**Abstract.** The Thwaites Eastern Ice Shelf continues to buttresses a significant portion of Thwaites Glacier through contact with a pinning point 40 km offshore of the present grounding line. Predicting future rates of Thwaites Glacier's contribution to sea-level rise depends on the evolution of this pinning point and the resultant change in the ice-shelf stress field since the break-up of the Thwaites Western Glacier Tongue in 2009. Here we use Landsat-8 feature tracking of ice velocity in combination with model perturbation experiments to show how past changes in flow velocity have been governed in large part by changes in lateral shear and pinning point interactions with the Thwaites Western Glacier Tongue. We then use recent satellite altimetry data from ICESat-2 to show that Thwaites Glacier's grounding line has continued to retreat rapidly; in particular, the grounded area of the pinning point is greatly reduced from earlier mappings in 2014, and grounded ice elevations continuing to decrease. This loss has created two pinned areas with ice flow now funneled between them. If current rates of surface lowering persist, the entire Thwaites Eastern Ice Shelf will unpin from the seafloor in less than a decade, despite our finding from airborne radar data that the seafloor underneath the pinning point is about 200 m shallower than previously reported. Advection of relatively thin and mechanically damaged ice onto the remaining portions of the pinning point and feedback mechanisms involving basal melting, may further accelerate the unpinning. As a result, ice discharge will likely increase along a 45 km stretch of the grounding line that is currently buttressed by the Thwaites Eastern Ice Shelf.

## 1 Introduction

The Amundsen Sea Coast of West Antarctica has been the setting of drastic glacier retreat, unprecedented ice-shelf thinning and associated speed-up since the beginning of the satellite measurement era (Scambos et al., 2017). Ice discharge across its grounding line – where ice becomes afloat on the ocean to form ice shelves and glacier tongues – is producing the majority of Antarctica's contribution to contemporary sea-level rise (Rignot et al., 2008; Shepherd et al., 2012). Wherever ice shelves reground on elevated seafloor such as offshore ridges and islands, significant resistance against the flow of floating ice controls

the overall ice-shelf buttressing which, in turn, stabilizes the location of the grounding line (e.g., Alley et al., 2015). This is supported by model experiments showing that reduced ice-shelf buttressing is linked to retreat of grounding lines even far upstream of the location where the change in buttressing occurred, leading to an overall net loss of ice volume above flotation (Dupont and Alley, 2005). Ungrounding of ice shelves from these pinning points, therefore, has the potential to initiate rapid changes on a regional scale (Goldberg et al., 2009; Favier et al., 2012; Favier and Pattyn, 2015; Favier et al., 2016; Reese et al., 2018).

Pinning points exist all around Antarctica's coastline and are classified as either ice rises or ice rumpled, depending on their ice-dynamical characteristics (MacAyeal et al., 1987; Matsuoka et al., 2015): Ice rises feature negligible surface motion and divert the general ice flow around them. Prominent examples include Crary Ice Rise on the Ross Ice Shelf, Hemmen Ice Rise on the Ronne-Filchner Ice Shelf, and Bawden Ice Rise on the Larsen C Ice Shelf. Ice rumpled, in contrast, maintain the general flow direction and are typically elevated only a few meters above the surrounding ice-shelf surface such as the Doake Ice Rumpel enclosed within the Ronne-Filchner Ice Shelf (Johnson and Smith, 1997). The common characteristics of both ice rises and rumpled is that they remain grounded throughout the tidal cycle and thus permanently resist the ice-shelf flow through shear stresses at their base. Depending on their formation, these features are categorized as (1) long-term stable, if an ice rise persisted over the last glacial cycle, (2) deglacial emergent, if ice remained locally grounded during ice-sheet retreat, (3) emergent from glacial isostatic adjustment, forming when floating ice regrounds due to post-glacial rebound of the Earth's crust, and (4) glaciological emergent, if thicker ice is advected onto elevated seafloor (Matsuoka et al., 2015).

During the Holocene deglaciation of Antarctica, Thwaites Glacier was grounded on a prominent seafloor ridge ranging between 300-700 m below present-day sea level. The exact timing of ungrounding, causing rapid retreat of about 40 km across a major marine channel (>1.5 km deep) to its present day grounding line, can only be estimated between 40 and 5000 years ago (Tinto and Bell, 2011). Until recently, the grounding line has been relatively stable on the same seafloor ridge (Fig. 1). Both the slow flowing Thwaites Eastern Ice Shelf and the much faster flowing Thwaites Western Glacier Tongue rested on deglacial emergent ice rises formed at the former grounding-line location. This relative stability changed drastically by 2009, when the Western Glacier Tongue largely detached from its pinning point and rapidly disaggregated within the following years (Tinto and Bell, 2011; MacGregor et al., 2012; Miles et al., 2020).

Ephemeral grounding closer to the 2011 grounding line was detected (Milillo et al., 2019), which indicates the presence of several local seafloor highs, but grounding at low tides generally provides little buttressing to ice flow (Schmeltz et al., 2001). The loss of contact with these small partially grounded seafloor highs, however, allowed the rapid formation of relatively large sub-glacial cavities in seafloor lows behind the initial grounding line, areas that were once shielded against the intrusion of warm modified Circumpolar Deep Water. An example is the 'butterfly' region near the eastern end of Thwaites Glacier's grounding line, where retreat rates doubled from 0.6 km yr<sup>-1</sup> between 1992 to 2011 to 1.2 km yr<sup>-1</sup> between 2011 to 2017 (Milillo et al., 2019). To the western end of Thwaites Glacier's grounding line, high rates of surface lowering (3-7 m yr<sup>-1</sup>) are attributed to dynamic thinning since the break-up of the Western Glacier Tongue in 2009. Here, the grounding line retreated 14 km between 2009 to 2017 along a deep seafloor trough underlying an embayment in the grounding line where Thwaites Glacier is moving the fastest (>3 km yr<sup>-1</sup>, Fig. 1 c and d). The remaining Eastern Ice Shelf is still confined by an elongated

ice rise that is oriented perpendicular to ice flow with the calving front directly downstream. This pinning point buttresses the Eastern Ice Shelf and thus a 45 km stretch of the eastern part of Thwaites Glacier's grounding line (more than one third of the full glacier width), but also provides an important control on the pathways for warm modified Circumpolar Deep Water intrusion into the sub-ice-shelf cavity (Wåhlin et al., 2021). The areal extent of the grounded ice on the pinning point not only shrank in half between 1992 and 2011, but the pinning point also split into a larger eastern and a much smaller western portion (Rignot et al., 2014). Further unpinning from its last anchoring points may cause a Western Glacier Tongue-like break-up of the Eastern Ice Shelf in the near future.

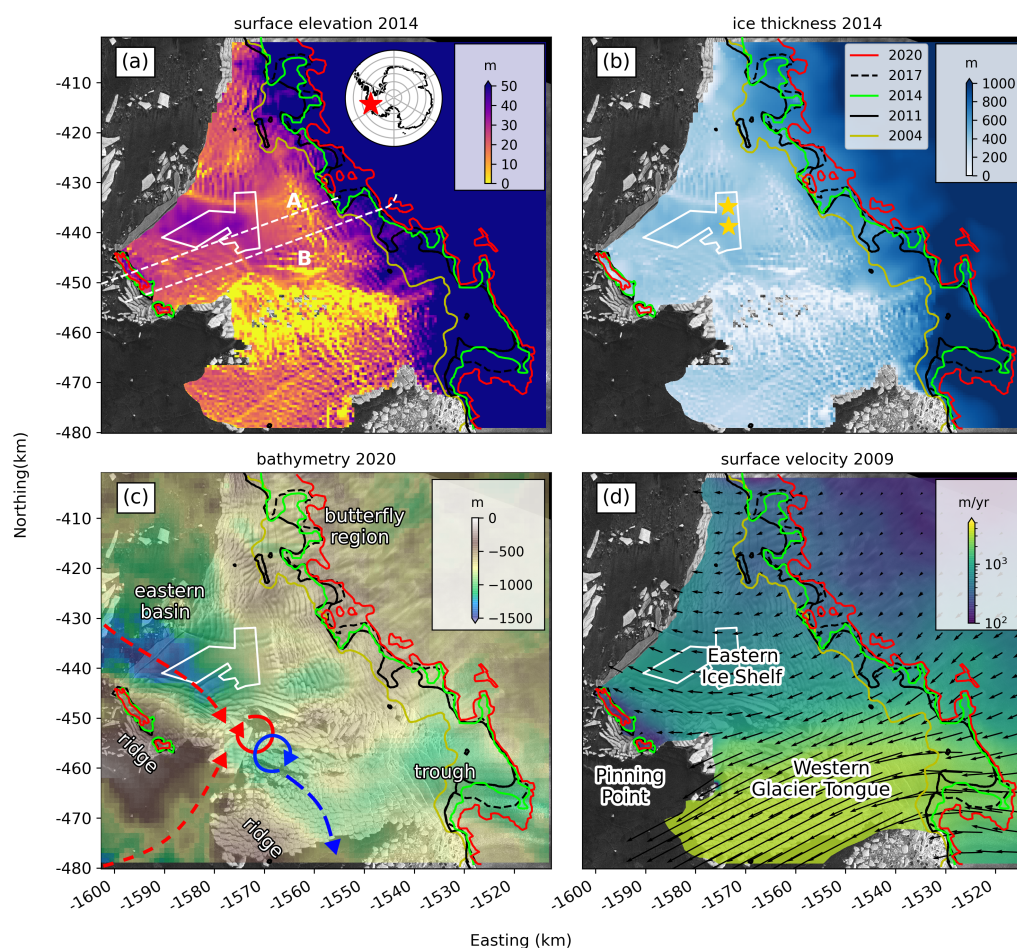

For these reasons it is crucial to assess the structural integrity of Thwaites pinning point as well as understand signs of its possible destabilization. Here we evaluate its stability through the integration of recent bathymetry estimates and airborne radar surveys from Operation IceBridge and the NERC/NSF International Thwaites Glacier Collaboration with new surface elevation measurements from ICESat-2 satellite laser altimetry. The former is necessary to assess how well the ice-shelf is locally pinned to the seafloor. The latter allows us to derive surface-lowering rates to predict the timing of unpinning and when this 45 km stretch of Thwaites Glacier's grounding line will become fully unconstrained by an ice shelf.

