## 20 **Abstract**

21 Thermokarst lake dynamics, which play an essential role in carbon release due to permafrost  
22 thaw, are affected by various geomorphological processes. In this study, we derive a three-  
23 dimensional (3D) Stefan equation to characterize talik geometry under a hypothetical  
24 thermokarst lake in the continuous permafrost region. Using the Euler equation in the calculus  
25 of variations, the lower bounds of the talik were determined as an extremum of the functional  
26 describing the phase boundary area with a fixed total talik volume. We demonstrate that the  
27 semi-ellipsoid geometry of the talik is optimal for minimizing the total permafrost thaw under  
28 the lake for a given annual heat supply. The model predicting ellipsoidal talik geometry was  
29 verified by talik thickness observations using transient electromagnetic (TEM) soundings in  
30 Peatball Lake on the Arctic Coastal Plain (ACP) of northern Alaska. The width-depth ratio of the  
31 elliptical sub-lake talik can characterize the energy flux anisotropy in the permafrost, although  
32 the lake bathymetry cross section may not be elliptic due to the presence of near-surface ice-rich  
33 permafrost. This theory suggests that talik development deepens lakes and results in more  
34 uniform horizontal lake expansion around the perimeter of the lakes while wind-induced waves  
35 and currents are likely responsible for the elongation and orientation of shallow thermokarst  
36 lakes without taliks in certain regions such as the ACP of northern Alaska.

## 37 **1. Introduction**

38 Thermokarst lakes are abundant in regions underlain by ice-rich permafrost including the Arctic  
39 Coastal Plain (ACP) of northern Alaska, northwestern Canada, and Siberia (Grosse et al., 2013;  
40 Jones et al., 2022). These lakes are formed due to permafrost degradation, and their basin  
41 evolution is fundamentally different from lakes formed in temperate and tropical regions.  
42 Thermokarst lakes affect the thermal regime of the surrounding permafrost, which controls the  
43 geomorphology and evolution of the lake basin (Brewer, 1958). If the lake bed has a mean  
44 annual temperature greater than 0 °C, the sub-lake permafrost will begin to thaw (Burn, 2002; Arp  
45 et al., 2016). This typically occurs in lakes that are deeper than the maximum winter ice  
46 thickness, where the ice cover floats above an unfrozen water layer (Jeffries et al., 1996; Burn,  
47 2002). In this case, unfrozen lake bed sediments persist, and the thaw front continues to  
48 penetrate deeper into the underlying permafrost. This results in a “talik”, or a perpetually  
49 unfrozen zone confined by permafrost, beneath the lake depending on local anomalies in  
50 thermal, hydrological, hydrogeological, or hydrochemical conditions (van Everdingen, 1998). In  
51 ice-rich permafrost, the conversion of ice to water with thaw causes a volumetric reduction in the  
52 unconsolidated material, and the lake bed consequently subsides significantly increasing the  
53 depth of initial basins (Czudek and Demek, 1970; Jorgenson and Shur, 2007; Shur and  
54 Osterkamp, 2007; Jorgenson, 2013; French, 2018). The total depth of thaw subsidence is  
55 determined by the amount and distribution of excess-ice content in the permafrost with depth. As  
56 the lake expands by lateral thermo-mechanical erosion of the banks, mineral and organic  
57 sediments from retreating shores are delivered to the lake basin (Farquharson et al., 2016).  
58 However, thaw-induced ground subsidence effectively deepens the basin, so volumetric capacity

59 can increase over time. Over decades and centuries, the talik increases in thickness, and lake bed  
60 subsidence continues as long as the thawing permafrost is ice-rich (West and Plug, 2008).

