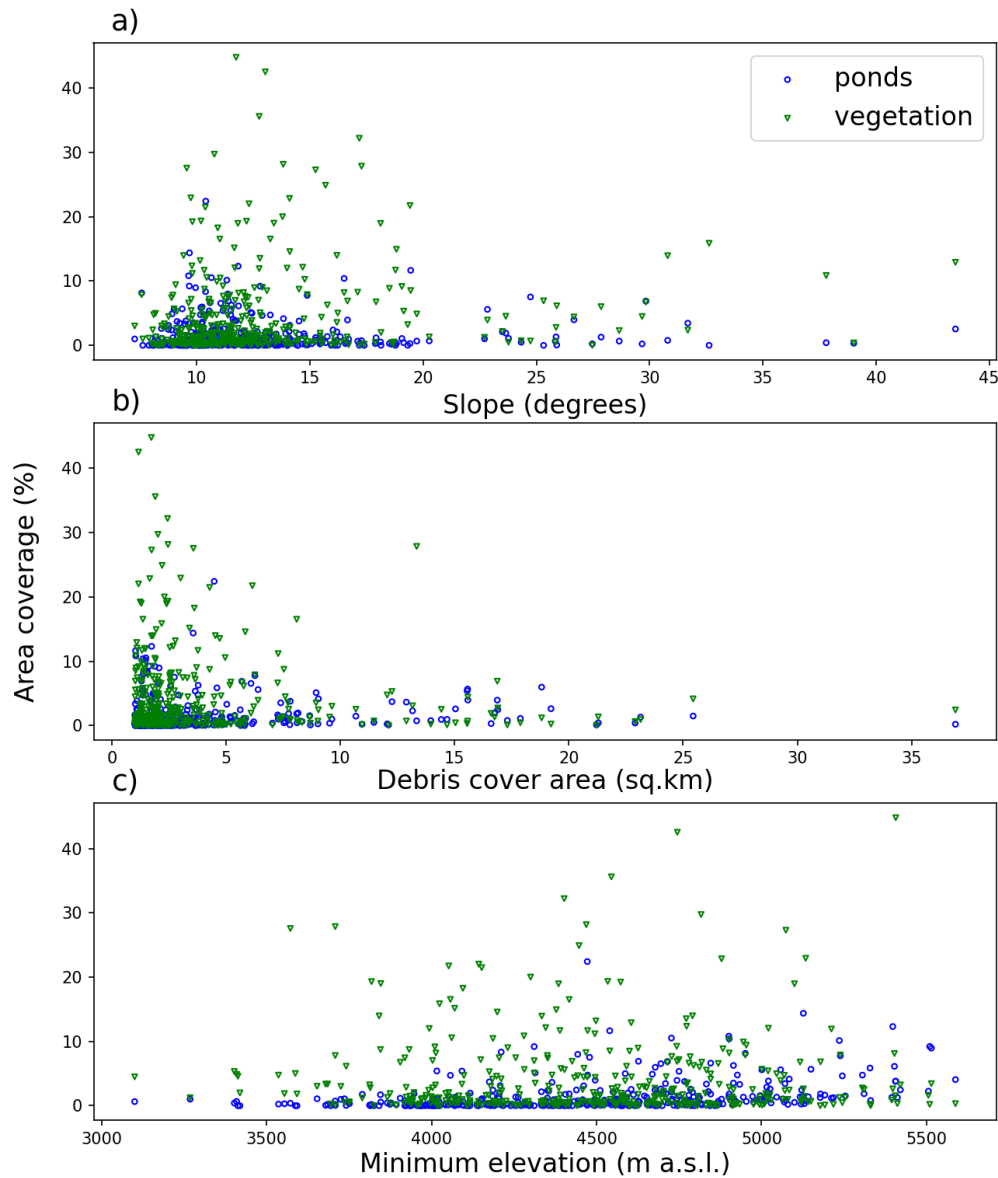

1200 **Fig. 10** Histograms of surface area (a) and slope (b) for the 408 glaciers with area > 1 km², over the entire Himalaya domain.