Using airborne radar data, we first modify the existing bathymetry model to match measured ice thickness across the eastern portion of the pinning point. To investigate changes in the regional stability of the Eastern Ice Shelf as well as its pinning point, we compute changes in height above flotation from the REMA digital elevation model (Howat et al., 2019) and more recent ICESat-2 satellite altimetry data (Smith et al., 2019). We then perform a series of numerical perturbation experiments to explain the dominant mechanisms behind the observed changes in regional ice-flow dynamics. Lastly, we estimate when Thwaites pinning point will become entirely ungrounded from the seafloor, if the current rates of surface lowering persist. We validate the results with ground-truth data collected in the 2019/20 Antarctic field season as part of the International Thwaites Glacier Collaboration (ITGC) TARSAN project. We then discuss analogies to the break-up of the Western Glacier Tongue and close by drawing conclusions about the role of the pinning point on tele-buttressing large parts of Thwaites Glacier.

## 2 Data and Methods

### 2.1 Bathymetry adjustment to airborne radar data

Sub-ice-shelf bathymetry of the Eastern Ice Shelf and other ice shelves in the Amundsen Sea was modeled through inversion of airborne gravity data by Jordan et al. (2020). While gravity data can be collected efficiently on a regional scale, they have relatively low spatial resolution (5 km) so only topographic features with wavelengths down to about 5 km are well resolved (Jordan et al., 2020). With a width of about 15 km, the general pattern of Thwaites pinning point is therefore resolved reasonably well, but absolute values remain uncertain (100 m standard deviation). Where ice is grounded on the seafloor, however, ice thickness measurements from airborne radar surveys can be used to further constrain the gravity-derived bathymetry. In addition to the 1000 m resolution bathymetry (Jordan et al., 2020), we also use the 500 m BedMachine v2 bed-elevation product (Morlighem, 2020), which was calculated from the mass conservation method where ice is grounded and gravity inversion where ice is floating (Morlighem et al., 2020).

**Figure 1.** Data sets assembled for the Eastern Ice Shelf and the Western Glacier Tongue study area overlain on a Sentinel 1 SAR image from October 2019: (a) Reference Elevation Model of Antarctica (REMA, Howat et al., 2019); (b) BedMachine version 2 ice thickness (Morlighem, 2020); (c) gravity-derived bathymetry (Jordan et al., 2020); (d) MEaSUREs ice surface velocity field before break-up of Western Glacier Tongue (Rignot et al., 2017). Past grounding lines: yellow is approximately 2004 (Bindshadler et al., 2008); black is 2011 from MEaSUREs, dashed black is 2017 from InSAR (Milillo et al., 2019). We define the green (2014) and red (2020) grounding lines from REMA and ICESat-2 data, respectively. The white outline shows the spatial extent of field operations in the 2019/20 Antarctic season. Airborne surveys from 2009 and 2019 (panel a) are shown as white dashed lines. The red star in the inset in panel (a) marks the location of Thwaites Glacier in the Amundsen Sea Embayment. The two yellow stars in panel (b) mark the locations of GPS and barometric pressure records used for tidal analysis (AMIGOS stations). The red and blue arrows in panel (c) indicate the pathways of warm Circumpolar Deep Water and cold ice-shelf melt water (Wåhlin et al., 2021). Coordinates in an Antarctic polar stereographic projection (EPSG:3031).

The airborne data we used were collected using the Multichannel Coherent Radar Depth Sounder (MCoRDS, Paden et al., 2010, updated 2018) in 2009, and a 600-900 MHz accumulation radar in 2019 (CReSIS, 2020). The ice base was picked from a series of synthetic aperture radar-processed radargrams in a semi-automated fashion. Where ice is grounded on the seafloor, a change in the strength of the basal radar reflection occurs (Schroeder et al., 2016). From the surveys on Thwaites Glacier, only two transects cross the edges of the pinning point in 2009 and only one crosses its central part in 2019. Figure 2 shows two airborne radar transects that reveal a heavily crevassed ice base, suggesting that the Eastern Ice Shelf is far from reaching an equilibrium with the underlying ocean system. If basal melting underneath the floating ice were homogeneous, the ice geometry would be expected to be more uniform (Jordan et al., 2020).

We compare ice thickness from airborne radar measurements over the pinning point to two bathymetry data sets: gravity-derived bathymetry for the Thwaites ice shelves of Jordan et al. (2020) and BedMachine Antarctica Version 2 (Morlighem, 2020). Directly subtracting these bathymetry estimates from the height of the ice base across the pinning point results in average differences of  $200 \pm 49$  m and  $-150 \pm 82$  m, respectively. We attribute these differences to the original gravity inversions not being constrained with the radar ice thickness at this isolated location. We therefore fit a quadratic plane to these differences and vertically adjust the bathymetry where ice is grounded. As a result of this adjustment, the mismatches between estimated and observed bathymetry are reduced to  $0 \pm 13$  and  $-74 \pm 121$  m, respectively (Fig. S1). Because of the large residual error in the BedMachine bathymetry for the eastern portion of the pinning point, we only use the adjusted bathymetry map that is based on Jordan et al. (2020) for further calculations outlined below.

## 2.2 Tidal corrections

Ocean tides as well as the elastic deformation of the Earth's crust underneath the moving water masses (referred to as load tides) influence ice-shelf surface elevation. The predictions of two tide models were validated with available GPS records from the Eastern Ice Shelf: the regional barotropic Circum-Antarctic Tidal Solution (CATS2008) model developed by Padman et al. (2008) and the fully global barotropic assimilation model (TPX09) from Oregon State University developed by Egbert and Erofeeva (2002). Tidal loading is regarded in TPX09, and was added to the CATS2008 model predictions. In addition to the tidal oscillation underneath the floating ice, a 1 hPa increase of barometric pressure on the ice surface causes an isostatic -1 cm response of the ice shelf (Padman et al., 2003). To correct for this inverse barometric effect, we used barometric pressure measured by an automatic weather station (AWS) on Thurston Island (approx. 500 km away across the Amundsen Sea). We validate this record with separate barometric pressure measured on the Eastern Ice Shelf over a 176-day period and find a very good correlation between the measured anomalies ( $R^2=0.94$ ). We note that the Thurston Island AWS also correlates well ( $R^2=0.86$ ) with a much closer AWS located on Bear Island (approx. 200 km away) between 2012 to 2019, before the latter stopped reporting data. The inclusion of the inverse barometric effect does not improve the fit to the GPS data (Fig. S2), suggesting that storm surges and local wind-forced effects on small-basin geometry could be significant (Padman, 2021). The resulting tide correction generally underestimates the vertical displacement measured at the Eastern Ice Shelf within around  $\pm 17$  cm, which is relatively poor compared to the Antarctic-wide accuracy of tide models in coastal areas of about  $\pm 10$  cm (Padman et al., 2002). The inaccuracy of the tidal correction translates to about  $\pm 3$  cm  $\text{yr}^{-1}$  in terms of the derived surface

**Figure 2.** Radargrams from airborne radar surveys (a) in Nov 2009 and (b) in Jan 2019 revealing a heavily crevassed ice-base topography. Transects from the grounded ice (right), across the tidal flexure zone as predicted by an elastic model based on the 2011 grounding line (Rignot et al., 2016) onto large parts of the freely-floating ice shelf and (left) ultimately crossing the pinning point that is buttressing the Eastern Ice Shelf. Colors show the percentage tidal displacement with red areas experiencing the full range of the tidal oscillation, while the remaining areas are subject to tidal ice-shelf flexure. Purple areas are grounded according to the 2011 grounding line for the pinning point and the 2017 main grounding line of Thwaites Glacier. The dashed white line shows flotation height. Grounded areas with surface elevation above flotation height are indicated by black arrows.

lowering rates between 2014 and 2020. We attribute this inaccuracy to either inaccurate tidal constituents in both tide models, errors in the bathymetry used by the tide models, grounding-line location and inaccurate ice-shelf thickness, as well as to insufficient knowledge of the ice-water drag coefficient (Padman et al., 2018).

Along a narrow band oceanward of the grounding line, ice is not freely floating because longitudinal stresses within the ice limit ice-shelf flexure. We numerically model the vertical displacement due to this tidal flexure with the well-known elastic approximation (Holdsworth, 1969; Vaughan, 1995; Schmeltz et al., 2002; Sayag and Worster, 2013) as formulated by Walker et al. (2013):

$$k\mathbf{w}(\mathbf{x}, \mathbf{y}) + \nabla^2 [\mathbf{D}\nabla^2 \mathbf{w}(\mathbf{x}, \mathbf{y})] = \mathbf{q}, \quad (1)$$

$$\mathbf{D} = \frac{E\mathbf{H}(\mathbf{x}, \mathbf{y})^3}{12(1 - \lambda^2)}, \quad (2)$$