61 In certain ice-rich permafrost regions in the Arctic, there is a preferential orientation and elliptic  
62 shape to the thermokarst lakes (Black and Barksdale, 1949; Hinkel et al., 2005; Grosse et al.,  
63 2013). In particular, elliptical oriented lake districts are found predominantly along the central  
64 north Siberian coast, northern Alaska and in northwest Canada (Grosse et al., 2013). On the  
65 ACP of northern Alaska, many elliptical thermokarst lakes have a long axis oriented 10–20  
66 degrees west from true north, which is nearly perpendicular to the prevailing wind direction  
67 (Carson, 1968; Sellmann, 1975; Carter, 1981). Hinkel et al. (2005, 2012) also showed  
68 significant correlation between lake orientation and summer wind direction by analyzing the  
69 geometric shape metrics of the thermokarst lakes and drained thermokarst lake basins (DTLB)  
70 on the ACP of Alaska. It has been proposed that winds at the lake surface cause currents and  
71 water waves, which trigger thermomechanical bank erosion, resulting in asymmetrical elliptical  
72 orientation (Livingstone, 1954; Rex, 1961; Carson and Hussey, 1962; Mackay, 1992; Arp et al.,  
73 2011). The sublittoral shelves and bars typically found in the deeper thermokarst lakes may also  
74 be formed by wind-driven currents and waves, and warmer water temperatures (Carson and  
75 Hussey, 1962). The axis-oriented sublittoral shelves make the orientation appear more  
76 pronounced in larger basins. Other processes also influence the orientation of thermokarst lakes  
77 such as historical drained lake geometry, ground ice distribution, and dune ridge orientation by  
78 aeolian sand transport (Carter, 1981).

79 Several numerical models have been proposed and applied that describe permafrost thaw for the  
80 purpose of analyzing water and carbon cycles (e.g., Kessler et al., 2012). However, Schuur et al.  
81 (2015) stress the need to better represent talik formation and geometries to parameterize

82 numerical models more effectively. Painter et al. (2016) demonstrated a coupled  
83 surface/subsurface permafrost thermal hydrology model at the multiple ice-wedge polygon scale.  
84 Kessler et al. (2012) simulated carbon mobilization over 10,000 years on two neighboring thaw  
85 lakes located on ice- and organic-rich Yedoma permafrost terrain (Kanevskiy et al., 2011;  
86 Schirrmeister et al., 2013) in the northern Seward Peninsula, Alaska using a 3D numerical  
87 thermal model. They demonstrated the effectiveness of model simulations for methane emission  
88 from thermokarst lakes. Ling and Zhang (2003b) provided a numerical parametrization of lake  
89 talik development and showed that shallow thermokarst lakes are a significant heat source  
90 affecting permafrost and talik geometries. Rowland et al. (2011) advanced the technique by  
91 including advective heat transport on talik evolution. West and Plug (2008) and Plug and West  
92 (2009) characterized the lake bathymetry including the effects of lake ice and littoral shelves.  
93 These thermal models use long-term mean lake temperature as the Dirichlet boundary condition  
94 and a uniform annual mean temperature profile as the initial condition. Analytical and numerical  
95 models can provide dynamic solutions for the heat transfer equation under quasi-steady state  
96 climate conditions. However, the existing models require prescribed lake shapes (circle or  
97 ellipse) to obtain information on talik depths as opposed to modeling the likely influence of talik  
98 evolution on lake shape – this work, in part, attempts to address this shortcoming.

99 Direct drilling measurements of taliks below thermokarst lakes are difficult to obtain and only  
100 exist in a few rare case studies (Brewer, 1958; Johnston and Brown, 1966; Roy-Leveillee and  
101 Burn, 2017; Heslop et al., 2015). Geophysical methods can be used (e.g., Schwamborn et al.,  
102 2000; Parsekian et al., 2019; Creighton et al., 2018; Sullivan et al., 2021; O’Neill et al., 2020);  
103 however, it is time consuming and laborious to produce 3D subsurface images at the large scale  
104 of lakes found in permafrost lowland regions. Since field measurements (coring, geophysics,

