## **Abstract**

*Perennial firn aquifers are subsurface meltwater reservoirs consisting of a meters-thick water-saturated firn layer that can form on spatial scales as large as tens of kilometers. They have been observed within the percolation facies of glaciated regions experiencing intense seasonal surface melting and high snow accumulation. Widespread perennial firn aquifers have been identified within the Greenland Ice Sheet (GrIS) via field expeditions, airborne ice-penetrating radar surveys, and satellite microwave sensors. In contrast, ice slabs are nearly-continuous ice layers that can also form on spatial scales as large as tens of kilometers as a result of surface and subsurface water-saturated snow and firn layers sequentially refreezing following multiple melting seasons. They have been observed within the percolation facies of glaciated regions experiencing intense seasonal surface melting, but in areas where snow accumulation is at least 25% lower as compared to perennial firn aquifer areas. Widespread ice slabs have recently been identified within the GrIS via field expeditions and airborne ice-penetrating radar surveys, specifically in areas where perennial firn aquifers typically do not form. However, ice slabs have yet to be identified from space. Together, these two ice sheet features represent distinct, but related, sub-facies within the broader percolation facies of the GrIS that can be defined primarily by differences in snow accumulation, which influences the englacial hydrology and thermal characteristics of firn layers at depth.*

*Here, for the first time, we use enhanced-resolution vertically-polarized L-band brightness temperature ( $T_V^B$ ) imagery (2015-2019) generated using observations collected over the GrIS by NASA's Soil Moisture Active Passive (SMAP) satellite to map perennial firn aquifer and ice slab areas together as a continuous englacial hydrological system. We use an empirical algorithm previously developed to map the extent of Greenland's perennial firn aquifers via fitting exponentially decreasing temporal L-band signatures to a set of sigmoidal curves. This algorithm is recalibrated to also map the extent of ice slab areas using airborne ice-penetrating radar surveys collected by NASA's Operation Ice Bridge (OIB) campaigns (2010-2017). Our SMAP-derived maps*

41 *show that between 2015 and 2019, perennial firn aquifer areas extended over 64,000 km<sup>2</sup>, and ice*  
42 *slab areas extended over 76,000 km<sup>2</sup>. Combined together, these sub-facies are the equivalent of*  
43 *24% of the percolation facies of the GrIS. As Greenland's climate continues to warm, seasonal*  
44 *surface melting will increase in extent, intensity, and duration. Quantifying the possible rapid*  
45 *expansion of these sub-facies using satellite L-band microwave radiometry has significant*  
46 *implications for understanding ice sheet-wide variability in englacial firn hydrology that may drive*  
47 *meltwater-induced hydrofracturing and accelerated ice flow as well as high-elevation meltwater run-*  
48 *off that can impact the mass balance and stability of the GrIS.*

## 49 **1 Introduction**

50 The recent launches of several satellite L-band microwave radiometry missions by NASA (Aquarius  
51 mission, Levine, et al., 2007; Soil Moisture Active Passive (SMAP) mission, Entekhabi et al., 2010) and  
52 ESA (Soil Moisture and Ocean Salinity (SMOS), Kerr et al., 2010) have provided a new Earth-observation  
53 tool capable of detecting meltwater stored tens of meters to kilometers beneath the ice sheet surface. Jezek  
54 et al. (2015) recently demonstrated that in the high-elevation (3500 m a.s.l.) dry snow facies of the Antarctic  
55 Ice Sheet, meltwater stored in subglacial Lake Vostok can be detected as deep as 4 km beneath the ice  
56 sheet surface. Subglacial lakes represent radiometrically cold subsurface meltwater reservoirs. Upwelling  
57 L-band emission from the radiometrically warm bedrock underlying the subglacial lakes is effectively  
58 blocked by high reflectivity and attenuation at the interface between the bedrock and the overlying lake  
59 bottom. This results in a lower observed microwave brightness temperature ( $T^B$ ) at the ice sheet surface  
60 as compared to other dry snow facies areas where bedrock contributes to L-band emission depth-integrated  
61 over the entire ice sheet thickness.

62 Similar to subglacial lakes, perennial firn aquifers also represent radiometrically cold subsurface  
63 meltwater reservoirs (Miller et al., 2020) consisting of a 4-25 m thick water-saturated firn layer (Koenig et  
64 al., 2014; Montgomery et al., 2017; Chu et al., 2018) that can form on spatial scales as large as tens of  
65 kilometers (Forster et al., 2014). Perennial firn aquifers have been identified via field expeditions (Forster  
66 et al., 2014), airborne ice-penetrating radar surveys (Miege et al., 2016), and satellite microwave sensors  
67 (Brangers et al., 2020; Miller et al., 2020) in the lower-elevation (<2000 m a.s.l.) percolation facies of the  
68 Greenland Ice Sheet (GrIS) at depths from between 1 m and 40 m beneath the ice sheet surface. They  
69 exist in areas that experience intense seasonal surface melting and rain (>650 mm w.e. yr<sup>-1</sup>) during the  
70 melting season and high snow accumulation (>800 mm w.e. yr<sup>-1</sup>) during the freezing season (Forster et al.,  
71 2014). High snow accumulation in perennial firn aquifer areas thermally insulates water-saturated firn layers  
72 from the cold atmosphere allowing seasonal meltwater to be stored in liquid form year-round if the overlying  
73 seasonal snow layer is sufficiently thick (Kuipers Munneke et al., 2014). Koenig et al. (2014) estimated that  
74 the volumetric fraction of meltwater stored within the pore space of Greenland's perennial firn aquifers just  
75 prior to melt onset ranges from between 10% and 25%, which limits the upward propagation of  
76 electromagnetic energy from greater depths within the ice sheet. Large volumetric fractions of meltwater  
77 within the firn pore space results in high reflectivity and attenuation at the interface between water-saturated

78 firn layers and the overlying refrozen firn layers, and between glacial ice or an impermeable layer and the  
79 overlying water-saturated firn layers. Upwelling L-band emission from deeper glacial ice and the underlying  
80 bedrock is effectively blocked.

81 While perennial firn aquifers are radiometrically cold, the slow refreezing of deeper firn layers  
82 saturated with large volumetric fractions of meltwater represents a significant source of latent heat that is  
83 continuously released throughout the freezing season. Refreezing of seasonal meltwater by the descending  
84 winter cold wave (Pfeffer et al., 1991), and the subsequent formation of embedded ice structures (i.e.,  
85 horizontally-oriented ice layers and ice lenses, and vertically-oriented ice pipes; Benson et al., 1960;  
86 Humphrey et al., 2012; Harper et al., 2012) within the upper snow and firn layers represents a secondary  
87 source of latent heat. These heat sources help maintain meltwater at depth. Perennial firn aquifer areas  
88 are radiometrically warmer than other percolation facies areas where the single source of latent heat is via  
89 refreezing of seasonal meltwater. This results in a higher observed  $T^B$  at the ice sheet surface during the  
90 freezing season as compared to other percolation facies areas where seasonal meltwater is fully refrozen  
91 and stored exclusively as embedded ice.

92 Recently, mapping the extent of Greenland's perennial firn aquifers from space was demonstrated  
93 using satellite L-band microwave radiometry (Miller et al., 2020). Exponentially decreasing temporal L-band  
94 signatures observed in enhanced-resolution vertically-polarized L-band brightness temperature ( $T_V^B$ )  
95 imagery (2015-2016) generated using observations collected over the GrIS by the microwave radiometer  
96 on NASA's SMAP satellite (Long et al., 2019) were correlated with a single year of perennial firn aquifer  
97 detections (Miège et al. 2016). These detections were identified via the Center for Remote Sensing of Ice  
98 Sheets (CReSIS) Multi-Channel Coherent Radar Depth Sounder (MCoRDS) flown by NASA's Operation  
99 Ice Bridge (OIB) campaigns (Rodriguez-Morales et al, 2014). An empirical algorithm to map extent was  
100 developed by fitting temporal L-band signatures to a set of sigmoidal curves derived from the continuous  
101 logistic model.

102 The relationship between the radiometric, and thus the physical, temperature of perennial firn  
103 aquifer areas, as compared to other percolation facies areas, forms the basis of the empirical algorithm.  
104 Miller et al. (2020) hypothesized that the dominant control on the relatively slow exponential rate of  $T^B$   
105 decrease over perennial firn aquifer areas is physical temperature versus depth. L-band emission from the  
106 radiometrically warm upper snow and firn layers decreases during the freezing season as embedded ice  
107 structures slowly refreeze at increased depths below the ice sheet surface. In the percolation facies,  
108 refreezing of seasonal meltwater results in the formation of an intricate network of embedded ice structures  
109 that are large (10-100 cm long, 10-20 cm wide; Jezek et al., 1994) relative to the L-band wavelength (21  
110 cm). Embedded ice structures induce strong volume scattering (Rignot et al., 1993; Rignot 1995) that  
111 decreases  $T^B$  (Zwally, 1977; Swift et al. 1985; Jezek et al., 2018).

112 Ice slabs are 1-16 m thick nearly-continuous ice layers that that can form on spatial scales as large  
113 as tens of kilometers as a result of surface and subsurface water-saturated snow and firn layers sequentially  
114 refreezing following multiple melting seasons (Machguth et al., 2016; MacFerrin et al., 2019). Over time,

115 they become dense low-permeability solid-ice layers overlying deeper permeable firn layers. Ice slabs have  
116 been identified via field expeditions and airborne ice-penetrating radar surveys in the lower-elevation  
117 (<2000 m a.s.l.) percolation facies of the GrIS at depths from between 1 m and 20 m beneath the ice sheet  
118 surface (MacFerrin et al., 2019). They exist in areas that experience intense seasonal surface melting and  
119 rain (266-573 mm w.e. yr<sup>-1</sup>) during the melting season, and lower snow accumulation (<572±32 mm w.e.  
120 yr<sup>-1</sup>) during the freezing season as compared to perennial firn aquifer areas (MacFerrin et al., 2019). Lower  
121 snow accumulation in ice slab areas results in a seasonal snow layer that is insufficiently thick to thermally  
122 insulate water-saturated firn layers and seasonal meltwater is instead stored as embedded ice. Refreezing  
123 of seasonal meltwater by the descending winter cold wave, and the subsequent formation of ice slabs as  
124 well as other embedded ice structures within the upper snow and firn layers is the single source of latent  
125 heat. While ice slab areas are radiometrically warmer than other percolation facies areas with a lower  
126 volumetric fraction of embedded ice, they are radiometrically colder than perennial firn aquifer areas. This  
127 results in typically higher observed  $T^B$  at the ice sheet surface during the freezing season in ice slab areas,  
128 as compared to other percolation facies areas, however, typically lower observed  $T^B$  as compared to  
129 perennial firn aquifer areas. Similar to temporal L-band signatures over perennial firn aquifer areas,  
130 temporal L-band signatures over ice slab areas are exponentially decreasing during the freezing season,  
131 however, the rate of  $T^B$  decrease is slightly more rapid.