$$\mathbf{q} = \rho_{sw} g [A - \mathbf{w}(\mathbf{x}, \mathbf{y})], \quad (3)$$

135 where  $\mathbf{w}(\mathbf{x}, \mathbf{y})$  is elastic vertical deflection,  $\nabla^2$  the 2D Laplace operator and  $k = 5 \text{ MPa m}^{-1}$  a spring constant of the foundation which is zero for the floating part.  $\mathbf{D}$  is vertically integrated ice-shelf stiffness while undergoing tidal bending (Love, 1906, p. 443) with  $E = 1.5 \text{ GPa}$  the effective Young's modulus,  $\mathbf{H}(\mathbf{x}, \mathbf{y})$ , is ice thickness given by BedMachine and  $\lambda = 0.4$  is Poisson's ratio of a Maxwell model (Gudmundsson, 2011) accounting for transverse deformation due to longitudinal strain. The tidal force underneath the floating ice,  $\mathbf{q}$ , is given by the tidal amplitude  $A = 1 \text{ m}$ , the density of ocean water  $\rho_{sw} =$   
 140  $1027 \text{ kg m}^{-3}$  and gravitational acceleration  $g = 9.81 \text{ m s}^{-2}$ . For boundary conditions, we implement a fulcrum at the grounding line ( $\mathbf{w} = 0$ ) and anchor the upstream boundaries of the model domain of the grounded portion rigidly ( $\mathbf{w} = 0, \nabla^2 \mathbf{w} = 0$ ). Generally, the elastic flexure pattern is time-invariant and only dependent on ice-shelf stiffness (Wild et al., 2017). We therefore normalize the finite-element solution for the deflection,  $\mathbf{w}(\mathbf{x}, \mathbf{y})$ , with the applied tidal forcing to derive tide-deflection ratio throughout the area ( $\alpha$ -map, Han and Lee, 2014, Fig. S3). By extracting the  $\alpha$ -value for a given location, tide model output  
 145 from freely-floating parts of the ice shelf can thus be directly scaled to include the effects of 2D elastic tidal flexure near grounding lines (Wild et al., 2019). The computationally expensive task of running the finite-element model over time is thus circumvented. By using the tide-deflection ratio, inaccuracies in the  $\alpha$ -map due to a possibly incorrect ice-shelf stiffness are always smaller than inaccuracies in the utilized tidal forcing. We estimate these within the reported uncertainty of the effective Young's modulus from tiltmeter data elsewhere ( $\pm 0.69 \text{ GPa}$ , Wild et al., 2017) to a maximum of  $\pm 0.08 \text{ m}$ . In areas where ice is  
 150 grounded,  $\alpha$ -values close to or equal zero prevent the application of any tidal correction of GPS and ICESat-2 measurements.

### 2.3 Height above flotation calculation

We use height above flotation as a proxy to assess changes in the degree of grounding. Ice-surface elevations are given by the continent-wide and time-stamped REMA data set (Howat et al., 2019). REMA data in our study area were mostly acquired in 2014 with feathered strip edges in the vicinity of our region of interest where we expect the largest inaccuracies. To detect  
 155 ice-surface elevation change since the acquisition of REMA, we use the ICESat-2 L3A Land Ice Height, Version 3, data set (Smith et al., 2019), which gives absolute ice-surface elevations with under 3 cm vertical and 9 cm horizontal accuracies (Brunt et al., 2019). We removed about 16 % of the ICESat-2 points with the provided quality summary flag. ICESat-2 data in our study region were acquired in 2019/20 and allow us to calculate changes in ice-surface elevation since 2014 when compared to REMA.

160 We first translate ice-shelf surface elevations from both REMA and ICESat-2 data to freeboard by using EIGEN6c4 geoid model (Förste et al., 2014) as the mean sea level. We neglect the effect of mean dynamic topography as it is not directly measurable on the ice-shelf surface and invert freeboard,  $z_f$ , to floating ice thickness,  $\mathbf{H}_f$ , based on hydrostatic equilibrium principles. Here, we take advantage of the two available airborne radar transects and use all traces acquired on the freely-floating part of the Eastern Ice Shelf to derive a single mean ice-column density ( $\bar{\rho}$ ) for this inversion from each of the radargrams  
 165 ( $893 \pm 21 \text{ kg m}^{-3}$  for 2009 and  $871 \pm 10 \text{ kg m}^{-3}$  for 2019/20, respectively). We attribute the decline in mean ice-column density

of the Eastern Ice Shelf to the interplay of a prolonged erosion of dense ice at the ice-shelf base where  $\rho_{ice} = 917 \text{ kg m}^{-3}$ , with an increase of relatively soft snow accumulation over the last decade on the surface where  $\rho_{firn} = 430 \pm 66 \text{ kg m}^{-3}$  from snow-pit measurements. Modelled surface mass balance further supports our observation (Keenan et al., 2021). This trend is independently confirmed by comparing REMA surface elevations and BedMachine ice thickness data from 2014 to  
 170 field measurements on 38 sites using GPS and phase-sensitive radar in the 2019/20 season ( $883 \pm 7$  and  $865 \pm 12 \text{ kg m}^{-3}$ , respectively). On grounded areas including the pinning point, we then directly subtract the adjusted seafloor depths from REMA and ICESat-2 surface elevations to calculate absolute ice thickness,  $H_a$ , in 2014 and 2019/20, respectively. Lastly, the difference between absolute and our hydrostatic ice thickness estimate is calculated and expressed as height above flotation,  $z_f$ :

$$175 \quad z_f = (H_f - H_a) \frac{\rho_{sw} - \bar{\rho}}{\rho_{sw}}. \quad (4)$$

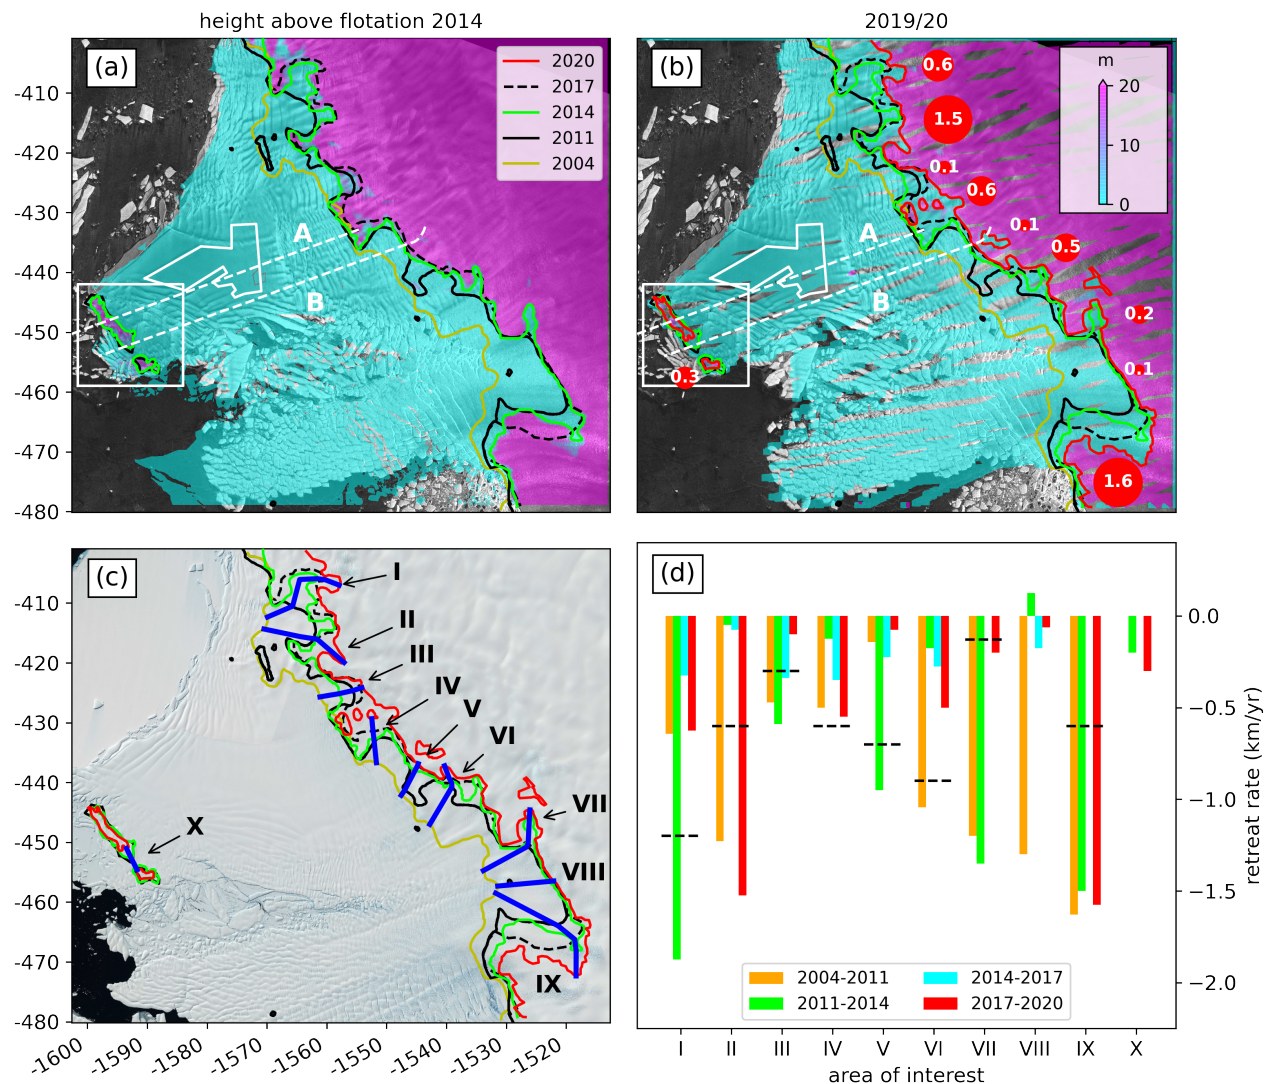

We then use the transition between grounded areas that always feature a positive height above flotation to floating areas ( $z_f = 0$ ), to manually delineate the location of the grounding line in 2014 and in 2019/20. Inaccuracies arising from manually picking the grounding line are estimated to result in an uncertainty in grounding-line retreat rates of  $\pm 0.1 \text{ km yr}^{-1}$ . We calculate retreat rates from comparison with the 2004 grounding line from Bindenschadler et al. (2011), the InSAR-derived 2017 grounding  
 180 lines from Milillo et al. (2019) and, where these are unavailable, such as at the pinning point, with the 2011 grounding line from Rignot et al. (2016).