105 etc.) are spatiotemporally limited, numerical and analytical modelling is used to gain critical  
106 insights into talik evolution. Mackay (1962) obtained the analytical vertical temperature profiles  
107 below the water at the center of a circular lake by analytically solving the heat transfer equation.  
108 Burn (2002) subsequently extended the solution for an elongated lake. This analytical model has  
109 been used for lake process characterization because the quasi-steady state model was able to  
110 reasonably quantify the talik thickness. For example, Hinkel and Arp (2015) applied the  
111 temperature profile to 2100 lakes and found that larger, long-lived lakes (more than 66 ha) may  
112 have taliks that penetrate through the permafrost (open taliks) to the ground-water system below  
113 in a region with permafrost that is up to 600 m thick.

114 These existing models require the prescribed lake shapes (circle or ellipse) to obtain the talik  
115 depth; in fact, no existing studies explicitly provide an answer to the fundamental question: why  
116 do thermokarst lakes tend to be elliptical and/or round? Also, in spite of several decades of  
117 research focused on the orientation of thermokarst lakes in certain regions, no existing studies  
118 explicitly explain why thermokarst lakes in some regions orient perpendicular to the prevailing  
119 wind direction. The objective of this work is to implement a novel mathematical framework that  
120 concurrently describes both the oriented nature of the thermokarst lakes and the talik depth  
121 below the lakes. Previous models have calculated the talik development due to heat flow, though  
122 most use some simplifying assumptions to reduce dimensionality. Separately, researchers have  
123 hypothesized about elliptical lake morphology by invoking winds, currents, and erosion. Here,  
124 we couple both the talik evolution and lake shape questions together in a single mathematical  
125 model. Additionally, we intend to use this theory to demonstrate that the thermal gradient could  
126 exert control on the depth/width ratio of the talik. In other words, the proposed theory aims to  
127 isolate the most important process – sub-lake permafrost thaw and subsidence – from other

128 effects such as wind-wave erosion, thaw slumping, sediment redistribution and incoming  
129 radiation imbalance, using thermally optimized lake geometry.

## 130 **2. Theory**

### 131 **2.1 Basin integrated energy equation**

132 The approach used in this study is based on Lagrangian mechanics, which generalizes the  
133 classical Newtonian mechanics, using the stationary action principle (the principle of least  
134 action). The action is defined as the integral of the Lagrangian, which consists of kinetic and  
135 potential energy of the system. In this application, the Lagrangian simply becomes the potential  
136 energy due to absence of kinetic energy. The variational principle that is the main tool in  
137 Lagrangian mechanics can indeed derive the equations in Newtonian mechanics. One of the  
138 related research topics using the variational principle to fluid mechanics is phase boundary  
139 propagation, which can be analyzed by the phase field model or diffusion-interface model  
140 (Cassel, 2013). This model explains the diffuse phase boundary without surface tension that  
141 appears in Newtonian interfacial physics between a liquid and a gas. According to the second  
142 law of thermodynamics, the free energy of the system must decrease monotonically to ensure a  
143 non-negative entropy production (Singer-Loginova and Singer, 2008). This requires that the time  
144 rate of change of the phase boundary be expressed by the functional derivative of the free energy  
145 functional, which corresponds to the talik total energy flux in relation to permafrost thaw. This  
146 study directly and analytically solves the Euler-Lagrange equation based on the stationary action  
147 principle rather than the entropy functional used in the phase field method.