132 In this study, we exploit the observed sensitivity of L-band emission to differences in the depth- and  
133 time-integrated dielectric and geophysical properties of the percolation facies of the GrIS to map perennial  
134 firn aquifer and ice slab areas together as a continuous englacial firn hydrological system using satellite L-  
135 band microwave radiometry

## 136 **2 Methods**

137 We adapt our previously developed empirical algorithm to map the extent of Greenland's perennial firn  
138 aquifers (Miller et al., 2020) using a multi-year calibration technique. We use enhanced-resolution L-band  
139  $T_V^B$  imagery (2015-2019) generated using observations collected over the GrIS by the microwave  
140 radiometer on NASA's SMAP satellite (Long et al., 2019) and airborne ice-penetrating radar surveys  
141 collected by NASA's OIB campaigns (Rodriguez-Morales et al., 2014). First, we correlate: (1) a 'firn  
142 saturation' parameter derived from a simple two-layer L-band brightness temperature model (Miller et al.,  
143 2021, in press), (2) maximum and (3) minimum  $T_V^B$  values, and (4) exponentially decreasing temporal L-  
144 band signatures, with five years of perennial firn aquifer detections (2010-2014) identified via the CReSIS  
145 Accumulation Radar (AR) (Miège et al. 2016), and three years of additional detections (2015-2017) more  
146 recently identified via MCoRDS (Miller et al., 2020). Next, we extend our empirical algorithm to map the  
147 extent of ice slab areas. We correlate the SMAP-derived parameters with five years of ice slab detections  
148 (2010-2014) recently identified via AR (MacFerrin et al., 2019). Finally, we re-calibrate our empirical model  
149 to map the extent of perennial firn aquifer and ice slab areas over the percolation facies. Interannual  
150 variability in extent is not resolved in this study, however, it will be explored further in future work.

## 151 **2.1 SMAP Enhanced-Resolution L-band $T^B$ Imagery**

152 The key science objectives of NASA's SMAP mission (<https://smap.jpl.nasa.gov/>) are to map terrestrial soil  
153 moisture and freeze/thaw state over Earth's land surfaces from space. However, the global L-band  $T^B$   
154 observations collected by the SMAP satellite also have cryospheric applications. Mapping perennial firn  
155 aquifer and ice slab areas over Earth's polar ice sheets represents an interesting analog and an innovative  
156 extension of the science objectives. The SMAP satellite was launched 31 January 2015 and carries a  
157 microwave radiometer that operates at an L-band frequency of 1.41 GHz (Enkentabi et al., 2010). It is  
158 currently collecting observations of vertically and horizontally-polarized  $T^B$  over Greenland. The surface  
159 incidence angle is  $40^\circ$ , and the radiometric accuracy is approximately 1.3 K (Piepmeier et al., 2017).

160 The Scatterometer Image Reconstruction (SIR) algorithm was originally developed to reconstruct  
161 coarse resolution satellite radar scatterometry imagery on a higher spatial resolution grid (Long et al., 1993;  
162 Early and Long, 2001). The SIR algorithm has been adapted for coarse resolution satellite microwave  
163 radiometry imagery (Long and Daum, 1998; Long and Brodzik, 2016; Long et al., 2019). The microwave  
164 radiometer form of the SIR algorithm (rSIR) uses the measurement response function (MRF) for each  
165 observation, which is a smeared version of the antenna pattern. Using the overlapping MRFs, the rSIR  
166 algorithm reconstructs  $T^B$  from the spatially filtered low-resolution sampling provided by the observations.  
167 In effect, it generates an MRF-deconvolved  $T^B$  image. Combining multiple orbital passes increases the  
168 sampling density, which improves both the accuracy and resolution of the SMAP enhanced-resolution  $T^B$   
169 imagery (Long et al., 2019).

170 Over Greenland, the rSIR algorithm combines satellite orbital passes that occur between 8 a.m.  
171 and 4 p.m. local time-of-day to reconstruct SMAP enhanced-resolution  $T^B$  imagery twice-daily (i.e., morning  
172 and evening orbital pass interval, respectively).  $T^B$  imagery is projected on a Northern Hemisphere (NH)  
173 Equal-Area Scalable Earth Grid (EASE-Grid 2.0; Brodzik et al., 2012) at a 3.125 km rSIR grid cell spacing  
174 (e.g., Fig. 1). The effective resolution for each grid cell is dependent on the number of observations used  
175 in the rSIR reconstruction and is coarser than the rSIR grid cell spacing. While the effective resolution of  
176 conventionally processed SMAP  $T^B$  imagery posted on a 25 km grid is approximately 30 km (e.g., Fig. 1a),  
177 the effective resolution of SMAP enhanced-resolution  $T^B$  imagery posted on a 3.125 km grid is  
178 approximately 18 km (e.g., Fig. 1b), an improvement of 60% (Long et al., 2020).

179 As previously noted, for our analysis of the percolation facies we use SMAP enhanced-resolution  
180  $T_V^B$  imagery over the GrIS. Compared to the horizontally-polarized channel, the vertically-polarized channel  
181 exhibits decreased sensitivity to variability in the volumetric fraction of meltwater, which is attributed to  
182 reflection coefficient differences between channels (Miller et al., 2020). Using the vertically polarized  
183 channel also results in a reduced chi-squared error statistic when fitting  $T_V^B$  time series to the sigmoid  
184 function (Section 2.3.4). We construct  $T_V^B$  imagery that alternate morning and evening orbital pass  
185 observations annually, beginning and ending just prior to melt onset. The Greenland Ice Mapping Project  
186 (GIMP) Land Ice and Ocean Classification Mask and Digital Elevation Model (Howat et al., 2014) are  
187 projected on the NH EASE-Grid 2.0 at a 3.125 km rSIR grid cell spacing.  $T_V^B$  imagery between 1 April 2015

188 and 31 March 2019 are ice sheet-masked, and an elevation for each rSIR grid cell is calculated.

## 189 **2.2 Airborne Ice-Penetrating Radar Surveys**

190 AR and MCoRDS (Rodriguez-Morales et al, 2014) were flown over the GrIS on a P-3 aircraft in April and  
191 May between 2010 and 2017 (Figs. 1c; 2). The AR instrument operates at a center frequency of 750 MHz  
192 with a bandwidth of 300 MHz, resulting in a range resolution in firn of 0.53 m (Lewis et al., 2015). The  
193 collected data have an along-track resolution of approximately 30 m with 15 m spacing between traces in  
194 the final processed radargrams. At a nominal flight altitude of 500 m above the ice sheet surface, the cross-  
195 track resolution varies between 20 m for a smooth surface, to 54 m for a rough surface with no appreciable  
196 layover. The MCoRDS instrument operated at three different frequency configurations: (1) a center with a  
197 bandwidth of 30 MHz (2010-2014, 2017, 2018), (2) a center frequency of 315 MHz with a band width of  
198 270 MHz (2015), and (3) a center frequency of 300 MHz with a bandwidth of 300 MHz (2016). The vertical  
199 range resolution in firn for each of these frequency configurations is 5.3 m, 0.59 m, and 0.53m, respectively  
200 (CReSIS, 2016). The collected data have an along-track resolution of approximately 25 m with 14 m spacing  
201 between traces in the final processed radargrams. At a nominal flight altitude of 500 m, the cross-track  
202 resolution varies between 40 m for a smooth surface in the highest bandwidth configuration, to 175 m for a  
203 rough surface with no appreciable layover in the lowest bandwidth configuration.

204 The multi-year calibration technique uses perennial firn aquifer detections previously identified  
205 along OIB flight lines via AR (2010-2014) and MCoRDS (2015-2017) radargram profiles and the  
206 methodology described in Miège et al. (2016). Bright lower reflectors that undulate with the local  
207 topographic gradient underneath which reflectors are absent in the percolation facies are interpreted as the  
208 upper surface of meltwater stored within perennial firn aquifers (e.g., Fig. 3a). The large dielectric contrast  
209 between refrozen and water-saturated firn layers results in high reflectivity at the interface. However, the  
210 presence of meltwater increases attenuation, limiting the downward propagation of electromagnetic energy  
211 through the water-saturated firn layer. The total number of AR derived perennial firn aquifer detections is  
212 325,000, corresponding to a total extent of 98 km<sup>2</sup>. The analysis assumes a smooth surface, which is typical  
213 of much of the percolation facies, and a grid cell size of 15 m x 20 m. The total number of MCoRDS-derived  
214 perennial firn aquifer detections is 142,000, corresponding to a total extent of 80 km<sup>2</sup>. This analysis also  
215 assumes a smooth surface, and a grid cell size of 14 m x 40 m. The combined total number of grid cells  
216 (467,000) and total extent (178 km<sup>2</sup>) is significantly larger than the total number of MCoRDS-derived grid  
217 cells (78,000) and total extent (44 km<sup>2</sup>) calculated for 2016 (Miller et al., 2020). Perennial firn aquifer  
218 detections are mapped in western, southern, and south and central eastern Greenland as well as the  
219 Maniitsoq and Flade Isblink Ice Caps (Figs. 1c; 2a). We project AR- and MCoRDS-derived perennial firn  
220 aquifer detections on the NH EASE-Grid 2.0 at an rSIR grid cell spacing of 3.125 km. Each rSIR grid cell  
221 has an extent of approximately 10 km<sup>2</sup>. The total number of rSIR grid cells with at least one perennial firn  
222 aquifer detection is 800, corresponding to a total extent of 8000 km<sup>2</sup>. However, given the limited AR and  
223 MCoRDS grid cell coverage, less than 1% of the rSIR grid cell extent has airborne ice-penetrating radar  
224 survey coverage. As compared to the total number of MCoRDS-derived perennial firn aquifer detections

225 (780) calculated for 2016 (Miller et al., 2020), the total number of rSIR grid cells with at least one detection  
226 is only increased by 20 for the multi-year calibration technique, corresponding to an increased total extent  
227 of 200 km<sup>2</sup>.

228 We also use ice slab detections previously identified along OIB flight lines via AR (2010-2014)  
229 radargram profiles and the methodology described in MacFerrin et al. (2019) in the multi-year calibration  
230 technique. Thick dark surface-parallel regions of low-reflectivity in the percolation facies are interpreted as  
231 ice slabs (e.g., Fig. 3b). The large dielectric contrast between ice slabs and the overlying and underlying  
232 snow and firn layers results in high reflectivity at the interfaces. However, electromagnetic energy is not  
233 scattered or absorbed within the homogeneous ice slab, it instead propagates downward through the layer  
234 and into the deeper firn layers. The total number of AR-derived ice slab detections is 505,000,  
235 corresponding to a total extent of 283 km<sup>2</sup>. Ice slab detections are mapped in western, central and north  
236 eastern, and northern Greenland as well as the Flade Isblink Ice Cap (Figs. 1c; 2b). We project the AR-  
237 derived ice slab detections on the NH EASE-Grid 2.0 at an rSIR grid cell spacing of 3.125 km. The total  
238 number of rSIR grid cells with at least one ice slab detection is 2000, corresponding to a total extent of  
239 20,000 km<sup>2</sup>. However, less than 2% of the rSIR grid cell extent has airborne ice-penetrating radar survey  
240 coverage.