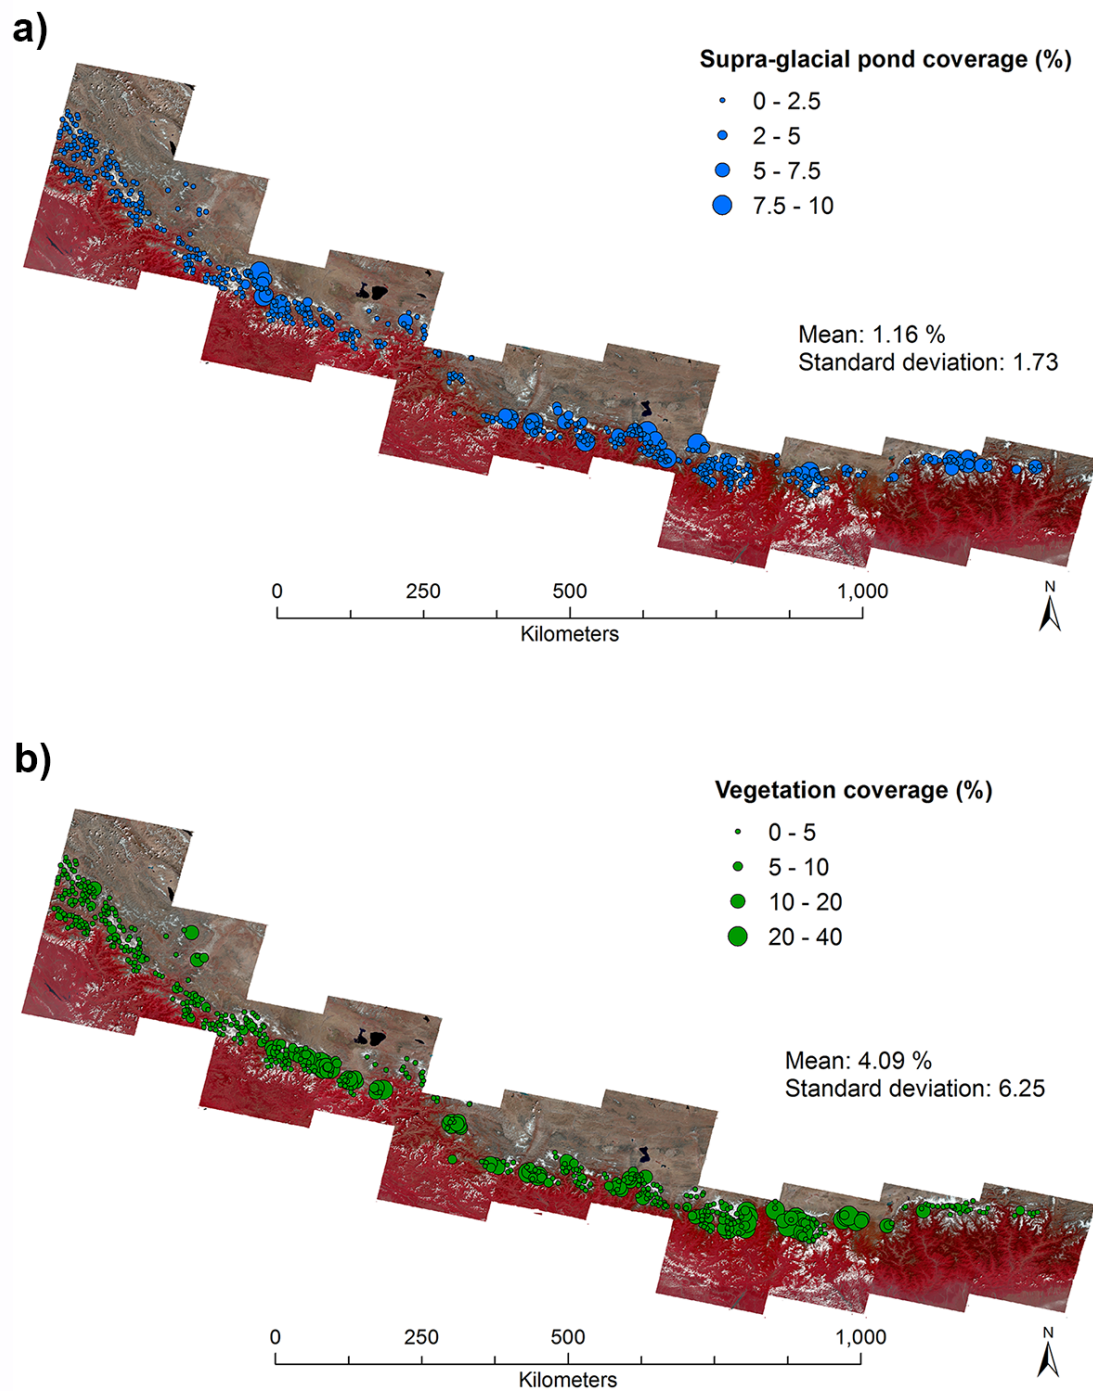

1205

1210

1240 **Fig. 11** Scatter plots of glacier-by-glacier supraglacial pond and vegetation coverage (expressed as percent of the debris cover area) versus (a) slope, (b) debris-covered area and (c) minimum debris cover elevation.

12/5

Fig. 12 Distribution of supra-glacial pond coverage (a) and supra-glacial vegetation (b) as percent of the debris-covered area on a glacier-by-glacier basis.

1315 **Fig. 13** Comparison of the fractional ponds from this study with two recent lake datasets based on 2015 Landsat imagery (same as our study) for the terminus of Ngozumpa Glacier and the Gokyo Lakes in Khumbu, shown on shaded relief. These regional datasets currently exclude most supraglacial ponds.