148 Heat energy collected by a waterbody is used for phase boundary expansion as well as heat  
149 conduction into the adjacent permafrost (e.g., French, 2018). From the energy balance equation

150 around the phase boundary, the energy for permafrost thaw is expressed as the subtraction of  
 151 heat conduction from the input energy at the phase boundary (Carslaw and Jaeger, 1959; Patel,  
 152 1968; Lunardini, 1981). The material of permafrost and talik is assumed to be fully saturated  
 153 with ice and water, respectively. Also, the thermal constants (thermal conductivity, latent heat,  
 154 and thawing temperature) are constant and isotropic, and the change in volume of water on  
 155 thawing and freezing is negligible. Under such assumptions, the energy conservation equation at  
 156 the phase boundary can be expressed as,

$$157 \quad \phi v \rho L = q_{suf} - k_L \frac{dT}{dn} - \left( -k_p \frac{dT}{dn} \right) \quad , \quad (1)$$

158 where  $\phi$  is volumetric water content ( $\text{m}^3/\text{m}^3$ );  $v$  is thaw rate or advancement of talik boundary  
 159 (m/s);  $\rho$  is density of water ( $\text{kg}/\text{m}^3$ );  $L$  is latent heat for ice thaw (liquid-solid) ( $\text{J kg}^{-1}$ );  $q_{suf}$  is  
 160 additional heat input from ground surface around the lake shore ( $\text{W}/\text{m}^2$ );  $k_L$  is thermal  
 161 conductivity of unfrozen soil ( $\text{W}/(\text{m}\cdot\text{C})$ ); and  $k_p$  is thermal conductivity of frozen soil  
 162 (permafrost) ( $\text{W}/(\text{m}\cdot\text{C})$ );  $T$  is temperature ( $\text{C}$ ); and  $n$  is outward normal from the interface into  
 163 the soil (m). The energy terms can be grouped into heat for permafrost thaw,  $q_{th}$  ( $\text{W}/\text{m}^2$ );  
 164 incoming heat at the phase boundary  $q_{in}$  ( $\text{W}/\text{m}^2$ ); and outgoing heat by conduction to the  
 165 permafrost  $q_{out}$  ( $\text{W}/\text{m}^2$ ). These heat fluxes can be evaluated by the following formulas:

$$166 \quad q_{th} = \phi v \rho L \quad , \quad (2)$$

$$167 \quad q_{in} = q_{suf} - k_L \frac{dT}{dn} \quad , \text{ and} \quad (3)$$

$$168 \quad q_{out} = -k_p \frac{dT}{dn}. \quad (4)$$

169 When heat input from the surface is consumed for phase change without any loss ( $q_{out} = q_{suf} =$   
170 0), the well-known Stefan equation can be obtained from Equations (1) through (4) under the  
171 quasi-steady state approximation (Stefan, 1891; Kurylyk & Hayashi, 2016). This study also  
172 adopts the quasi-steady state approximation for the talik shape characterization.  
173 As the thawing process is direction-dependent, it is convenient to use vector notation (Figure 1).  
174 That is,

$$175 \quad \mathbf{q}_{th} = \mathbf{q}_{in} - \mathbf{q}_{out} \quad . \quad (5)$$

176 A vector is denoted by a bold letter. The talik expansion flux vector corresponds to thaw  
177 direction, which is affected by the other two heat fluxes. Figure 1 illustrates the thermal profiles  
178 around the thaw lake in warm and cold seasons. The horizontal near-surface heat conduction is  
179 influenced by the seasonality of the surface heat budget while the vertical heat conduction under  
180 the lake remains unidirectional throughout the years. Clearly, the presence of the thaw lake  
181 considerably alters the heat environment of the permafrost while the temperature slope at the  
182 bottom of the permafrost may be approximated by the geothermal gradient in regions with thick  
183 continuous permafrost such as the ACP. This directionality in the heat environment around the  
184 lake may cause anisotropic talik expansion. Here, the phase change heat vector is expressed as  
185 proportional to the normal heat input  $q_{in}$ , as follows:

$$186 \quad \mathbf{q}_{th} = (q_{th,x}, q_{th,y}, q_{th,z}) = (\xi q_{in}, \eta q_{in}, \zeta q_{in}) = q_{in}(\xi, \eta, \zeta) \quad (6)$$