241 An advantage of the multi-year calibration technique as compared to the single-coincident year  
242 calibration technique (Miller et al., 2020) is that it increases the number of rSIR grid cells that can be  
243 assessed. It also provides repeat targets that can account for variability in the depth- and time-integrated  
244 dielectric and geophysical properties that influence the radiometric temperature in stable perennial firn  
245 aquifer and ice slab areas. Uncertainty is introduced by correlating the SMAP-derived parameters with AR-  
246 and MCoRDS-derived detections that are not coincident in time. The multi-year calibration technique  
247 assumes the extent of each area remains stable, which is not necessarily the case as climate extremes  
248 (Cullather et al., 2020) can influence each of these sub-facies. The assumption of stability neglects  
249 boundary transitions in the extent of perennial firn aquifer areas associated with refreezing of shallow water-  
250 saturated firn layers, englacial drainage of meltwater into crevasses at the periphery (Poinar et al., 2017;  
251 Poinar et al, 2019), and transient upslope expansion (Montgomery et al., 2017). Once formed, ice slabs are  
252 essentially permanent features within the upper snow and firn layers of the percolation facies until they are  
253 compressed into glacial ice. However, they may transition into superimposed ice at the lower boundary of  
254 ice slab areas or rapidly expand upslope, particularly following extreme melting seasons (MacFerrin et al.,  
255 2019). Thus, we simply consider our mapped extent a high-probability area for the preferential formation of  
256 each of these sub-facies, with continued presence dependent on seasonal surface melting and snow  
257 accumulation in subsequent years.

258 Annual perennial firn aquifer and ice slab detections that may introduce significant uncertainty into  
259 the multi-year calibration technique include those following the 2010 melting season, which was  
260 exceptionally long (Tedesco et al., 2010), the anomalous 2012 melting season, during which seasonal  
261 surface melting extended across 99% of the GrIS (Nghiem et al., 2012), and the 2015 melting season,

262 which was especially intense in western and northern Greenland (Tedesco et al., 2016). Following these  
263 extreme melting seasons, significant changes in the dielectric and geophysical properties likely occurred  
264 across large portions of the GrIS, including perennial firn aquifer recharging resulting in increases in  
265 meltwater volume and decreases in the depth to the upper surface of stored meltwater. The upper snow  
266 and firn layers of the dry snow facies and percolation facies were also saturated with relatively large  
267 volumetric fractions of meltwater as compared to the negligible to limited volumetric fractions of meltwater  
268 that percolates during more typical seasonal surface melting on the GrIS.

269 Seasonal meltwater was refrozen into spatially coherent melt layers following the 2010 and 2012  
270 melting seasons (Culberg et al., 2021) as well as more recently following the 2015, and 2018 melting  
271 seasons identified as part of the temporal L-band signature analysis in this study (Section 2.3.1). As  
272 compared to ice slabs, which are dense low-permeability solid-ice layers, spatially coherent melt layers are  
273 a network of embedded ice structures primarily consisting of discontinuous horizontally-oriented ice layers  
274 and ice lenses sparsely connected via vertical-oriented ice pipes (Culberg et al., 2021). Spatially coherent  
275 melt layers are relatively thin (0.02 cm-2 m) and can rapidly form across the high-elevation (up to 3200 m  
276 a.s.l.) dry snow facies at depths of less than 1 m beneath the ice sheet surface following a single extreme  
277 melting season. They can further merge together into thicker solid-ice layers following multiple extreme  
278 melting seasons. Spatially coherent melt layers are exceptionally bright in AR radargrams (e.g., Fig 3a).  
279 The large dielectric contrast between the spatially coherent melt layer and the overlying, underlying, and  
280 interior snow and firn layers results in high reflectivity at the interfaces. However, electromagnetic energy  
281 still propagates downward through the high reflectivity layer into the deeper firn layers. Culberg et al., (2021)  
282 recently demonstrated mapping the extent of spatially coherent melt layers formed following the 2012  
283 melting season (Nghiem et al., 2012) via AR (Figs. 1c; 2).

## 284 **2.3 Empirical Algorithm**

### 285 **2.3.1 Temporal L-band Signatures over the Percolation Facies**

286  $T^B$  expresses the satellite-observed magnitude of thermal emission and is influenced by the microwave  
287 instrument's observation geometry as well as the depth- and time-integrated dielectric and geophysical  
288 properties of the ice sheet (Ulaby et al., 2014). The most significant geophysical property influencing  $T^B$  is  
289 the volumetric fraction of meltwater within the snow and firn pore space (Mätzler and Hüppi, 1989). During  
290 the melting season, the upper snow and firn layers of the percolation facies are saturated with large  
291 volumetric fractions of meltwater that percolates vertically into the deeper firn layers (Benson, 1960;  
292 Humphrey et al., 2012). Increases in the volumetric fraction of meltwater results in rapid relative increases  
293 in the imaginary part of the complex dielectric constant (Tiuri et al., 1984). This typically increases  $T^B$ , and  
294 decreases volume scattering and penetration depth. The L-band penetration depth can rapidly decrease  
295 from tens to hundreds of meters to less than a meter, dependent on the local snow and firn conditions.  
296 During the freezing season, surface and subsurface water-saturated snow and firn layers and embedded  
297 ice structures subsequently refreeze. Decreases in the volumetric fraction of meltwater results in rapid

298 relative decreases in the imaginary part of the complex dielectric constant. This decreases  $T^B$ , and  
299 increases volume scattering and penetration depth. The L-band penetration depth increases back to tens  
300 to hundreds of meters on variable time scales.

301 We analyze melting and freezing seasons in temporal L-band signatures exhibited in  $T_V^B$  time series  
302 over and near the AR- and MCoRDS-derived perennial firn aquifer and ice slab detections projected on the  
303 NH EASE-Grid 2.0 (Fig. 4; Table 1). We project ice surface temperature observations calculated using  
304 thermal infrared brightness temperature collected by the Moderate Resolution Imaging Spectroradiometer  
305 (MODIS) on the Terra and Aqua satellites (Hall et al., 2012) on the NH EASE-Grid 2.0 at a 3.125 km rSIR  
306 grid cell spacing. We then derive melt onset and surface freeze-up dates for each rSIR grid cell using the  
307 methodology described in Miller et al., (2020). We set a threshold of ice surface temperature  $>-1^\circ\text{C}$  for  
308 meltwater detection (Nghiem et al., 2012), consistent with the  $\pm 1^\circ\text{C}$  accuracy of the ice surface temperature  
309 observations. For temperatures that are close to  $0^\circ\text{C}$ , ice surface temperatures are closely compatible with  
310 contemporaneous NOAA near-surface air temperature observations (Shuman et al., 2014). Melt onset and  
311 surface freeze-up dates are overlaid on  $T_V^B$  time series to partition the melting and freezing seasons. Melt  
312 onset dates typically occur between April and July, and surface freeze-up dates typically occur between  
313 July and September. The melting season increases in duration moving downslope from the dry snow facies,  
314 and ranges from a single day in the highest elevations ( $>2500$  m) of the percolation facies, to 150 days in  
315 the ablation facies. Similarly, the freezing season decreases in duration moving downslope, and ranges  
316 from between 215 days and 365 days.

317 Over perennial firn aquifer areas (e.g., Fig. 4a, SMAP Test Site A:  $66.2115^\circ\text{N}$ ,  $39.1795^\circ\text{W}$ , 1625 m  
318 a.s.l.), maximum  $T_V^B$  ( $T_{V,max}^B$ ) values are radiometrically warm during the melting season. Vertically  
319 percolating meltwater and gravity-driven meltwater drainage seasonally recharges perennial firn aquifers  
320 at depth (Fountain and Walder et al., 1998). Minimum  $T_V^B$  ( $T_{V,min}^B$ ) values remain radiometrically warm during  
321 the freezing season as a result of latent heat continuously released by the slow refreezing of the deeper  
322 firn layers that are saturated with large volumetric fractions of meltwater (Miller et al, 2020). Temporal L-  
323 band signatures exhibit slow exponential decreases and approach, and sometimes achieve, stable  $T_V^B$   
324 values.  $T_V^B$  can decrease by more than 50 K during the freezing season, which represents the descent of  
325 the upper surface of stored meltwater by depths of meters to tens of meters beneath the ice sheet surface  
326 (Miège et al., 2016).

327 Over ice slab areas (e.g., Fig. 4b, SMAP Test Site B:  $66.8850^\circ\text{N}$ ,  $42.7765^\circ\text{W}$ , 1817 m a.s.l.),  $T_{V,max}^B$   
328 values are typically radiometrically colder than over perennial firn aquifer areas during the melting season.  
329 The presence of dense low-permeability solid-ice layers reduces the snow and firn pore space available to  
330 store seasonal meltwater at depth. Meltwater may alternatively run-off ice slabs downslope towards the wet  
331 snow facies.  $T_{V,min}^B$  values are also typically radiometrically colder than over perennial firn aquifer areas  
332 during the freezing season as a result of the absence of meltwater stored at depth. Temporal L-band  
333 signatures exhibit exponential decreases that are slightly more rapid than over perennial firn aquifer areas,  
334 and often achieve stable  $T_V^B$  values.

335 Over other percolation facies areas (e.g., Fig. 4c, SMAP Test Site C: 66.9024°N, 44.7528°W, 2350  
336 m a.s.l.), where seasonal meltwater is fully refrozen and stored exclusively as embedded ice,  $T_{V,max}^B$  values  
337 are typically radiometrically colder than over perennial firn aquifer and ice slab areas during the melting  
338 season.  $T_{V,min}^B$  values are also typically radiometrically cold during the freezing season. Temporal L-band  
339 signatures exhibit rapid exponential decreases, and achieve stable  $T_V^B$  values. However, over the highest  
340 elevations (>2500 m a.s.l.) of the percolation facies approaching the dry snow line, where seasonal surface  
341 melting and the formation of embedded ice structures is limited,  $T_{V,min}^B$  values remain radiometrically warm  
342 during the freezing season.  $T_V^B$  decreases, often step-responses exceeding 10 K, are a result of an increase  
343 in volume scattering from newly formed embedded ice structures within a spatially coherent melt layer.  
344 Temporal L-band signatures that increase several K on time scales of years indicate the burial of spatially  
345 coherent melt layers formed following the 2010, 2012, 2015, and 2018 melting seasons by snow  
346 accumulation.