## 2.4 Lagrangian analysis of surface lowering

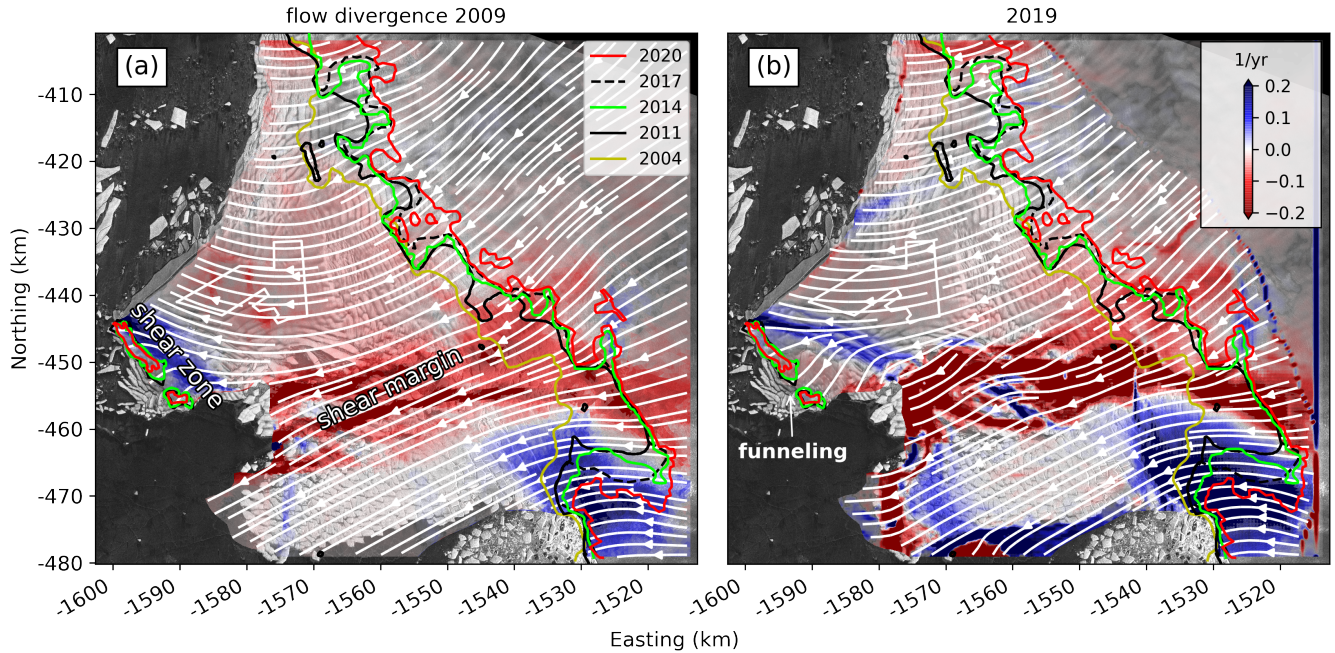

A Lagrangian framework tracks ice parcels with time and thus corrects for the effects of ice-flow advection during change calculation. This is necessary as the uneven ice base of the Eastern Ice Shelf (Fig. 2) combined with relatively fast ice flow  
 185 induces an advection signal that may spuriously be misinterpreted as rapid surface-height change if left uncorrected for. We use the annual velocity field composite from Landsat-8 feature tracking between 2013 and 2020 (Alley et al., 2021, in review) and migrate the ICESat-2 point cloud back in time to where each point would have been when REMA data were acquired. We therefore capture ice-dynamical changes such as an observed counter-clockwise rotation of the ice flow and the associated change in ice-flow divergence in the migration. No seasonality of flow-direction nor any inter-annual change in speed were  
 190 detected in the velocity record. We are confident in the validity of this record and estimate accuracy to  $25 \text{ m yr}^{-1}$ , or 3.5 % of the average flow speed.

We then use the  $\alpha$ -map in combination with tide modeling to correct for elastic tidal flexure as ICESat-2 points acquired at different times migrate along streamlines across the grounding zone. As a result, rates of surface lowering are valid on both grounded and floating ice. We then rasterized the migrated ICESat-2 point cloud using a 2D Gaussian kernel to obtain an  
 195 approximately 68-m resolution map of surface-lowering rates since 2014, when REMA data were acquired. Overall accuracy of these rates is estimated to be the squared sums of errors from REMA, ICESat-2, the applied tidal correction and the accuracy of our velocity record, divided by the 5-6 years of time difference to ICESat-2 data acquisition. This conservative estimate results in an accuracy of the derived surface lowering-rates of  $\pm 1.25 \text{ m yr}^{-1}$  at a maximum, which is well below the detected change

**Figure 3.** Regional changes: Height above flotation from (a) REMA data in 2014 and (b) ICESat-2 surface altimetry data in 2019/20 overlain on a Sentinel 1 SAR image from October 2019. Airborne surveys from 2009 and 2019 (panels a and b) are shown as white dashed lines. Red circles in panel (b) show rates of grounding-line retreat since the last assessment in 2017 (Milillo et al., 2019). Roman numerals in panel (c) refer to areas of interest discussed in the text and are overlain on the Landsat Image Mosaic of Antarctica (Bindshadler et al., 2008). Panel (d) shows histograms of grounding-line retreat rates along the (light blue) profiles in panel (c) in comparison to (dashed black) the InSAR-derived retreat rates between 2011 to 2017 from Milillo et al. (2019). The white rectangle (panels a and b) shows the spatial extent of Figure 5. The white outline shows the area of field operations in the 2019/20 Antarctic season.

**Figure 4.** Ice flow divergence from (a) MEaSUREs data in 2009 and (b) Landsat-8 feature tracking in 2019 overlain on a Sentinel 1 SAR image from October 2019. Blue colors denote flow divergence, red colors flow convergence. Note the upstream migration of the shear zone near the pinning point and the funneling of ice streamlines between the two remaining portions of the pinning point.

signal. We note that uncertainties in REMA are the largest contribution to this accuracy estimate and originate mainly from a narrow area where REMA strip edges have been feathered to form a seamless mosaic. This narrow area lies largely outside of our region of interest (Fig. 6 b), which increases our confidence in accuracy within the boundaries of individual REMA strips.

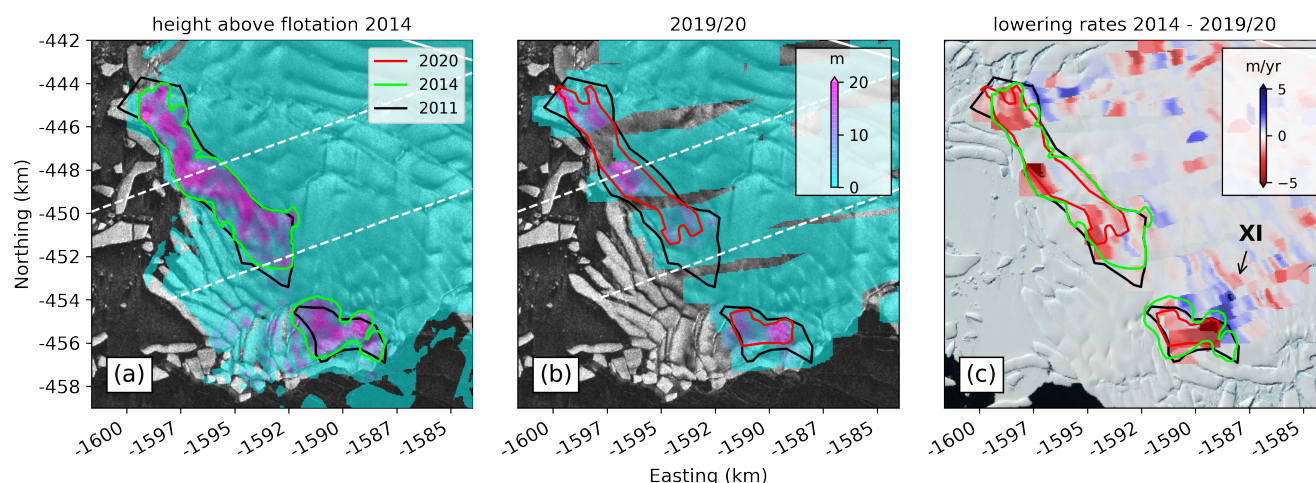

## 2.5 Ice-dynamics modeling

ISSM is a thermo-mechanically coupled model capable of calculating higher-order stress components of ice dynamics that relies on the classical conservation laws of physics such as the balance of stresses and the relative incompressibility of ice. Deforming ice is represented in the model equations with a purely viscous, non-linear rheology following the generalized Glen's flow law (Glen, 1955). Our model simulations employ a depth-averaged flow law parameter with a creep exponent of  $n = 3$ . Where ice is grounded, friction at the ice base exerts a drag force,  $\tau_b$ , opposing the ice flow that is directly proportional to the basal velocity,  $\mathbf{v}_b$  (Cuffey and Paterson, 2010):

$$\tau_b = -\beta^2 \mathbf{N} \mathbf{v}_b, \quad (5)$$

where  $\mathbf{N}$  is the effective water pressure at the ice base given by  $\mathbf{N} = g \mathbf{z}_f$ , which becomes zero for floating ice to eliminate vertical gradients of horizontal velocities within ice shelves.  $\beta$  is the basal friction coefficient, which cannot be measured

**Figure 5.** Close-up of the pinning point area and calculated height above flotation (a) from REMA and (b) ICESat-2 data. (c) Lagrangian rates of surface lowering. Red colours indicate thinning, while blue areas delineate thickening. The green and red lines show the reduced extent of the pinning point as estimated from height above flotation in 2014 and 2019/20, respectively. Map background is a Sentinel 1 SAR image from October 2019, and the Landsat Image Mosaic of Antarctica (Bindshadler et al., 2008). The Roman numeral in panel (c) refers to an area of interest discussed in the text.

directly. On grounded ice, positive values of  $\beta$  thus enable horizontal shear within the ice column, which can be used to infer properties of the bed itself by comparing observed and modeled velocity fields on the ice surface. Here we apply the Shelvesy-Stream Approximation (Morland, 1987; MacAyeal, 1989) to infer  $\beta$  in an inverse step by minimizing the mismatch between  
 215 observed and modeled velocity fields, and solve the stress balance using the Blatter and Pattyn approximation (Blatter, 1995; Pattyn, 2003) to the Full-Stokes equations in a series of diagnostic model runs. The finite-element mesh is optimized using static anisotropic adaptation techniques to provide fine resolution near grounding lines and narrow shear zones as guided by surface velocity fields during model initialisation (Larour et al., 2012).