187 where  $q_{in}$  is the input heat normal to the phase boundary,  $\xi, \eta,$  and  $\zeta$  are the thaw energy  
188 fractions of the heat input normal to the phase boundary with respect to x, y, and z directions,  
189 respectively. The depth of the phase boundary (m) ,  $z = \varphi(x, y)$ , may be expressed as an  
190 arbitrary 3D surface as,

191 
$$g(x, y, z) = \varphi(x, y) - z = 0. \quad (7)$$

192 Hence, the normal vector  $\mathbf{n}$  at any location on the phase boundary  $g$  can be written as follows:

193 
$$\mathbf{n} = \frac{\nabla g}{|\nabla g|} = \frac{1}{|\nabla g|} (g_x, g_y, g_z) = \frac{1}{\sqrt{\varphi_x^2 + \varphi_y^2 + 1}} (\varphi_x, \varphi_y, -1) \quad (8)$$

194 where the subscript in this expression denotes partial derivative (e.g.  $\varphi_x = \partial\varphi/\partial x$ ) and  $\nabla$  is a  
 195 vector differential operator ( $\partial/\partial x, \partial/\partial y, \partial/\partial z$ ). As such, the vector of the input heat to the  
 196 phase boundary  $\varphi$  is

197 
$$\mathbf{q}_{in} = |\mathbf{q}_{in}| \mathbf{n} = q_{in} \mathbf{n} = \frac{q_{in}}{\sqrt{\varphi_x^2 + \varphi_y^2 + 1}} (\varphi_x, \varphi_y, -1), \quad (9)$$

198 and the corresponding thaw heat vector is,

199 
$$\mathbf{q}_{th} = \frac{q_{in}}{\sqrt{\varphi_x^2 + \varphi_y^2 + 1}} (\xi\varphi_x, \eta\varphi_y, -\zeta). \quad (10)$$

200 Next, the thaw heat magnitude can be evaluated using a Euclidian norm as,

201 
$$|\mathbf{q}_{th}| = \frac{q_{in}}{\sqrt{\varphi_x^2 + \varphi_y^2 + 1}} \sqrt{\xi^2\varphi_x^2 + \eta^2\varphi_y^2 + \zeta^2} = \frac{\zeta q_{in}}{\sqrt{\varphi_x^2 + \varphi_y^2 + 1}} \sqrt{\alpha_x^2\varphi_x^2 + \alpha_y^2\varphi_y^2 + 1} \quad (11)$$

202 where

203 
$$\alpha_x = \frac{\xi}{\zeta}, \quad \alpha_y = \frac{\eta}{\zeta}. \quad (12)$$

204 The parameters  $\alpha_x$  and  $\alpha_y$  (unitless ratio) describe the anisotropic thermal condition between  
 205 horizontal and vertical directions. The parameters  $\alpha_x$  and  $\alpha_y$  are greater than one when the  
 206 vertical temperature gradient is steeper than in horizontal gradient. The total thaw energy over  
 207 the lake can be computed by the area integral on the phase boundary  $\Gamma$ . That is,

$$\begin{aligned}
208 \quad \int_{\Gamma} |\mathbf{q}_{th}| d\Gamma &= \iint_B |\mathbf{q}_{th}| \sqrt{\varphi_x^2 + \varphi_y^2 + 1} dx dy \\
209 \quad &= \zeta q_{in} \iint_B \sqrt{\alpha_x^2 \varphi_x^2 + \alpha_y^2 \varphi_y^2 + 1} dx dy. \quad (13)
\end{aligned}$$

210 This expression indicates that the heat required for lake expansion is proportional to the weighted  
211 phase boundary area with the weights  $\alpha_x$  and  $\alpha_y$ .