347 Exponentially decreasing temporal L-band signatures transition smoothly between perennial firn  
348 aquifer, ice slab, and other percolation facies areas – there are no distinct temporal L-band signatures that  
349 delineate boundaries between these sub-facies. Boundary transitions between the dry snow facies and the  
350 wet snow facies, however, are delineated above and below the percolation facies. Over the dry snow facies  
351 (e.g., Fig. 4d, SMAP Test Site D: 66.3649°N, 43.2115°W, 2497 m a.s.l.),  $T_{V,max}^B$  and  $T_{V,min}^B$  values are  
352 radiometrically warm during the melting and freezing seasons. Temporal L-band signatures that increase  
353 on time scales of years are observed throughout the dry snow facies at elevations as high as Summit  
354 Station (3200 m a.s.l) and indicate the burial of the spatially coherent melt layer formed following the 2012  
355 melting season (Nghiem et al., 2012) by snow accumulation (Culberg et al., 2021). Over the wet snow  
356 facies (e.g., Fig. 4e, SMAP Test Site E: 67.3454°N, 48.4789°W, 1469 m a.s.l.), where seasonal meltwater  
357 is fully refrozen and stored as superimposed ice,  $T_{V,max}^B$  values are radiometrically warm during the melting  
358 season. As compared to the percolation facies, where temporal L-band signatures exhibit rapid increases  
359 following melt onset, temporal L-band signatures reverse and exhibit rapid decreases. These reversals are  
360 a result of high reflectivity and attenuation at the fully water-saturated snow layer and/or at the wet rough  
361 superimposed ice-air interface. Meltwater runs-off superimposed ice downslope towards the ablation facies.  
362  $T_{V,min}^B$  values remain radiometrically warm during the freezing season. Temporal L-band signatures exhibit  
363 rapid increases, and achieve stable  $T_V^B$  values.

### 364 **2.3.2 Two-Layer-L-band Brightness Temperature Model**

365 Based on our analysis of  $T_{V,max}^B$  and  $T_{V,min}^B$  in temporal L-band signatures over the percolation facies  
366 (Section 2.3.1), we derive a ‘firn saturation’ parameter using a simple two-layer L-band brightness  
367 temperature model (Ashcraft and Long, 2006; Miller et al., 2021, in press). The ‘firn saturation’ parameter  
368 is similar to the ‘melt intensity’ parameter derived in Hicks and Long (2011) that uses enhanced resolution  
369 vertically-polarized Ku-band radar backscatter imagery (2003) collected by the SeaWinds radar  
370 scatterometer that was flown in tandem on NASA’s Quick SCATterometer (QuikSCAT) satellite (Tsai et al.,

2000) and JAXA's Advanced Earth Observing Satellite 2 (ADEOS-II) (Freilich et al., 1994). We use the firn saturation parameter to estimate the maximum seasonal volumetric fraction of meltwater within the saturated upper snow and firn layers of the percolation facies using  $T_{V,max}^B$  and  $T_{V,min}^B$  values extracted from  $T_V^B$  time series. We calculate the firn saturation parameter for each rSIR grid cell within the ice sheet-masked extent of the GrIS as part of our adapted empirical algorithm (Section 2.3.4).

We assume a base layer underlying a water-saturated firn layer with a given depth and volumetric fraction of meltwater. Each of the layers is homogenous. The ice sheet is discretely layered to calculate  $T_V^B$  at an oblique incidence angle (Eq. 1). Emission from the base layer is a function of both the macroscopic roughness and the dielectric properties of the layer. It occurs in conjunction with volume scattering at depth, and is locally dependent on embedded ice structures, spatially coherent melt layers, ice slabs, and perennial firn aquifers. Reflectivity at depth (i.e., at the base layer-water-saturated firn layer interface), and at the ice sheet surface (i.e., at the water-saturated firn layer-air interface) is neglected. The contribution from each layer is individually calculated.

The two-layer L-band brightness temperature model is represented analytically by

$$T_{V,max}^B = T(1 - e^{-\kappa_e d \sec \theta}) + T_{V,min}^B e^{-\kappa_e d \sec \theta}, \quad (\text{Eq. 1})$$

where  $T_{V,max}^B$  is the maximum vertically-polarized L-band brightness temperature at the ice sheet surface, and represents emission from the maximum seasonal volumetric fraction of meltwater stored within the water-saturated firn layer.  $T_{V,min}^B$  is the minimum vertically-polarized L-band brightness temperature emitted from the base layer.  $T$  is the physical temperature of the water-saturated firn layer,  $\theta$  is the transmission angle,  $\kappa_e$  is the extinction coefficient, and  $d$  is depth.

We invert Eq. 1 and solve for the firn saturation parameter ( $\xi$ )

$$\xi = \ln \left( \frac{T_{V,max}^B - T}{T_{V,min}^B - T} \right) \cos \theta, \quad (\text{Eq. 2})$$

where  $\xi = \kappa_e d$ . The maximum vertically-polarized L-band brightness temperature asymptotically approaches the physical temperature of the water-saturated firn layer as the extinction coefficient and the depth of the water-saturated firn layer increases. For simplicity, we follow Jezek et al., (2015) and define the extinction coefficient as the sum of the Raleigh scattering coefficient ( $\kappa_s$ ) and the absorption coefficient ( $\kappa_a$ ). This assumes scattering from snow grains, which are small (millimeter scale) relative to the L-band wavelength (21 cm), and neglects Mie scattering from large (centimeter scale) embedded ice structures. However, for water-saturated firn, absorption dominates over scattering, and increases in the extinction coefficient are controlled by the volumetric fraction of meltwater ( $m_v$ ).

We assume that thicker water-saturated firn layers with larger volumetric fractions of meltwater generate higher firn saturation parameter values. However, the thickness of the water-saturated firn layer is limited by the L-band penetration depth. Theoretical L-band penetration depths calculated for a water-saturated firn layer range from between 10 m for small volumetric fractions of meltwater ( $m_v < 1\%$ ), and 1 cm for large volumetric fractions of meltwater ( $m_v = 20\%$ ) (Fig. 5). Large volumetric fractions of meltwater

406 results in high reflectivity and attenuation at the water-saturated firn layer-air interface , and a radiometrically  
 407 cold firn layer.

### 408 **2.3.3 Continuous Logistic Model**

409 We adapt our previously developed empirical algorithm to map the extent of Greenland's perennial firn  
 410 aquifers (Miller et al., 2020) to also map the extent of ice slab areas. The empirical algorithm is derived from  
 411 the continuous logistic model, which is based on a differential equation that models the decrease in physical  
 412 systems as a function of time using a set of sigmoidal curves. These curves begin at a maximum value with  
 413 an initial interval of decrease that is approximately exponential. Then, as the function approaches its  
 414 minimum value, the decrease slows to approximately linear. Finally, as the function asymptotically reaches  
 415 its minimum value, the decrease exponentially tails off and achieves stable values. We use the continuous  
 416 logistic model to parametrize the refreezing rate within the water-saturated upper snow and firn layers of  
 417 the percolation facies using  $T_V^B$  time series that are partitioned using  $T_{V,max}^B$  and  $T_{V,min}^B$  values. We calculate  
 418 the refreezing rate for each rSIR grid cell within the percolation facies extent as part of our adapted empirical  
 419 algorithm (Section 2.3.4).

420 The continuous logistic model is described by a differential equation known as the logistic equation

$$421 \quad \frac{dx}{dt} = \zeta x(1 - x) \quad (\text{Eq. 3})$$

422 that has the solution

$$423 \quad x(t) = \frac{1}{1 + \left(\frac{1}{x_0} - 1\right)e^{-\zeta t}}, \quad (\text{Eq. 4})$$

424 where  $x_0$  is the function's initial value,  $\zeta$  is the function's exponential rate of decrease, and  $t$  is time. The  
 425 function  $x(t)$  is also known as the sigmoid function. We use the sigmoid function to model the exponentially  
 426 decreasing temporal L-band signatures observed over the percolation facies as a set of decreasing  
 427 sigmoidal curves.

428 We first normalize  $T_V^B$  time series for each rSIR grid cell

$$429 \quad T_{V,N}^B(t) = \frac{T_V^B(t) - T_{V,min}^B}{T_{V,max}^B - T_{V,min}^B}, \quad (\text{Eq. 5})$$

430 where  $T_{V,min}^B$  is the minimum vertically-polarized L-band brightness temperature, and  $T_{V,max}^B$  is the maximum  
 431 vertically-polarized L-band brightness temperature. We then apply the sigmoid fit

$$432 \quad T_{V,N}^B(t \in [t_{max}, t_{min}]) = \frac{1}{1 + \left(\frac{1}{T_{V,N}^B(t_{max})} - 1\right)e^{-\zeta t}}. \quad (\text{Eq. 6})$$

433  $T_{V,N}^B(t \in [t_{max}, t_{min}])$  is the normalized vertically-polarized L-band brightness temperature on the time  
 434 interval  $t \in [t_{max}, t_{min}]$ , where  $t_{max}$  is the time the function achieves a maximum value, and  $t_{min}$  is the  
 435 time the function achieves a minimum value. The initial normalized vertically-polarized L-band brightness  
 436 temperature ( $T_{V,N}^B(t_{max})$ ) is the function's maximum value. The final normalized vertically-polarized L-band

437 brightness temperature ( $T_{V,N}^B(t_{min})$ ) is the function's minimum value. The function's exponential rate of  
 438 decrease represents the refreezing rate parameter ( $\zeta$ ). An example set of simulated sigmoidal curves is  
 439 shown in Fig. 6.

#### 440 **2.3.4 SMAP-Derived Perennial Firn Aquifer and Ice Slab Mapping**

441 Our adapted empirical algorithm is implemented in two steps: (1) mapping the extent of the percolation  
 442 facies using the firn saturation parameter derived from the simple two-layer L-band brightness temperature  
 443 model (Section 2.3.2), and (2) mapping the extent of perennial firn aquifer and ice slab areas over the  
 444 percolation facies using the continuous logistic model (Section 2.3.3) we calibrate using airborne ice-  
 445 penetrating radar surveys (Section 2.2).

446 Using Eq. 2, we first set a threshold for the firn saturation parameter ( $\xi_T$ ) defined by the relationship

$$447 \xi_T = (\kappa_s + \kappa_a)d \leq \xi . \quad (\text{Eq. 7})$$

448 We calculate the Raleigh scattering coefficient ( $\kappa_s$ ) in Eq. 7 using

$$449 \kappa_s = N_d \frac{8}{3} k_o^4 r^6 \left| \frac{\epsilon_r - 1}{\epsilon_r + 2} \right|^2 , \quad (\text{Eq. 8})$$

450 where  $N_d$  is the particle density,  $k_o$  is the wave number of the background medium of air,  $r$  is the snow  
 451 grain radius set to  $r=2$  mm, and  $\epsilon_r$  is the complex dielectric constant. The particle density is defined by

$$452 N_d = \frac{\rho_{firn}}{\rho_{ice}} \frac{1}{\frac{4}{3}\pi r^3} , \quad (\text{Eq. 9})$$

453 where  $\rho_{firn}$  is firn density set to  $\rho_{firn}=400$  kg/m<sup>3</sup>, and  $\rho_{ice}$  is ice density set to  $\rho_{ice}=917$  kg/m<sup>3</sup>. Our grain  
 454 radius and firn density estimates are consistent with measurements within the upper snow and firn layers  
 455 of the percolation facies of south eastern Greenland at the Helheim Glacier field site (Fig. 2a, blue circle),  
 456 where in situ perennial firn aquifer measurements have recently been collected (Miller et al., 2017).