Two different velocity data sets are compared in our modeling work to invert for  $\beta$  over grounded ice. To compute an  
 220 unperturbed reference state, we use the MEaSUREs product (Rignot et al., 2017), which originates from interferometric synthetic aperture radar data acquired between 2007 and 2009 when the Western Glacier Tongue was largely intact. We compare MEaSUREs with a recent velocity field in 2019, which we derived from Landsat-8 imagery collected after the break-up of the Western Glacier Tongue. The horizontal resolution of the final mesh is 100 m. Bed elevation and ice thickness are prescribed by our adjusted bathymetry and the REMA surface elevation. We set grounded and floating basal melt rates as well  
 225 as modeled thinning rates to zero, because the velocity solution is only a function of instantaneous geometry. For the perturbation experiments, we first delineate the computational domain using visible satellite imagery pre- and post-break-up of the

**Figure 6.** Validation of remote sensing observations with static and kinematic GPS measurements on the Eastern Ice Shelf overlain on a Sentinel 1 SAR image from October 2019: (a) Counter-clockwise rotation of ice flow between 2009 from MEaSURES to 2019 from Landsat-8 feature tracking in comparison with results from a recent GPS repeat survey. The black Landsat-8 vectors have been lengthened by 33 % to increase visibility under the red GPS vectors and are in excellent agreement with the measurements. (b) Comparison between recent Lagrangian rates of surface lowering from a kinematic GPS survey to validate Lagrangian surface-lowering rates derived from ICESat-2 data. Positive values indicate thickening, while negative-value areas delineate vertical thinning. White colours were coded transparent in the ICESat-2 data to highlight the GPS tracks. Tracks were plotted at their migrated locations in 2014. The letters U and D indicate areas of local hydrostatic imbalance, where the ice surface is going up and down, respectively. The dashed white oval shows the location of a spurious thickening signal that we interpret as an artefact from feathering between individual REMA strips.

Western Glacier Tongue, and later modify the grounded mask at the pinning point as guided by our analysis of height above flotation. We note that the diagnostic model does not solve for the temporal evolution of the ice geometry as a response to the applied environmental perturbations, but proves valuable to identify the main drivers behind the observed ice-dynamical changes between the two velocity fields by solving the stress balance.

230

### 3 Results

#### 3.1 Regional grounding-line retreat

Integrating data from airborne radar surveys with the REMA digital elevation model and recent ICESat-2 measurements reveals temporal changes in height above flotation from 2014 to 2020. Grounding-line retreat of Thwaites Glacier is known to be heterogeneous with retreat rates averaging to about  $0.8 \text{ km yr}^{-1}$  and peaking up to  $1.2 \text{ km yr}^{-1}$  between 2011 and 2017 along preferential channels in the bathymetry since the last assessment (Milillo et al., 2019). Our results show continued grounding-line retreat along a 45-km stretch of Thwaites Glacier's grounding line, with sporadically accelerating retreat rates.

While a number of new ice rises emerged during recent deglaciation on bathymetric bumps, several new cavities are forming or have already opened up to the intrusion of seawater. To highlight this heterogeneity we present ten areas of interest that show different retreat patterns (Fig. 3 c and d): (I) Retreat on the Eastern wing of what is referred to as the 'butterfly' region in the literature has slowed down from  $1.2 \text{ km yr}^{-1}$  between 2011 to 2017 to about  $0.6 \text{ km yr}^{-1}$  between 2017 to 2020. The maximum inland reach of its western wing remained stable since 2017 as this cavity is enclosed by a well-grounded bathymetric ridge that is currently preventing further retreat. Height above flotation indicates that the majority of the 'butterfly' region was already floating, or at least close to flotation in 2014, suggesting that ungrounding likely occurred between 2011 and 2014 with retreat rates up to  $1.9 \text{ km yr}^{-1}$ . (II) To the West of the 'butterfly' region, a newly formed cavity is rapidly expanding with retreat rates up to  $1.5 \text{ km yr}^{-1}$  since 2017. Further retreat along this narrow bathymetric low would cut off a newly formed ice rise. However this is unlikely in the near future as the remaining 2.5 km are well grounded with  $z_f > 15 \text{ m}$ . (III) Grounding-line retreat rates within this narrow embayment steadily decelerated since 2011, which is in conjunction with the bed elevation rising in the inland direction as observed in the bathymetry data (Fig. 1 c) and matches the  $0.3 \text{ km yr}^{-1}$  between 2011 to 2017 from Milillo et al. (2019). (IV) A large grounded protrusion at this location has been retreating constantly at an accelerating rate of  $0.4\text{-}0.6 \text{ km yr}^{-1}$  within the central part of the grounding line, and it has now formed three well-grounded ice rises with  $z_f > 18 \text{ m}$ . (V) Here, rapid retreat of  $1 \text{ km yr}^{-1}$  between 2011 to 2014 slowed down to about  $0.1 \text{ km yr}^{-1}$  due to a bathymetric bump. (VI) Similar to area II, a new ice rise will likely emerge within only a few years as the remaining 1.6 km between the current grounding line and an inland bathymetric depression ungrounds at a rate of  $0.5 \text{ km yr}^{-1}$ . (VII) Grounding-line retreat of up to  $0.5 \text{ km yr}^{-1}$  is observed compared to the 2017 grounding line along a cavity that stretches into the main trunk of Thwaites Glacier. However, our analysis of height above flotation reveals that much of this cavity was already close to flotation in 2014, which would change this rate to  $0.8 \text{ km yr}^{-1}$  between 2014 to 2020. Further inland, we detect an isolated area that is already at its level of flotation but is currently shielded from warm water intrusion by a seafloor saddle. (VIII) Here, the grounding line remained almost stable since 2011 due to the locally elevated seafloor that is separating the eastern from the western branch of Thwaites Glacier, feeding into the former Western Glacier Tongue. (IX) Accelerated grounding-line retreat up to  $1.6 \text{ km yr}^{-1}$  along this deep seafloor trough where Thwaites Glacier flows the fastest. (X) Further offshore, where the Eastern Ice Shelf is confined by the pinning point, the two remaining eastern and western portions are separating at an accelerated rate of  $0.3 \text{ km yr}^{-1}$  between 2014 to 2020, compared to  $0.2 \text{ km yr}^{-1}$  between 2011 to 2014.

### 3.2 Changes in ice-dynamics

Here we summarize the relevant processes that directly impact stability of the pinning point. An in-depth study on the history of dynamical changes at both the Eastern Ice Shelf and Western Glacier Tongue during the satellite measurement era is published in Alley et al. (2021, in review).

We use the two velocity fields and detect significant changes in ice-flow divergence over the last decade (Fig. 4). Before the break-up of the Western Glacier Tongue, ice flowed mainly through the calving front to the east. We interpret this as evidence of significant buttressing of the Eastern Ice Shelf through the pinning point. In the years following the break-up of the Western Glacier Tongue in 2009, the ice flow on the main floating part of the Eastern Ice Shelf has (i) rotated counter-clockwise, (ii) streamlines are now funneling through a narrow gap between the eastern and western portions of the pinning point (white streamlines in Fig. 4 b and 8 b), and (iii) the shear zone upstream of the pinning point weakened and migrated up to 10 km upstream. Alley et al. (2021, in review) hypothesize that this counter-clockwise rotation is attributed to the break-up of the Western Glacier Tongue, following years of increased lateral drag.

Along the coast, flow across the eastern half of Thwaites Glacier's grounding line has remained largely unchanged. This indicates the sustained ice-shelf buttressing of this area by the Eastern Ice Shelf. The western half, in turn, exhibits increased absolute values of flow divergence, which is either a result of accelerating ice discharge across the grounding line as the grounded ice is still adjusting to the removal of the Western Glacier Tongue or triggered by reduced ice-shelf buttressing and subsequent new ice divergence because of shrinking of the pinning point.

We validate these remote-sensing observations with ground-truth data from a 12-day GPS repeat-survey collected in the 2019/20 season. GPS data were processed using the Precise Point Positioning kinematic solutions from the Canadian Geodetic Survey (<https://webapp.geod.nrcan.gc.ca/geod/tools-outils/ppp.php>). Errors were estimated from the standard deviation of the solutions. At 38 sites distributed on the freely floating part of the Eastern Ice Shelf, our GPS measurements support the counter-clockwise rotation of the ice flow observed with satellite data from  $89 \pm 8^\circ$  in 2009 to  $101 \pm 6^\circ$  in 2019/20 from east with an average flow direction of  $99 \pm 6^\circ$  in the GPS observation. Simultaneously, average flow velocities at these sites decreased from  $661 \pm 79 \text{ m yr}^{-1}$  in 2009 to  $597 \pm 23 \text{ m yr}^{-1}$  in 2019, which fits well with  $625 \pm 28 \text{ m yr}^{-1}$  of the GPS observation. The spatial distribution of these changes shows that the largest counter-clockwise rotation of ice flow occurred just a few kilometers

upstream of the pinning point, where the ice flow accelerated since 2009 (Fig. 6 a). Because our velocity field derived from  
 290 Landsat-8 feature tracking captures the measured velocity field at these 38 sites within the errors, we trust the validity of  
 satellite-derived streamlines in areas beyond the field survey, such as near the pinning point and the grounding line where a  
 series of rifts and crevasses prevented the collection of further ground-truth data.

### 3.3 Ungrounding of the pinning point

The bathymetry product of Jordan et al. (2020) shows that the elevation of the seafloor ridge on which the pinning point is  
 295 located is  $-498 \pm 72$  m. Airborne radar data from 2009 and 2019 reveal that underneath the eastern portion of the pinning point,  
 the ridge is several hundred meters higher at  $-348 \pm 74$  m when compared to the BedMap2 dataset from Fretwell et al. (2013).  
 The average height above flotation of the eastern pinning point is  $7.6 \pm 6.3$  m in 2019/20 indicating that only modest ice-column  
 thinning is required to detach from the seafloor ridge underneath (Fig. 5).