## 212 **2.2 Optimum phase boundary shape**

213 The calculus of variation, often referred to as a functional analysis, is the mathematical technique  
214 to find an extremum (minimum or maximum) of the system in terms of a function type instead of  
215 a variable (e.g., Courant and Hilbert, 1954; Gelfand and Fomin, 1963). Thermally optimum  
216 function types  $\varphi(x, y)$  of the phase boundary can be derived using this method. As presented in  
217 the previous section, the heat consumption rate for talik expansion is represented by the weighted  
218 phase boundary area while the time-integrated heat supply is equivalent to the thawed permafrost  
219 volume. Assuming heat thaws the most susceptible region of the permafrost near the heat source  
220 first, the shape of a talik may minimize the total permafrost thaw with a given amount of  
221 incoming energy. In other words, as the free energy of the system must decrease monotonically  
222 to ensure a non-negative entropy production (the second law of thermodynamics), the optimum  
223 talik shape should minimize the phase boundary area for a specified talik volume. The weighted  
224 phase boundary area  $A$  and its volume  $V$  can be expressed as follows:

$$225 \quad \begin{cases} V[\varphi] = \iint_B \varphi dx dy \\ A[\varphi] = \iint_B \sqrt{\alpha_x^2 \varphi_x^2 + \alpha_y^2 \varphi_y^2 + 1} dx dy \end{cases} \quad (14)$$

226 To obtain the optimum talik shape, the functional  $F$  is formulated using the method of Lagrange  
227 multipliers as,

228 
$$F[\varphi] = \lambda V[\varphi] + A[\varphi] = \iint_B (\lambda \varphi + \sqrt{\alpha_x^2 \varphi_x^2 + \alpha_y^2 \varphi_y^2 + 1}) dx dy \quad (15)$$

229 where  $\lambda$  is the Lagrange multiplier. The minimum of the functional  $F$  can be determined for  $\lambda <$   
 230 0 because both  $V$  and  $A$  are monotonic functions. Let

231 
$$f(\varphi, \varphi_x, \varphi_y) = \lambda \varphi + \sqrt{\alpha_x^2 \varphi_x^2 + \alpha_y^2 \varphi_y^2 + 1}. \quad (16)$$

232 Equation (15) becomes,

233 
$$F[\varphi] = \lambda V[\varphi] + A[\varphi] = \iint_B f(\varphi, \varphi_x, \varphi_y) dx dy. \quad (17)$$

234 Note that this functional can be interpreted as the Lagrangian of the system. Therefore, to find  
 235 the extremal phase-boundary shape  $\varphi$  that minimizes the functional  $F[\varphi]$ , the Euler-Lagrange  
 236 equation can be formulated as,

237 
$$\frac{\partial f(\varphi, \varphi_x, \varphi_y)}{\partial \varphi} - \frac{\partial}{\partial x} \left( \frac{\partial f(\varphi, \varphi_x, \varphi_y)}{\partial \varphi_x} \right) - \frac{\partial}{\partial y} \left( \frac{\partial f(\varphi, \varphi_x, \varphi_y)}{\partial \varphi_y} \right) = 0. \quad (18)$$

238 Substituting Equation (16) to (18) yields,

239 
$$\lambda - \frac{\partial}{\partial x} \left( \frac{\alpha_x^2 \varphi_x}{\sqrt{1 + \alpha_x^2 \varphi_x^2 + \alpha_y^2 \varphi_y^2}} \right) - \frac{\partial}{\partial y} \left( \frac{\alpha_y^2 \varphi_y}{\sqrt{1 + \alpha_x^2 \varphi_x^2 + \alpha_y^2 \varphi_y^2}} \right) = 0. \quad (19)$$

240 By analogy to two-dimensional application in Ohara and Yamatani (2019), an ellipsoid is one of  
 241 the solutions of Equation (19), as follows:

242 
$$z = -\varphi = -\sqrt{\frac{4}{\lambda^2} - \frac{x^2}{\alpha_x^2} - \frac{y^2}{\alpha_y^2}} + d, \text{ or} \quad (20)$$