457 We calculate the absorption coefficient ( $\kappa_a$ ) in Eq. 7 using

$$458 \kappa_a = -2k_o \Im\{\sqrt{\epsilon_r}\} , \quad (\text{Eq. 10})$$

459 where  $\Im\{\}$  represents the imaginary part. We calculate the complex dielectric constant of the water-  
 460 saturated firn layer in Eq. 8 and Eq. 10 using the empirically derived models described in Tiuri et al., (1984).  
 461 We set the volumetric fraction of meltwater to  $m_v=1\%$ . We set the depth of the water-saturated firn layer in  
 462 Eq. 7 to  $d=1$  m. These values are consistent with typical lower frequency (e.g., 37 GHz, 13.4 GHz, 19 GHz)  
 463 passive (e.g., Mote, et al. 1995; Abdalati and Steffen, 1997; Ashcraft and Long, 2006) and active (e.g.,  
 464 Hicks and Long, 2011) microwave algorithms used to detect seasonal surface melting over the GrIS. Using  
 465 the results of Eq. 7, 8, 9, and 10, we calculate the firn saturation parameter threshold to be  $\xi_T=0.1$ .

466 The first step in our adapted empirical algorithm is to map the extent of the percolation facies. For  
 467 each rSIR grid cell within the ice sheet-masked extent of the GrIS, we smooth the corresponding  $T_V^B$  time  
 468 series using a 14-observation (1 week) moving window. We extract the minimum vertically-polarized L-  
 469 band brightness temperature ( $T_{V,min}^B$ ), and the maximum vertically-polarized L-band brightness temperature

470 ( $T_{V,max}^B$ ). We set the physical temperature of the water-saturated firn layer to  $T=273.15$  K, and the  
471 transmission angle to  $\theta=40^\circ$ . We then calculate the firn saturation parameter ( $\xi$ ) using Eq. 2. If the  
472 calculated firn saturation parameter exceeds the firn saturation parameter threshold, the rSIR grid cell is  
473 converted to a binary parameter to map the total extent of the percolation facies.

474 We note that smoothing  $T_V^B$  time series will mask brief low-intensity seasonal surface melting that  
475 occurs in the high-elevation (>2500 m) percolation facies, where seasonal meltwater is rapidly refrozen  
476 within the colder snow and firn layers (e.g., Fig. 4d). Thus, the calculated firn saturated parameter will not  
477 exceed the firn saturation parameter threshold, and these rSIR grid cells are excluded from the algorithm.  
478 The exclusion of rSIR grid cells in the high-elevation percolation facies is not expected to have a significant  
479 impact on our results as our algorithm targets rSIR grid cells in areas that experience intense seasonal  
480 surface melting. The exclusion of rSIR grid cells may slightly underestimate the mapped percolation facies  
481 extent.

482 The second step in our adapted empirical algorithm is to map the extent of perennial firn aquifer  
483 and ice slab areas over the percolation facies. For each rSIR grid cell within the mapped percolation facies  
484 extent, we normalize the corresponding  $T_V^B$  time series ( $T_{V,N}^B(t)$ ) using Eq. 5. We then extract the initial  
485 normalized vertically-polarized L-band brightness temperature ( $T_{V,N}^B(t_{max})$ ) and the final normalized  
486 vertically-polarized L-band brightness temperature ( $T_{V,N}^B(t_{min})$ ), and partition  $T_{V,N}^B(t)$  on the time interval  $t \in$   
487  $[t_{max}, t_{min}]$ . We smooth  $T_{V,N}^B(t \in [t_{max}, t_{min}])$  using a 56-observation (4 week) moving window. The  
488 sigmoid fit is then iteratively applied using Eq. 6. Smoothing reduces the chi-squared error statistic when  
489 fitting  $T_{V,N}^B(t \in [t_{max}, t_{min}])$  to the sigmoid function. We fix the initial normalized vertically-polarized L-band  
490 brightness temperature at  $T_{V,N}^B(t_{max})=0.99$ , which provides a uniform parameter space in which the  
491 refreezing rate parameter ( $\zeta$ ) can be analyzed. Variability in  $T_{V,N}^B(t_{max})$  is controlled by the volumetric  
492 fraction of meltwater within the upper snow and firn layers of the percolation facies, and is accounted for in  
493 the firn saturation parameter ( $\xi$ ), which is analyzed separately.  $T_{V,N}^B(t \in [t_{max}, t_{min}])$  iteratively fit to the  
494 sigmoid function converge quickly (i.e., algorithm iterations  $I \in [5, 15]$ ), and observations are a good fit (i.e.,  
495 chi squared error statistic is  $\chi^2 \in [0, 0.1]$ ).

496 Using the SMAP-derived  $T_{V,N}^B(t_{max})$  and  $T_{V,N}^B(t_{min})$ , rather than the MODIS-derived initial  
497 normalized vertically-polarized L-band brightness temperature at the surface freeze-up date ( $T_{V,N}^B(t_{sfu})$ ),  
498 and final normalized vertically-polarized L-band brightness temperature at the melt onset date ( $T_{V,N}^B(t_{mo})$ )  
499 that were used in the empirical algorithm described in Miller et al., 2020 has several advantages. The key  
500 advantage of this approach is that maps can be generated using  $T^B$  imagery collected from a single satellite,  
501 which simplifies our adapted empirical algorithm. Another advantage is that unlike  $T^B$  collected at shorter-  
502 wavelength thermal infrared frequencies (e.g., MODIS),  $T^B$  collected at longer wavelength microwave  
503 frequencies (e.g., SMAP) is not sensitive to clouds, which eliminates observational gaps and cloud  
504 contamination, and provides more accurate time series partitioning and more robust curve fitting.

505 We calibrate our adapted empirical algorithm using the AR- and MCoRDS-derived perennial firn  
506 aquifer and ice slab detections projected on the NH EASE-Grid 2.0. For each rSIR grid cell with at least  
507 one detection, we extract the correlated maximum vertically-polarized L-band brightness temperature  
508 ( $T_{V,max}^B$ ), the minimum vertically-polarized L-band brightness temperature ( $T_{V,min}^B$ ), the firn saturation  
509 parameter ( $\xi$ ), and the refreezing rate parameter ( $\zeta$ ). For each of the extracted calibration parameters, we  
510 calculate the standard deviation ( $\sigma$ ). Thresholds of  $\pm 2\sigma$  are set in an attempt to eliminate peripheral rSIR  
511 grid cells near the ice sheet edge and near the boundaries of each sub-facie, where L-band emission can  
512 be influenced by morphological features, such as crevasses, superimposed and glacial ice, and spatially  
513 integrated with emission from rock, land, the ocean, and adjacent percolation facies and wet snow facies  
514 areas. The calibration parameter intervals are given in Table 2. We apply the calibration to each rSIR grid  
515 cell within the percolation facies extent. If the extracted calibration parameters are within the intervals, the  
516 rSIR grid cell is converted to a binary parameter to map the total extent of each of these sub-facies.

517 Miller et al., 2020 cited significant uncertainty in the SMAP-derived perennial firn aquifer extent as  
518 a result of the lack of a distinct temporal L-band signature delineating the boundary between perennial firn  
519 aquifer areas and adjacent percolation facies areas. In this study, similar uncertainty exists in the SMAP-  
520 derived perennial firn aquifer and ice slab extents. This uncertainty could, at least in part, be a result of the  
521 rSIR algorithm. An rSIR grid cell corresponds to the weighted average of  $T^B$  over SMAP's antenna footprint  
522 (Long et al., 2020). The weighting is the grid cell's spatial response function (SRF), which is approximately  
523 18 km (i.e., the effective resolution) in diameter. The SRF is centered on the rSIR grid cell. Since the  
524 effective resolution (i.e., the size of the 3 dB contour of the SRF) is less than the rSIR grid cell spacing,  
525 rSIR grid cell SRF's overlap and the grid cells  $T^B$  values are not statistically independent. This uncertainty,  
526 however, could also have a geophysical basis, as it is unlikely that the boundaries between sub-facies as  
527 well as between facies are distinct. The thickness of the water-saturated firn layer or ice slab may thin and  
528 taper-off at the periphery, and sub-facies and facies may become spatially scattered and merge together.

529 The limited extent (AR, 15 m x 20 m; MCoRDS, 14 m x 40 m) of the airborne ice-penetrating radar  
530 surveys as compared to the rSIR grid cell extent (3.125 km) and the effective resolution of the SMAP  
531 enhanced-resolution  $T_V^B$  imagery is also cited in Miller et al., 2020 as a source of uncertainty in the empirical  
532 algorithm. In this study, similar uncertainty exists in our adapted empirical algorithm. The total rSIR grid cell  
533 extent with airborne ice-penetrating radar survey coverage is less than 2%. Thus, 98% of the total rSIR grid  
534 cell extent from which the SMAP-derived calibration parameter intervals are extracted is unknown.  
535 Calculating the total rSIR grid cell extent where detections are absent along OIB flight lines and statistically  
536 integrating this calculation into the multi-year calibration technique may help reduce the uncertainty,  
537 particularly the significant uncertainty in the interannual variability in extent, which we have yet to resolve.  
538 A sensitivity analysis suggests that even small changes in the SMAP-derived calibration parameter intervals  
539 (i.e., several K for  $T_{V,min}^B$ , and  $T_{V,max}^B$ , several tenths of a percentage point for  $\xi$ , and several hundredths of  
540 a percentage point for  $\zeta$ ) can result in variability in the mapped extents of hundreds of square kilometers,  
541 and boundary transitions between perennial firn aquifer and ice slab areas. Thus, the mapped extent of

542 each of these sub-facies should simply be considered an initial result demonstrating the potential of our  
543 adapted empirical algorithm for future work.

### 544 **3. Results and Discussion**

545 The SMAP-derived maximum vertically-polarized L-band brightness temperature values generated by our  
546 adapted empirical algorithm range from between  $T_{V,max}^B=150$  K and 275 K, and the minimum vertically-  
547 polarized L-band brightness temperature values range from between  $T_{V,min}^B=130$  K and 250 K. These values  
548 are consistent with the range of  $T_{V,max}^B$  and  $T_{V,min}^B$  values given in the temporal L-band signature analysis  
549 (Table 1). Firn saturation parameter values range from between  $\xi=0.1$  and 4.0. Refreezing rate parameter  
550 values range from between  $\zeta=-0.09$  and -0.01. The observed lower bound ( $\zeta=-0.09$ ) of the refreezing rate  
551 parameter is significantly higher than the predicted lower bound ( $\zeta=-1$ ) in our example set of simulated  
552 sigmoidal curves (black line, Fig. 6).