Rates of surface-height change also reveal a thickening signal upstream of the smaller western portion of the pinning point of  
 300 up to  $5 \text{ m yr}^{-1}$  (area of interest XI in Fig. 5 c). The additional basal shear stress from localized grounding induces compressional  
 stresses, and thus thickening, upstream. A similar thickening signal, although of smaller magnitude ( $3 \text{ m yr}^{-1}$ ) is observed  
 upstream of the eastern edge of the pinning point. Validation of the lowering rates from satellite data with kinematic GPS data  
 acquired within the area of safe field operations in the 2019/20 field season shows a similar pattern as observed with ICESat-2  
 (Fig. 6 b). Differences between the derived lowering rates are  $-0.28 \pm 0.66 \text{ m yr}^{-1}$  with ICESat-2, slightly underestimating the  
 305 GPS measurements. We attribute this small mismatch to moving sastrugi on the ice-shelf surface. We also identify a series of  
 alternating thickening and thinning signals oblique to ice flow, which we interpret as the ice shelf's response to heterogeneous  
 basal melt patterns and subsequent small-scale hydrostatic adjustment.

With the derived information about stability and rate of destabilization of the pinning point, it is possible to estimate when the  
 Eastern Ice Shelf will likely unpin entirely from the seafloor ridge. Average height above flotation on both remaining portions  
 310 of the pinning point is about  $8.0 \pm 6.5$  m (Fig. 5 b). Assuming that average surface-lowering rates between 2014 and 2019/20 of  
 $-0.3 \pm 1.5 \text{ m yr}^{-1}$  persist, it is possible that the pinning point will unground entirely in less than one decade.

### 3.4 Numerical modeling of the ice-shelf response

The basal friction coefficients as derived from the two velocity fields show relatively low to moderate values around 10-100  
 ( $\text{Pa yr/m})^{1/2}$  for the majority of the grounded areas (Fig. S5). This is in general agreement with Full-Stokes inverse modeling  
 315 efforts from Morlighem et al. (2013), with values between 0-50 ( $\text{Pa yr/m})^{1/2}$ . Low basal friction coefficients indicate that  
 sliding over the ice-bed interface is more likely than a no-slip type of internal deformation, when ice is frozen to the bed.  
 Lubricated subglacial conditions, in turn, increase the radar basal reflectivity, which led to the conclusion that much of Thwaites  
 Glacier's bed is thawed (Schroeder et al., 2016). At the pinning point and isolated bathymetric highs along the 2011 grounding  
 line, we significantly increased the basal friction coefficient up to 1000 ( $\text{Pa yr/m})^{1/2}$  to match the satellite observed velocity  
 320 fields. These unrealistically high values were necessary to slow down the modeled ice flow, because the isotropic consideration  
 prevents ISSM from resolving small-scale areas of localized deformation such as in the shear zone just upstream of the pinning

point. In reality, continued straining and fracturing in this area lowers the effective ice viscosity, which reduces longitudinal stresses on the pinning point and thus basal drag.

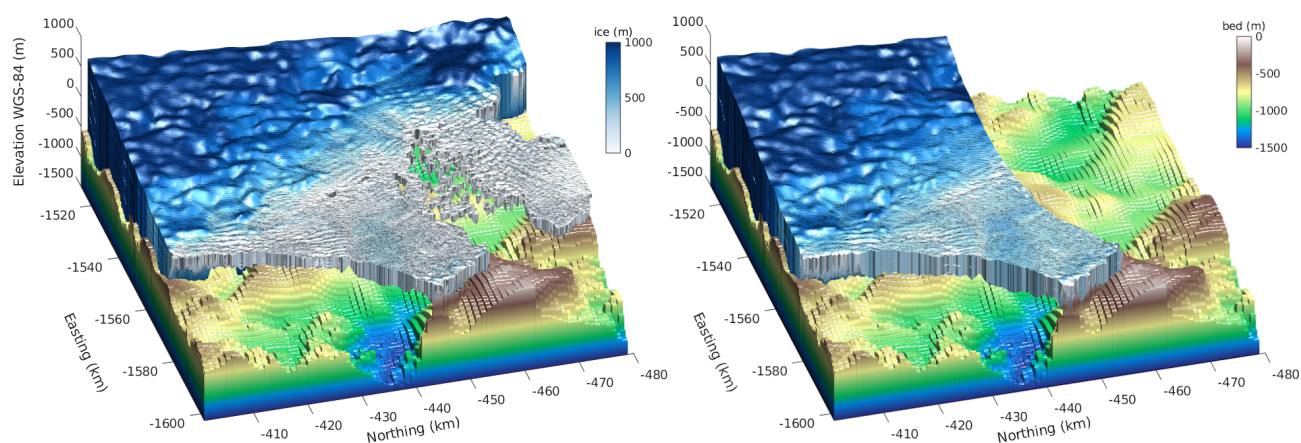

To investigate the effects of the break-up of the Western Glacier Tongue and a vanishing pinning point on the regional ice-  
 325 flow configuration, we use diagnostic model simulations in the Ice-sheet and Sea-level System Model (ISSM, Larour et al., 2012). We note that diagnostic experiments are only informative by using an elimination approach, rather than describing the dynamic ice-shelf response as in a transient experiment. We therefore perform a series of perturbation experiments (Tab. 1) to detect the underlying mechanisms behind the observed changes in ice dynamics: (i) counter-clockwise rotation of the ice flow since break-up of Western Glacier Tongue; and (ii) ice funneling through the two remaining portions of the pinning point. To  
 330 address (i), we run the model with and without the full extent of the Western Glacier Tongue (Fig. 7). Then, (ii) is addressed by reducing the spatial extent of the pinning point as guided by our analysis of height above flotation and comparison with model solutions when the pinning point has its full 2011 extent. Finally, we entirely unpin the Eastern Ice Shelf from the pinning point and recalculate the stress balance to model the regional response of the ice-shelf system on the predicted ungrounding. All other ISSM simulations use the 2011 location of the grounding line.

335 The control run that consists of the MEaSUREs velocity field, a model domain that includes the Western Glacier Tongue, and the full extent of the 2011 pinning point shows that the inversion is successful in finding a basal friction coefficient field that reproduces the observed velocity field (Fig. 8 a). We then remove the Western Glacier Tongue from the computational domain and solve the stress balance again for the modelled velocity field, keeping the basal friction coefficients from the control run. The modeled streamlines are almost perpendicular to the orientation of the pinning point and represent a counter-clockwise  
 340 rotation not observed in the MEaSUREs velocity field (Fig. S4 b). This experiment suggests that the Western Glacier Tongue was still affecting ice dynamics on the Eastern Ice Shelf when data for the MEaSUREs product were acquired. However, relative to the field-acquired GPS vectors (Fig. 6 a), the modeled streamlines slightly overestimate the influence of the Western Glacier Tongue. This is likely a consequence of the model's assumption of an isotropic rheology throughout the computational domain. In reality, weakening due to crevasses and damage within the ice reduces lateral drag along the shear margin between  
 345 the Eastern Ice Shelf and Western Glacier Tongue compared to isotropic poly-crystalline ice.

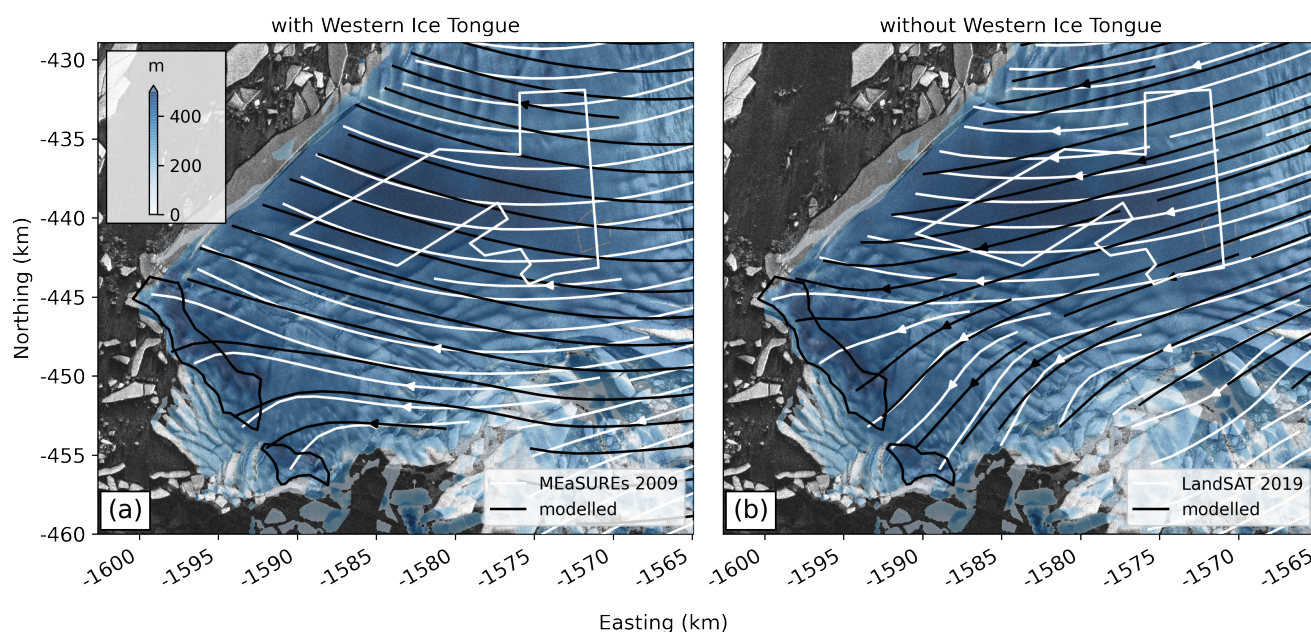

To further test the hypothesis whether the counter-clockwise rotation of ice flow is a consequence of the break-up of the Western Glacier Tongue we repeat the perturbation of removing the Western Glacier Tongue from the model domain but replace the MEaSUREs velocity field from 2009 with our Landsat-8 record from 2019. The modeled streamlines of the second control run miss the counter-clockwise rotation of ice flow that is apparent in the satellite derived streamlines (Fig. S4 c). This  
 350 mismatch is a consequence of including the Western Glacier Tongue in the model domain, which had largely disaggregated before the 2019 velocity field was acquired. The model is thus over-estimating lateral drag across the shear margin between the Eastern Ice Shelf and Western Glacier Tongue, which results in a streamline pattern that is similar to the MEaSUREs-derived flowfield, when the influence of the Western Glacier Tongue on the Eastern Ice Shelf was still strong. This is supported by removing the Western Glacier Tongue from the model domain, which results in modeled streamlines that reproduce the  
 355 Landsat-8 derived ice flow patterns well (Fig. 8 b).