553 The SMAP-derived perennial firn aquifer, ice slab, and percolation facies extents are shown in Figs.  
554 7a-9a. The percolation facies extent ( $5.8 \times 10^5$  km<sup>2</sup>) is mapped at elevations between 500 m a.s.l. and  
555 3000 m a.s.l., and extends over 32 % of the GrIS extent ( $1.8 \times 10^6$  km<sup>2</sup>). The perennial firn aquifer extent  
556 ( $64,000$  km<sup>2</sup>) is mapped at elevations between 600 m a.s.l and 2600 m a.s.l., and extends over 11% of the  
557 percolation facies extent, and 4% of the GrIS extent. Predominately high  $T_{V,max}^B$ ,  $T_{V,min}^B$ ,  $\xi$ , and  $\zeta$  values  
558 mapped within the perennial firn aquifer extent indicates the widespread presence of thicker water-  
559 saturated firn layers with larger volumetric fractions of meltwater that are radiometrically warm during both  
560 the melting and freezing seasons, and have extended refreezing rates. The ice slab extent ( $76,000$  km<sup>2</sup>) is  
561 mapped at elevations between 800 m a.s.l and 2700 m a.s.l., and extends over 13 % of the percolation  
562 facies extent, and 4 % of the GrIS extent. As compared to perennial firn aquifer areas, decreased  $T_{V,max}^B$ ,  
563  $T_{V,min}^B$ ,  $\xi$  and  $\zeta$  values in ice slabs areas indicates the presence of thinner water-saturated firn layers with  
564 lower volumetric fractions of meltwater that are radiometrically colder, and have slightly more rapid  
565 refreezing rates. Combined together, the total extent ( $140,000$  km<sup>2</sup>) is the equivalent of 24% of the  
566 percolation facies extent, and 10% of the GrIS extent. The extents of these sub-facies are generally isolated  
567 and somewhat scattered within the percolation facies. However, in several areas in south, south and central  
568 eastern, and northern Greenland, the sequential formation of facies and sub-facies (dry snow facies -  
569 percolation facies - ice slab - perennial firn aquifer – ablation facies) is mapped.

570 Figs. 7b-9b shows perennial firn aquifers, ice slabs, and spatially coherent melt layers detected by  
571 airborne ice-penetrating radar surveys overlaid on the SMAP-derived percolation facies extent. The SMAP-  
572 derived perennial firn aquifer extent mapped in southern, and south and central eastern Greenland is  
573 consistent with the AR- and MCoRDS-derived perennial firn aquifer detections. Additional smaller perennial  
574 firn aquifer areas are mapped in northern Greenland. The SMAP-derived ice slab extent mapped in south  
575 western, and central eastern Greenland is generally consistent with the spatial patterns of the AR-derived  
576 ice slab detections, however, is significantly expanded upslope in each of these areas. In northern

577 Greenland, perennial firn aquifers areas are alternatively mapped, and additional expansive ice slab areas  
578 are mapped upslope of perennial firn aquifer areas. Additional smaller ice slab areas are mapped in south  
579 and south eastern Greenland. We note that the AR- and MCoRDS-derived perennial firn aquifer and ice  
580 slab detections are limited in space and time, particularly in northern Greenland, with a time interval as  
581 large as nine years between the airborne ice-penetrating radar surveys and the SMAP enhanced-resolution  
582  $T_V^B$  imagery we use in our adapted empirical algorithm. In western and northern Greenland, the 2015 melting  
583 season was especially intense (Tedesco et al., 2016). And, in northern Greenland, the ablation facies have  
584 recently (2010-2019) increased in extent (Noël et al., 2019), and supraglacial lakes have recently (2014-  
585 2019) advanced inland (Turton et al., 2021), indicating a possible geophysical basis for the observed  
586 formation, boundary transitions, and expansion. Neither perennial firn aquifer or ice slab areas are mapped  
587 on the Maniitsoq and Flade Isblink Ice Caps, where spatially integrated L-band emission results in  
588 calibration parameter values outside the defined intervals for each of these sub-facies.

589 Although the AR-derived spatially coherent melt layers detections are often observed to be adjacent  
590 to perennial firn aquifer and ice slab areas, these sub-facies were masked in the original airborne ice  
591 penetrating radar survey analysis by Culberg et al., (2021). Spatially coherent melt layers often overlay  
592 perennial firn aquifers (e.g., Fig. 3a), and merge with ice slabs (Culberg et al., 2021; Fig.4).

593 Shallow buried supraglacial lakes have recently been identified within the percolation facies of  
594 western, northern, and north and central eastern Greenland using airborne ice-penetrating radar surveys  
595 (Koenig et al., 2015) and satellite synthetic aperture radar imagery (Miles et al., 2017; Schröder et al., 2020;  
596 Dunmire et al., 2021). These buried supraglacial lakes are within the SMAP-derived perennial firn aquifer  
597 and ice slab extents, however, are not expected to significantly influence L-band emission in these areas  
598 for two reasons. (1) As compared to SMAP's 18 km footprint, the mean extent of buried supraglacial lakes  
599 is limited (less than 1 km<sup>2</sup>), and they are sparsely distributed in perennial firn aquifer and ice slab areas  
600 (Dunmire et al., 2021). (2) Supraglacial lakes form during the melting season as a result of meltwater  
601 storage within topographic depressions at the ice sheet surface (Echelmeyer et al. 1991). Similar to  
602 subglacial lakes (Jezek et al., 2015) and perennial firn aquifers (Miller et al., 2020), supraglacial lakes  
603 represent radiometrically cold near-surface meltwater reservoirs. Upwelling L-band emission from deeper  
604 firn layers, superimposed and/or glacial ice, and the underlying bedrock are effectively blocked by high  
605 reflectivity and attenuation at the interface between the lake bottom and the underlying impermeable layer.  
606 This results in low observed  $T_V^B$  at the upper surface of meltwater stored within supraglacial lakes. During  
607 the freezing season, the upper surface of meltwater refreezes and forms a partial or solid-ice cap that is  
608 sometimes buried by snow accumulation (Koenig et al., 2015). Airborne ice-penetrating radar surveys in  
609 April and May between 2009 and 2012 suggest the mean depth to the upper surface of meltwater stored  
610 within buried supraglacial lakes is approximately 2 m (Koenig et al., 2015). Over buried supraglacial lakes,  
611 L-band emission from the refreezing partial or solid-ice cap, which is smooth relative to the L-band  
612 wavelength (21 cm), likely induces surface scattering. As a result,  $T_V^B$  decreases over buried supraglacial

613 lakes are likely negligible. Thus, over SMAP's 18 km footprint, we postulate water-saturated firn layers  
614 dominate L-band emission over the percolation facies of the GrIS.

615 The SMAP-derived perennial firn aquifer extent (64,000 km<sup>2</sup>) generated by our adapted empirical  
616 algorithm and the multi-year calibration technique (2015-2019) is consistent with the extent (66,000 km<sup>2</sup>)  
617 generated by the previously developed empirical algorithm and the single-coincident year calibration  
618 technique (2016) described in Miller et al., 2020. The SMAP-derived perennial firn aquifer extent is generally  
619 consistent with previous C-band (5.3 GHz) satellite radar scatterometer-derived perennial firn aquifer  
620 extents mapped using the Advanced SCATterometer (ASCAT) on the European Organization for the  
621 Exploitation of Meteorological Satellites (EUMETSAT) Meteorological Operational A (MetOp-A) satellite  
622 (2009-2016, 52 000-153 000 km<sup>2</sup>; Miller, 2019), and the Active Microwave Instrument in radar scatterometer  
623 mode (ESCAT) on ESA's European Remote Sensing (ERS) satellite series (1992-2001, 37 000-64 000 km<sup>2</sup>;  
624 Miller, 2019) as well as the C-band (5.4 GHz) synthetic aperture radar-derived extent mapped using ESA's  
625 Sentinel-1 satellite (2014-2019, 54 000 km<sup>2</sup>; Brangers et al., 2020). The exception is the ASCAT-derived  
626 perennial firn aquifer extent (2012-2013, 153,000 km<sup>2</sup>; Miller, 2019) mapped following the 2012 melting  
627 season (Nghiem et al., 2012) in which significant changes in the dielectric and geophysical properties that  
628 influence radar backscatter likely occurred. The unreasonably expansive (i.e., more than twice the mean)  
629 mapped extent is a result of ASCAT'S shallow (several meters) C-band penetration depth (Jezek et al.,  
630 1994), and the simple threshold-based algorithm, which was not calibrated for an extreme melting season  
631 that included saturation of the upper snow and firn layers of the dry snow facies and percolation facies with  
632 relatively large volumetric fractions of meltwater (Miller et al., 2019). Water-saturated firn layers had  
633 extended refreezing rates, however, seasonal meltwater was not stored at depth. Widespread spatially  
634 coherent melt layers were alternatively formed in many of the mapped areas (Culberg et al., 2021). The  
635 SMAP-derived ice slab extent (76,000 km<sup>2</sup>) is also consistent with previous AR-derived ice slab extents  
636 (2010-2014, 64,800 km<sup>2</sup>-69,400 km<sup>2</sup>; McFerrin et al., 2019).

637 Although we simply consider our mapped extents a high-probability area for preferential formation,  
638 the maps generated by our adapted empirical algorithm and the multi-year calibration technique for  
639 individual years suggest there reasonable interannual variability in perennial firn aquifer and ice and slab  
640 extents (Table 3). Our results demonstrate sensitivity to the variability in the depth- and time-integrated  
641 dielectric and geophysical properties of the percolation facies that influence the radiometric temperature,  
642 even during the 2015 melting season (Tedesco et al., 2016).

#### 643 **4 Implications**

644 Seasonal surface melting over the GrIS has increased in extent, intensity, and duration since early in the  
645 satellite era (Steffen et al., 2004; Tedesco e al., 2008; Tedesco et al., 2011; Nghiem et al., 2012; Tedesco  
646 et al., 2016; Tedesco and Fettweis, 2020; Cullather et al., 2020). Consistent with recent seasonal surface  
647 melting trends, meltwater run-off has accelerated to become the dominant mass loss mechanism over the  
648 GrIS (van den Broeke et al., 2016). Meltwater storage in both solid (i.e., embedded ice structures, including  
649 ice slabs, spatially coherent melt layers) and liquid (i.e., perennial firn aquifers) form can buffer meltwater

650 run-off in the percolation facies and delay its eventual release into the ocean (Harper et al., 2012). However,  
651 significant uncertainty remains in meltwater run-off estimates as a result of the lack of knowledge of  
652 heterogeneous infiltration and refreezing processes within the snow and firn layers (Pfeffer and Humphrey,  
653 1996), and the depths to which meltwater can descend beneath the ice sheet surface (Humphrey et al.,  
654 2012).

655         If the increasing seasonal surface melting trend continues (Franco et al., 2013; Noël et al., 2021),  
656 perennial firn aquifer formation and expansion may increase the possibility of crevasse-deepening via  
657 meltwater-induced hydrofracturing (Alley et al., 2005; van der Veen, 2007), especially if crevasse fields  
658 expand into perennial firn aquifer areas as a result of accelerated ice flow (Colgan et al., 2016). Meltwater-  
659 induced hydrofracturing is an important component of supraglacial lake drainage during the melting season  
660 (Das et al., 2008; Stevens et al., 2015) leading to at least temporary localized accelerated ice flow velocities  
661 (Zwally et al., 2002; Joughin et al., 2013; Moon et al., 2014) as well as ice discharge from outlet glaciers  
662 (Chudley et al., 2019), and mass balance changes (Joughin et al., 2008). Perennial firn aquifers may also  
663 support meltwater-induced hydrofracturing, even during the freezing season (Poinar et al., 2017; Poinar et  
664 al., 2019).

665         The formation and expansion of ice slabs reduces permeability within the upper snow and firn  
666 layers and facilitates lateral meltwater flow with minimum vertical percolation into the deeper firn layers,  
667 thereby enhancing meltwater run-off and mass loss at the periphery (MacFerrin et al., 2019). Lateral  
668 meltwater flow across ice layers overlying deeper permeable firn layers was first postulated by Müller  
669 (1962). The theory was then further developed by Pfeffer et al., (1991) as an end-member case for  
670 meltwater run-off in the percolation facies, with the other end member case being lateral meltwater flow  
671 across superimposed ice. Lateral meltwater flow and high-elevation (1850 m a.s.l) meltwater run-off across  
672 ice slabs in the percolation facies was recently observed in visible satellite imagery collected by the NASA-  
673 USGS Landsat 7 mission during the 2012 melting season (MacFerrin et al., 2019).

674         Spatially coherent melt layers represent a newly identified refreezing mechanism in the dry snow  
675 facies (Culberg et al., 2021). Similar to ice slabs, the formation and expansion of spatially coherent melt  
676 layers reduces the pore space within the upper snow and firn layers, and can limit meltwater flow with  
677 minimum vertical percolation into the deeper firn layers, thereby potentially preconditioning the dry snow  
678 facies for enhanced meltwater run-off from significantly higher elevations on accelerated time scales. If  
679 spatially coherent melt layers merge with ice slabs upslope of perennial firn aquifers areas they might also  
680 simultaneously accelerate both meltwater run-off and meltwater-induced hydrofracturing during extreme  
681 melting seasons. The formation of spatially coherent melt layers overlying deeper perennial firn aquifers  
682 may result in the formation of shallow perched firn aquifers (Culberg et al., 2021), or may terminate gravity-  
683 driven meltwater drainage and seasonal recharging (Fountain and Walder, 1998), which may eventually  
684 completely refreeze stored meltwater into ice slabs or decimeters thick solid-ice layers overlying deeper  
685 glacial ice.

686

## 687 **5 Summary and Future Work**

688 In this study, for the first time, we have demonstrated the novel use of the L-band microwave radiometer  
689 on NASA's SMAP satellite for mapping perennial firn aquifers and ice slabs together as a continuous system  
690 over the percolation facies of the GrIS. We have adapted our previously developed empirical algorithm  
691 (Miller et al., 2020) by expanding our analysis of spatiotemporal differences in SMAP enhanced-resolution  
692  $T_V^B$  imagery and temporal L-band signatures. We have used this analysis to derive a firn saturation  
693 parameter from a simple two-layer L-band brightness temperature model (Miller et al., 2021, in press). And,  
694 we have used the firn saturation parameter to map the extent of the percolation facies. We have found that  
695 by correlating maximum and minimum  $T_V^B$  values, the firn saturation parameter, and the refreezing rate  
696 parameter with perennial firn aquifer and ice slab detections identified via the CReSIS AR and MCoRDS  
697 instruments flown by NASA's OIB campaigns that we can calibrate our previously developed empirical  
698 algorithm (Miller et al., 2020) to map plausible extents.

699 We note that significant uncertainty exists in the mapped extents as a result of: (1) correlating the  
700 SMAP-derived parameters with airborne ice-penetrating radar detections that are not coincident in time, (2)  
701 the lack of a distinct temporal L-band signature delineating the boundary between perennial firn aquifer  
702 areas, ice slabs areas, and adjacent percolation facies areas, and (3) the limited extent of the airborne ice-  
703 penetrating radar detections as compared to the rSIR grid cell extent and the effective resolution of the  
704 SMAP enhanced-resolution  $T_V^B$  imagery.

705 Miller et al., (2020) normalized SMAP enhanced-resolution  $T_V^B$  time series and converted the  
706 exponential rate of  $T_V^B$  decrease over perennial firn aquifer areas to a binary parameter to map extent. In  
707 this study, we have converted the SMAP-derived parameters to binary parameters to map the extent of  
708 both perennial firn aquifer and ice slab areas. Moreover, we have included additional analysis of the  
709 spatiotemporal differences in maximum and minimum  $T_V^B$  values, the firn saturation parameter, and the  
710 refreezing rate parameter. We have shown that spatiotemporal differences in the SMAP-derived  
711 parameters are consistent with our assumption of spatiotemporal differences in the englacial hydrology and  
712 thermal characteristics of firn layers at depth.

713 Future work will focus on simulating temporal L-band signatures observed over perennial firn  
714 aquifer and ice slab areas for a wide range of geophysical properties. To better interannual variability in  
715 extent, we will interpret our results together with climatological parameters, such as snow accumulation,  
716 liquid water content, and surface mass balance simulated by the Regional Atmospheric Climate Model  
717 (RACMO2.3p2; Noël et al., 2018). Additionally, we will simulate the distinct temporal L-band signatures  
718 observed over spatially coherent melt layers and explore mapping the extent.

719 Combining multi-layer depth-integrated L-band brightness temperature models (e.g., Jezek et al.,  
720 2015) that include embedded ice structure parametrizations (e.g., Jezek et al., 2018) with models of depth-  
721 dependent geophysical parameters can lead to an improved understanding of the extremely complex and  
722 poorly described physics controlling L-band emission over the percolation facies. Key geophysical  
723 parameters include atmospheric temperature forcing, physical temperature versus depth, latent heat, snow

724 accumulation, the volumetric fraction and depth of meltwater, and the volumetric fraction and geometric  
725 configuration of embedded ice structures. The development of more sophisticated empirical algorithms that  
726 incorporate multi-layer depth-integrated L-band brightness temperature models that are constrained by in  
727 situ measurements can help reduce the significant uncertainty in the current mapped extents, and provide  
728 more accurate boundary delineation that can be used to further quantify the interannual variability in future  
729 mapped extents of perennial firn aquifer, ice slab and spatially coherent melt layer areas.

### 730 **Data Availability**

731 SMAP Radiometer Twice-Daily rSIR-Enhanced EASE-Grid 2.0 Brightness Temperatures, Version 1 (2015-  
732 2019) have been produced as part of the NASA Science Utilization of SMAP project and are available at  
733 <https://doi.org/10.5067/QZ3WJNOUZLFK> (Brodzik et al., 2019). The NASA MEaSURES Greenland Ice  
734 Mapping Project (GIMP) Land Ice and Ocean Classification Mask, Version 1, is available at  
735 <https://doi.org/10.5067/B8X58MQBFUPA> (Howat, 2017), and the Digital Elevation Model, Version 1, is  
736 available at <https://nsidc.org/data/nsidc-0645/versions/1> (Howat et al., 2015). The coastline data are  
737 available from GSHHG – A Global Self-consistent, Hierarchical, High-resolution Geography Database  
738 <https://doi.org/10.1029/96JB00104> (Wessel and Smith, 1996). Ice surface temperature imagery (2015-  
739 2019) have been produced as part of the Multilayer Greenland Ice Surface Temperature, Surface Albedo,  
740 and Water Vapor from MODIS V001 data set and are available at  
741 <https://doi.org/10.5067/7THUWT9NMPDK> (Hall and DiGirolamo, 2019). OIB AR- and MCoRDS-derived  
742 perennial firn aquifers detections (2010-2017) are available at  
743 <https://arcticdata.io/catalog/view/doi:10.18739/A2985M> (Miège et al., 2016). OIB AR-derived ice slab  
744 detections (2010-2014) are available at <https://doi.org/10.6084/m9.figshare.8309777> (MacFerrin et al.,  
745 2019). OIB AR-derived spatially coherent melt layer detections (2017) are available at  
746 (<https://doi.org/10.18739/A2736M33W>) (Culberg et al., 2021). OIB AR L1B Geolocated Radar Echo  
747 Strength Profiles, Version 2, are available at, <https://doi.org/10.5067/OZY1XYHNIQNY> (Paden et al., 2018).  
748 NASA MEaSURES MODIS Mosaic of Greenland (MOG) 2015 Image Map, Version 2, is available at  
749 <https://nsidc.org/data/NSIDC-0547/versions/2> (Haran et al., 2018). SMAP-derived perennial firn aquifer, ice  
750 slab, and perched firn aquifer extents are available from JZM upon request.

### 751 **Author Contributions**

752 JZM initiated the study, adapted the empirical model, performed the analyses, and wrote the manuscript.  
753 RC processed and interpreted the OIB AR radargram profiles. RC and DMS provided the spatially coherent  
754 melt layer detections. All authors participated in discussions and reviewed manuscript drafts.

### 755 **Competing Interests**

756 The authors declare that they have no conflict of interest.

1137 **Figure 1**

1138 (a) Gridded (25 km gridding, 30 km effective resolution), and (b) enhanced-resolution (3.125 km gridding,  
 1139 18 km effective resolution) L-band  $T_V^B$  imagery generated using observations collected 15 April 2016 by the  
 1140 microwave radiometer on the SMAP satellite during the evening orbital pass interval over Greenland (Long  
 1141 et al., 2019) overlaid with the 2000 m a.s.l. contour (black line), and the 2500 m a.s.l. contour (dotted black  
 1142 line; Howat et al., 2014); the ice sheet extent (purple line; Howat et al., 2014); and the coastline (black  
 1143 peripheral line; Wessel and Smith, 1996). (c) SMAP enhanced-resolution L-band  $T_V^B$  imagery overlaid with  
 1144 AR- and MCoRDS-derived 2010-2017 perennial firn aquifer (blue shading; Miège et al., 2016), 2010-2014  
 1145 ice slab (cyan shading; MacFerrin et al., 2019), and 2012 spatially coherent melt layer (white shading;  
 1146 Culberg et al., 2021) detections along OIB flight lines (black interior lines); zoom areas over south eastern  
 1147 Greenland (red box; Fig. 2a), and south western Greenland (orange box; Fig. 2b); and AR radargram  
 1148 transect A-B (red line; Fig. 3a) and C-D (orange line; Fig. 3b).