Finally, we investigate the effect of continued weakening of the pinning point on the regional ice flow pattern (simulations e and f) by reducing the spatial extent of the pinning point as guided by our analysis of height above flotation from ICESat-2. This requires modifying the grounded mask in ISSM by designating pixels between the eastern and western portion of the pinning point as floating. ISSM then solves the stress balance again in a diagnostic forward step that is directly compared to the simulation based on the full 2011 extent of the pinning point (simulation c). Differences between the modeled stress balances show increased ice funneling across a narrow bathymetric saddle between the eastern and western portion of the pinning point (Fig. 9 a) that is also evident in visible satellite imagery (Fig. S6). The induced weakening leads to an increase of ice flow velocities that reaches from the floating parts of the Eastern Ice Shelf upstream and across the grounding line. The western half of the Eastern Ice Shelf is more affected than its eastern half, with a mean increase in ice flow velocities of  $130 \text{ m yr}^{-1}$  across the grounding line or about 7.4 % of the 2019 velocity from Landsat-8 feature tracking. Between the two remaining portions of the pinning point, ice velocities almost double with the removal of basal shear stress, underlining the funneling effect between the eastern and western portions of the pinning point. Entire ungrounding from the pinning point (Fig. 9 b) causes a widespread reconfiguration of regional ice dynamics with the Eastern Ice Shelf doubling in speed according to the stress balance. We interpret this as the model's representation of a Western Glacier Tongue-like break-up following the unpinning. Mean ice-flow velocities across the grounding line increase by  $177 \text{ m yr}^{-1}$  corresponding to 9.2 % of the 2019 velocity.

**Figure 7.** ISSM computational domains used for perturbation experiments with and without the Western Glacier Tongue. Note the deep bathymetric trough stretching from the pinning point area far beneath the Western Glacier Tongue. The bathymetry is our adjusted version of the Jordan et al. (2020) product, and ice thickness is derived from hydrostatic principles on floating parts and from differencing the REMA surface elevation with the bathymetry on grounded parts.

**Figure 8.** Comparison between (white) satellite derived streamlines and (black) numerical solutions from ISSM: (a) The situation before the break-up of Western Glacier Tongue in 2009 with a relatively well-grounded pinning point. (b) Removing the Western Glacier Tongue from the model domain, and thus weakening its influence on the Eastern Ice Shelf, reproduces both the observed counter-clockwise rotation of ice flow and the flow divergence around the pinning point as observed in the satellite data. Blue colors correspond to the ice thickness estimate derived in this study.

#### 4 Discussion

Our perturbation experiments confirm our hypothesis that weakening of the lateral shear margin in the years following break-up of the Western Glacier Tongue is the mechanism behind the observed counter-clockwise rotation of ice flow. This rotation is most pronounced closer to the former shear margin with the Western Glacier Tongue, where fast horizontal gradients in ice flow and the associated lateral drag pushed the ice flow on the Eastern Ice Shelf towards the east. Both the observed and modeled deceleration of ice velocity is further supporting this finding, because reduced lateral drag is slowing down ice dynamics at the same time as the Eastern Ice Shelf is dragged forward less by the Western Glacier Tongue. This experiment also shows that the Eastern Ice Shelf has not yet fully decoupled from the influence of the remaining parts of the Western Glacier Tongue; measured streamlines in 2019 still show an eastward deflection of ice flow that is not present in the modeled streamlines that completely decouple the Eastern Ice Shelf from any influence of the Western Glacier Tongue (Fig. 8 b). With continued decoupling of this shear margin in the years to come, it can be expected that the Eastern Ice Shelf will continue to rotate until streamlines align perpendicular to the orientation of the pinning point.

The ISSM experiments further underline the importance of the pinning point on the regional stress balance and thus on  
 385 the ice-flow dynamics on the Eastern Ice Shelf. Although absolute ice velocities have decreased when compared to those  
 in MEaSUREs product for 2009, we attribute the deceleration to weakening of the shear margin with the adjacent Western  
 Glacier Tongue and not to potential regrounding of relatively thicker ice on the pinning point through advection. Continued  
 observations, especially of an increase in ice flow velocities across the bathymetric saddle at the pinning point are necessary to  
 assess the future state of the ice-shelf system, now that the majority of the Western Glacier Tongue's lateral pull on the Eastern  
 390 Ice Shelf has been removed.

Our model results partially contradict a similar perturbation experiment of Nias et al. (2016), which suggested that removal  
 of the pinning point does not substantially decrease ice-shelf buttressing. We attribute this discrepancy to the coarse resolution  
 of previous bathymetry estimates, which underestimated the elevation of the seafloor ridge underneath the pinning point, as  
 well as the depth of the trough underneath the Eastern Ice Shelf. The height of this ridge changed from about -800 to -600 m  
 395 in the BedMap2 dataset (Fretwell et al., 2013) to -400 to -200 m below the WGS-84 ellipsoid in our adjusted bathymetry.  
 For a given surface elevation, halving the ice thickness beneath sea level and thus reducing hydrostatic uplift doubles the  
 corresponding height above flotation and thus the potential of the net buttressing force exerted on the ice shelf. When an ice  
 surface is well above the buoyancy level, a thicker ice column acts as an obstacle to ice-shelf flow. Furthermore ocean tides are  
 less likely to lift the ice and cause ephemeral grounding. For reference, ocean tides within the Amundsen Sea are diurnal and  
 400 reach amplitudes up to  $\pm 1$  m during fortnightly spring tides (our GPS measurements, Padman et al., 2002). Increased ice-shelf  
 buttressing, in turn, stabilizes the location of the grounding line (e.g., Dupont and Alley, 2005) if no other forcings such as an  
 increase in sub-ice-shelf melting or hydrofracturing are exerted.

The shape of the pinning point and its orientation within the flow field is also important to define its role in ice-shelf but-  
 tressing. Streamlined ice rises and rumples provide less stabilization than obliquely oriented grounded areas (Still et al., 2019).  
 405 Although funneling of the ice between the two remaining portions of the pinning point increases lateral shearing, which itself  
 increases the net resistance to ice-shelf flow, shearing also generates rifts, and a preferred crystallographic orientation develops  
 with cumulative strain, such that net resistance decreases compared to initially isotropic poly-crystalline ice (MacAyeal et al.,  
 1998; Hulbe and Fahnestock, 2007; Hudleston, 2015). The magnitude and direction of lateral drag can be calculated using a  
 force budget approach, indicating that effective resistance does not only depend on spatial extent and associated height above  
 410 flotation of the pinning point but also on the properties of the seafloor materials (Still et al., 2019). With a clear upstream thick-  
 ening signal (XI in Fig. 5 c) that we attribute to relative compression preceding the redirection of ice flow around it, the smaller  
 western portion of the pinning point is therefore likely frozen to solid bedrock rather than grounded on softer sediments.

Similarly, the effect of bulk rheological weakening of the ice (through crystal orientation fabric from deformation and  
 damage from fracturing) is not included directly, but integrated into the the derivation of the basal friction coefficient when  
 415 inverting surface velocity fields for basal drag. We have assumed an isotropic rheology throughout the computational domain,  
 while continued straining as well as wide-spread fracturing is clearly present in the study area. As a consequence, our model  
 simulations are incapable of reproducing the observed velocity field within the reported limits of the basal friction coefficient.  
 In reality, localized deformation within the narrow shear zone upstream of the pinning point (Alley et al., 2021, in review) is

likely the source of mechanically weakened ice that is missed in the model simulations. This increases longitudinal stresses  
 420 against the pinning point that the model compensates by a four-fold increase of the basal friction coefficient to slow down the  
 ice. A more sophisticated model that accounts for ice heterogeneity would help evaluate these factors and distinguish their  
 impact on the flow.

Delineating grounding lines from height above flotation is generally considered less accurate than estimates from double-  
 differential interferometric synthetic aperture radar (Brunt et al., 2010). With the absence of temporally-dense SAR data ac-  
 425 quisition that is required by the fast-flowing Thwaites Glacier, only dedicated satellite missions can provide the necessary  
 coherence to allow the application of InSAR (e.g., Milillo et al., 2019). The highly dynamic character of Thwaites Glacier's  
 response to the ongoing destabilization of the ice sheet-shelf system therefore stresses the use of alternative techniques, such as  
 analysis of height above flotation as a proxy for ice-shelf buttressing (Dupont and Alley, 2005). The launch of Sentinel 1c that  
 is currently scheduled for 2022 will provide the necessary temporal resolution to monitor the anticipated dynamical changes on  
 430 Thwaites Glacier. Similarly, tidal oscillations of the grounding line were not captured with ICESat-2's repeat pass of 91 days,  
 which is locally significant in areas where bedrock slopes are shallow, such as along the main trunk of the Western Glacier  
 Tongue (Milillo et al., 2019). Complementing InSAR with height-above-flotation-derived grounding lines allowed us to refine  
 previously published retreat rates. An example is the 'butterfly' region where the reported rapid retreat up to  $1.2 \text{ km yr}^{-1}$   
 between 2011 to 2017 (Milillo et al., 2019) was narrowed down to have occurred mainly between 2011 to 2014. Furthermore,  
 435 the calculation of height above flotation is independent of the presence of tidal surface flexure that is required to delineate  
 grounding lines from the analysis of InSAR data. This enabled us to locate two areas landward of the present-day grounding  
 line, which are already at flotation because of depressions in the bed (Fig. 3 b). Continued retreat across the seafloor saddles  
 that currently prevent the intrusion of seawater into these areas will spark an inland grounding-line jump of up to 3 km.