1149

1150 **Figure 2**

1151 *Enhanced-resolution (3.125 km gridding, 30 km effective resolution) L-band  $T_V^B$  imagery generated using*  
 1152 *observations collected 15 April 2016 by the microwave radiometer on the SMAP satellite during the evening*  
 1153 *orbital pass interval over (a) south eastern Greenland (red box, Fig. 1c), and (b) south western Greenland*  
 1154 *(orange box, Fig. 1c,) (Long et al., 2019) overlaid with the ice sheet extent (purple line; Howat et al., 2014);*  
 1155 *the coastline (black peripheral line; Wessel and Smith, 1996); the AR- and MCoRDS-derived 2010-2017*  
 1156 *perennial firn aquifer (blue shading; Miège et al., 2016), 2010-2014 ice slab (cyan shading; MacFerrin et*  
 1157 *al., 2019), and 2012 spatially coherent melt layer (white shading; Culberg et al., 2021) detections along OIB*  
 1158 *flight lines (black interior lines); AR transect A-B (red line; Fig. 3a), and C-D (orange line; Fig. 3b); and*  
 1159 *SMAP Test Site A (blue circle; Fig. 4a), B (cyan circle; Fig. 4b), C (orange diamond; Fig. 4c), D (red triangle;*  
 1160 *Fig. 4d), and E (yellow circle; Fig. 4e).*

1161

1162

**Figure 3**

1163

*AR transect (a) A-B (red line, Fig. 2a) collected on 22 April 2017, and (b) C-D (orange line, Fig. 2b) collected on 5 May 2017 (Rodriguez-Morales et al, 2014). (c) AR transect A-B (red line), and C-D (orange line)*

1164

*elevation profiles. The exceptionally bright upper surface-parallel reflector in (a) is a spatially coherent melt layer. The bright lower reflector in (a) is the upper surface of meltwater stored within a perennial firn aquifer.*

1165

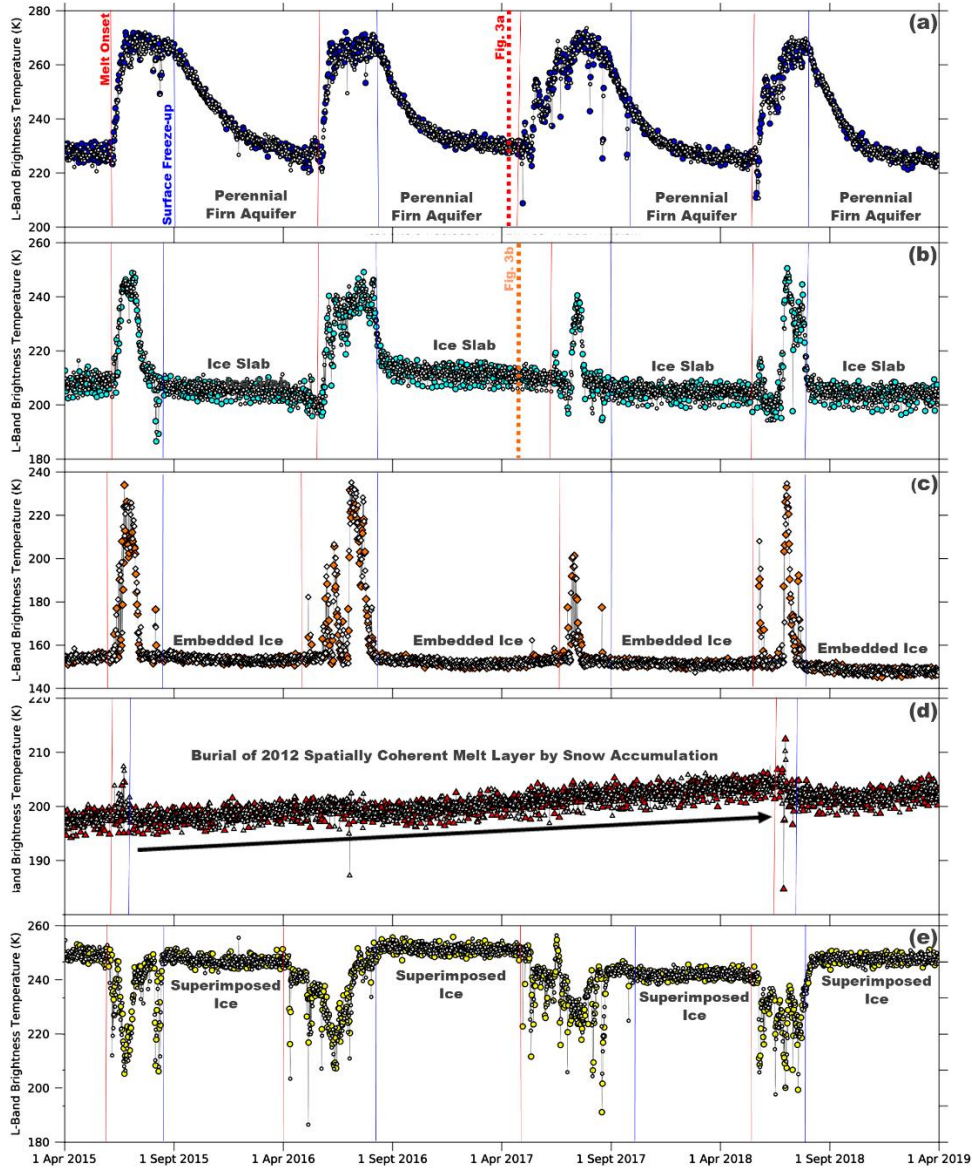

*The thick dark surface-parallel regions of low-reflectivity in (b) are ice slabs. The alternating sequences of bright and dark surface-parallel reflectors in (b) are seasonal snow accumulation layers.*

1166

1167

1168

1169

1170 **Figure 4**

1171 *Temporal L-band signatures that alternate morning (white symbols) and evening (colored symbols) orbital*  
 1172 *pass interval enhanced-resolution  $T_V^B$  generated using observations collected over the GRIS by the*  
 1173 *microwave radiometer on the SMAP satellite (Long et al., 2019) over (a) SMAP Test Site A (blue circles;*  
 1174 *Fig. 2a), (b) B (cyan circles; Fig. 2b), (c) C (orange diamonds; Fig. 2b), (d) D (red triangles; Fig. 2a), and (e)*  
 1175 *E (yellow circles; Fig. 2b). Melt onset (red lines) and surface freeze-up (blue lines) dates derived from*  
 1176 *thermal infrared  $T^B$  collected by MODIS on the Terra and Aqua satellites (Hall et al, 2012). AR transect A-*  
 1177 *B (red dashed line; Figs. 3a) collected on 22 April 2017, and C-D (orange dashed line; Fig. 3b) collected*  
 1178 *on 5 May 2017.*

1179

1180 **Figure 5**

1181 *Theoretical L-band penetration depths for of uniform layer of (a) refrozen, and (b) water-saturated firn.*

1182 *Penetration depths  $\left(\frac{1}{\kappa_s + \kappa_a}\right)$  are calculated as a function of the Raleigh scattering coefficient ( $\kappa_s$ ; Eq. 8), and*

1183 *the absorption coefficient ( $\kappa_a$ ; Eq. 10). The complex dielectric constant is calculated using the empirically*

1184 *derived models described in Tiuri et al., (1984). Refrozen firn penetration depths are calculated as a function*

1185 *of firn density ( $\rho_{firn}$ ), and the curves are plotted for snow grain radii ( $r$ ) set to  $r=0.5$  mm (upper curve), and*

1186  *$r=4$  mm (lower curve). Water-saturated firn penetration depths are calculated as a function of the volumetric*

1187 *fraction of meltwater ( $m_v$ ), and the curves are plotted for firn density set to  $\rho_{firn}=400$  kg/m<sup>3</sup> (upper curve),*

1188 *and  $\rho_{firn}=917$  kg/m<sup>3</sup> (lower curve). Given the complexity of modeling embedded ice structures, they are*

1189 *excluded from the penetration depth calculation. Increases in the volumetric fraction of embedded ice within*

1190 *the firn will result in an increase in volume scattering, which will decrease and compress the distance*

1191 *between the penetration depth curves for both refrozen and water-saturated firn.*

1192

1193 **Figure 6**

1194 *Example set of simulated sigmoidal curves that represent our model of the exponentially*  
 1195 *decreasing temporal L-band signatures predicted over the percolation facies. The initial*  
 1196 *normalized vertically-polarized L-band brightness temperature was fixed at a value of  $T_{V,N}^B(t_{max})$*   
 1197 *= 0.99, and the time interval was set to a value of  $t \in [t_{max}, t_{min}] = 300$  observations. The*  
 1198 *refreezing rate parameter was set to values between  $\zeta = [-1, 0]$  incremented by steps of 0.02.*  
 1199 *The blue lines correspond to the interval  $\zeta \in [-0.04, -0.02]$  and produce curves similar to those*  
 1200 *observed over perennial firn aquifer areas. The cyan lines correspond to the interval  $\zeta \in [-0.06, -$*   
 1201 *0.03] and produce curves similar to those observed over ice slab areas. The black line is the*  
 1202 *observed lower bound ( $\zeta = -0.09$ ) of the refreezing rate parameter of partitioned  $T_V^B$  time series*  
 1203 *iteratively fit to the sigmoid function (Section 2.3.4).*

1239 **Table 1.**

1240 *MODIS-derived total number of days in the melting and freezing seasons; SMAP-derived maximum*  
 1241 *vertically-polarized L-band brightness temperature ( $T_{V,max}^B$ ); minimum vertically-polarized L-band brightness*  
 1242 *temperature ( $T_{V,min}^B$ ); time scale scales of exponential decrease following the surface freeze-up date for*  
 1243 *perennial firn aquifer, ice slab, percolation facies, dry snow facies, and wet snow facies areas.*

	<b>Melting Season (days)</b>	<b>Freezing Season (days)</b>	<b><math>T_{V,max}^B</math> (K)</b>	<b><math>T_{V,min}^B</math> (K)</b>	<b>Exponential Decrease (time scale)</b>
<b>Perennial Firn Aquifers</b>	75 - 100	265 - 290	200 - 275	180 – 250	weeks – months
<b>Ice Slabs</b>	60 -90	275 - 305	170 - 260	130 – 240	days - weeks
<b>Percolation Facies</b>	1 - 60	305 - 364	150 - 200	130 – 220	days
<b>Dry Snow Facies</b>	-	365	200 - 240	200 – 240	-
<b>Wet Snow Facies</b>	90 - 120	245 - 275	230 - 250	230 – 250	-

1244

1245 **Table 2.**

1246 *SMAP-derived calibration parameter intervals used for mapping perennial firn aquifer and ice slab extents.*

	$\xi$	$T_{V,max}^B$ (K)	$T_{V,min}^B$ (K)	$\zeta$
<b>Perennial Firn Aquifers</b>	0.2 – 4	200 – 275	180 – 250	-0.04 – -0.02
<b>Ice Slabs</b>	0.1 – 2	170 – 260	130 – 240	-0.06 – -0.03

1247

1248 **Table 3.**

1249 *Interannual variability in SMAP-derived perennial firn aquifer and ice slab extents.*

	<b>Perennial Firn Aquifers (km<sup>2</sup>)</b>	<b>Ice Slabs (km<sup>2</sup>)</b>
<b>2015-2019</b>	66,000	76,000
<b>2015-2016</b>	63,000	23,000
<b>2016-2017</b>	69,000	48,000
<b>2017-2018</b>	73,000	27,000
<b>2018-2019</b>	70,000	38,000