Although our analysis of changes in height above flotation shows the spatial distribution of grounding-line retreat and surface  
 440 lowering, it does not allow direct conclusions about pathways of warm Circumpolar Deep Water intrusion. New observations  
 collected by an autonomous underwater vehicle reveal that warm water penetrates into the sub-ice-shelf cavity from both sides  
 of the pinning point (Fig. 1 c, Wåhlin et al., 2021). These water masses then converge beneath the Eastern Ice Shelf where a  
 density-driven overturning circulation induces vertical mixing which, in turn, enhances the heat transport from the ocean to the  
 ice base. Cold and freshened meltwater then exits the sub-ice-shelf cavity to the west. This insight highlights the vulnerability  
 445 of the pinning point to non-linear processes, because the eastern branch of warm water intrusion originates in Pine Island  
 Bay where local meteorological conditions drive variability in ocean forcing of Pine Island Glacier (Webber et al., 2017).  
 Basal melting may be pronounced in the vicinity of the pinning point, because the western branch of warm water intrusion is  
 characterized by southward inflow for all depths across the seafloor ridge (Wåhlin et al., 2021). This hypothesis is supported by  
 ice thinning against the ice-flow direction in the airborne radar transects (Fig. 2), as well as local weakening observed in visible  
 450 satellite imagery (Fig. S6). Upstream thinning, in turn, reduces the likelihood of regrounding of thicker ice through advection  
 onto the pinning point.

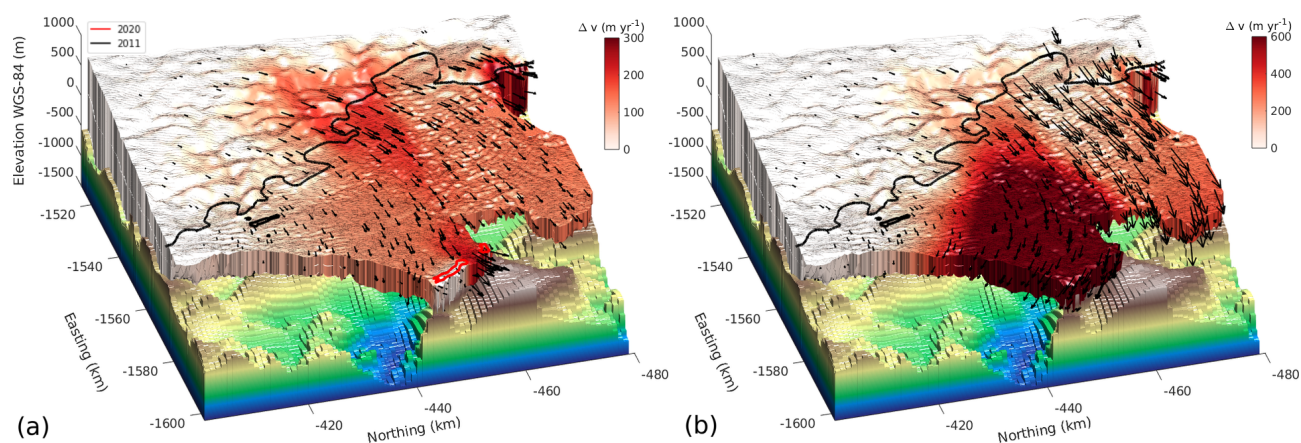

Ocean temperature variability was also linked to the timing of retreat and intermittent re-advance of the Western Glacier  
 Tongue within the last two decades (Miles et al., 2020). A period of extremely warm ocean temperatures coincides with rapid

acceleration of the Western Glacier Tongue between 2006 to 2012, followed by cooler ocean temperatures during deceleration  
 455 between 2012 to 2015. Miles et al. (2020) hypothesize that this intermittent slow down is due to strengthening and re-advance  
 of the shear margin with the Eastern Ice Shelf and is not linked to regrounding of thicker ice on former pinning points. Our  
 analysis of height above flotation in 2014 supports their hypothesis, because we do not observe re-grounding near the ice edge  
 of the Western Ice Tongue in REMA (Fig. 3 a). Since 2016 the shear margin has weakened, causing rapid acceleration and  
 wide-spread break-up of the Western Glacier Tongue to an ice-mélange that is bound together by landfast sea ice. A large  
 460 tabular iceberg, named B-22a, which calved off the Western Glacier Tongue in 2002 and is since caught on the seafloor in the  
 Thwaites embayment, might control the persistence of sea ice in this area and thus the integrity of the remainder of the Western  
 Glacier Tongue (Miles et al., 2020). Removal of this iceberg and subsequent loss of landfast sea ice is not only likely to modify  
 regional ocean circulation, but an open-water regime would also allow the seasonal inflow of solar-heated surface water that  
 increase basal melting (Stewart et al., 2019).

465 Our analysis of height above flotation shows that ungrounding of the pinning point is possible within a decade, if the average  
 surface-lowering rates from ICESat-2 between 2014 to 2020 continue linearly. Although the Eastern Ice Shelf might retain  
 contact to its pinning point for up to three decades at its maximum height above flotation of >20 m, the present nonlinear  
 processes such as the advection of structurally weak ice onto the pinning point and feedback mechanisms involving oceanic  
 variability in the Amundsen Sea might accelerate this trend. Entire unpinning of the Western Glacier Tongue from a peak on  
 470 the seafloor ridge between 1996 (Rignot, 2001) and 2011 (Rignot et al., 2016) preceded its break-up from a structurally-intact  
 ice tongue to a mélange of smaller fractured icebergs. We therefore see the break-up of the Western Glacier Tongue as an  
 analog for the time post-unpinning of the Eastern Ice Shelf.

**Figure 9.** The effect of sustained ungrounding between the two remaining portions of Thwaites pinning point on regional ice dynamics, as modeled with ISSM. The black line shows the 2011 grounding line. (a) The red line shows the spatial extent of ungrounding and is guided by our analysis of height above flotation from ICESat-2. Note the funneling of ice over the bathymetric saddle and the increase in ice flow velocities on the Eastern Ice Shelf and further upstream. (b) Modelled acceleration following the entire ungrounding of the Eastern Ice Shelf from the pinning point.

## 5 Conclusions

We present two maps of height above flotation to assess changes in structural stability of the Eastern Ice Shelf between 2014 and 2019/20 by integrating ICESat-2 altimetry data with recent airborne radar surveys. The results show asymmetric grounding-line retreat along the coast accompanied by vigorous expansion of newly formed cavities around a series of emerging ice rises sitting on local seafloor highs. The largest retreat rates of up to  $1.5 \text{ km yr}^{-1}$  are found within rapidly retreating narrow cavities. The pinning point that is currently constraining the Eastern Ice Shelf has separated into a quickly destabilizing eastern portion and a smaller, but structurally stronger western portion as concluded from a pronounced upstream ice thickening signal.

Guided by airborne radar data, our estimate of the height of the seafloor ridge that comprises the pinning point is several hundreds of meters higher than in previously published data sets. This emphasizes the role of the pinning point in buttressing of Thwaites Glacier and will help to improve models used to predict its retreat and sea-level contributions.

Since the break-up of the Western Glacier Tongue in 2009, the ice flow on the Eastern Ice Shelf has slowed down, rotated counter-clockwise, and now funnels through a bathymetric saddle between the two remaining portions of Thwaites pinning point. Model simulations using ISSM reproduce this counter-clockwise rotation of ice flow with the removal of Western Glacier Tongue from the stress balance and attribute the satellite-observed ice funneling to weakening of the pinning point and opening of the saddle. Given current rates of surface lowering from ICESat-2 laser altimetry data in this area, in combination with the advection of thinner and mechanically damaged ice upstream, Thwaites pinning point will reach flotation within less than one decade with implications for the stability of the Eastern Ice Shelf and thus the whole Thwaites Glacier.

Compared to other proposed scenarios of ice-shelf break-up in the near future, such as cracking through the central part of the Eastern Ice Shelf or failure along rifts within the narrow shear zone upstream of the pinning point, our analysis strongly supports that unpinning of the Eastern Ice Shelf from the seafloor ridge and subsequent loss of its structural integrity as a short-range mechanism for break-up. We conclude that unpinning within the next decade is possibly the most likely scenario of regional destabilization, followed by break-up similar to the Western Glacier Tongue. Following other ice shelf disintegration events (e.g., Scambos et al., 2004; Rack and Rott, 2004) we expect increased ice discharge along a 45-km stretch of the grounding line thereafter.

*Data availability.* Data sources are referenced in the text.

*Author contributions.* CTW led data analysis, modelling and writing. KEA derived the velocity records from feature tracking and assisted in analysis of ICESat-2 and REMA data. AM guided the bathymetry model adjustment. MT processed GPS data. TAS and ECP assisted in data analysis and design of the study. All authors conducted field work, contributed to writing and approve the final manuscript.

*Competing interests.* The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

*Acknowledgements.* We would like to acknowledge the tireless commitment of the rest of the TARSAN on-ice team Bruce Wallin, Douglas Fox, Dale Pomraning and our field guides Cecelia Mortensen and Blair Fyffe. We thank John Paden for assistance with the airborne radar data and acknowledge the use of data products from CReSIS generated with support from the University of Kansas, NASA Operation IceBridge grant NNX16AH54G, NSF grants ACI-1443054, OPP-1739003, and IIS-1838230, Lilly Endowment Incorporated, and Indiana METACyt Initiative. We also thank Laurie Padman for discussions regarding tidal analysis. The authors appreciate the support of the University of Wisconsin-Madison Automatic Weather Station Program for the data set, data display, and information (NSF:Grant 1924730). This work is from the TARSAN project, a component of the International Thwaites Glacier Collaboration (ITGC). Support from National Science Foundation (NSF: Grant 1929991) and Natural Environment Research Council (NERC: Grant NE/S006419/1). Logistics provided by NSF-U.S. Antarctic Program and NERC-British Antarctic Survey. ITGC Contribution No. ITGC-045. CTW also thanks Wolfgang Rack for providing access to the COMSOL Multiphysics finite-element software. Editor and reviewers later.