243 
$$\left( \frac{x}{\frac{2\alpha_x}{|\lambda|}} \right)^2 + \left( \frac{y}{\frac{2\alpha_y}{|\lambda|}} \right)^2 + \left( \frac{z-d}{\frac{2}{|\lambda|}} \right)^2 = 1. \quad (21)$$

244 Detailed alternative derivation using isoperimetric inequality is available in the Appendix A. The  
 245 coefficients  $d$  and  $\lambda$  can be determined by further variational analysis explained in Appendix B.  
 246 As such, Equations (20) and (21) become

$$247 \quad \varphi = \sqrt{D^2 - \frac{x^2}{\alpha_x^2} - \frac{y^2}{\alpha_y^2}}, \text{ and} \quad (22)$$

$$248 \quad \left(\frac{x}{\alpha_x D}\right)^2 + \left(\frac{y}{\alpha_y D}\right)^2 + \left(\frac{z}{D}\right)^2 = 1, \text{ respectively.} \quad (23)$$

249  $D$  is the talik center depth,  $\alpha_x$  &  $\alpha_y$  are the cross-sectional aspect ratios. Hence, the semi-  
 250 ellipsoidal geometry of the phase boundary (i.e., the boundary between the permafrost and talik)  
 251 was explicitly derived as a thermally optimum shape based on the variational principle using the  
 252 thermal quasi-steady state approximation. As the Stefan equation describes the phase boundary  
 253 depth (active layer depth or frost depth) under a uniform and flat landscape, the solution of the  
 254 Euler-Lagrange equation (Equation 22) is the 3D Stefan Equation for the talik beneath a  
 255 thermokarst lake.

### 256 **2.3 Thermokarst lake bathymetry and phase boundary geometry**

257 When top-down permafrost thaw dominates the process, the thermokarst lake bottom shape  
 258  $\psi(x, y)$  may be similar to the phase boundary shape, as illustrated in Figure 2. However, the  
 259 lake bathymetry can be related to the permafrost degradation rate  $r_{deg}$  (ratio; m/m) defined as,

$$260 \quad r_{deg} = \frac{D_{thaw}}{D_{frzn}} \sim 1 - \frac{\psi(x,y)}{\varphi(x,y)} \sim 1 - \frac{H}{D}, \quad (24)$$

261 where  $H$  and  $D$  denote the water depth and the talik thickness at the lake center, respectively.

262  $D_{frzn}$  is the frozen soil thickness (m) and  $D_{thaw}$  is the corresponding thawed soil thickness depth  
 263 (m), which is strongly dependent on the excess ground ice content; excess ice is defined as the

264 volume of ice in the ground, which exceeds the total pore volume that the ground would have  
265 under natural unfrozen conditions (van Everdingen, 1998). Therefore, thaw settlement is  
266 typically computed from excess-ice content and the thickness of the layer with excess ground  
267 ice. However, as the consolidation settlement effect, which is a function of void ratio and  
268 effective stress, may not be separated, we use the simple permafrost degradation rate (Equation  
269 24) in this study.

270 If the permafrost degradation rate is uniform and constant throughout the basin (Panel A:  
271 uniform permafrost in Figure 2), the lake bathymetry tends to be an ellipsoid shape. However, as  
272 the ice-rich layer is typically developed near the surface on the ACP (e.g., Kanevskiy et al.,  
273 2011, 2013), the bathymetry may have a flatter bottom like a rectangular cross section (Panel B:  
274 layered permafrost in Figure 2) because the ice-rich layer is characterized by much higher thaw  
275 settlement than the ice-poor permafrost at depth. Therefore, proportionality between talik  
276 thickness and lake water depth is unlikely reasonable assumption due to the ice-rich layer  
277 presence. Indeed, Hinkel et al. (2012) showed many flat-bottomed lakes through the extensive  
278 bathymetry surveys across the ACP of Alaska using a GPS-enabled sonar from a boat.

279 Additionally, as hydrology also affects the lake water level, the apparent lake bathymetry or lake  
280 water depth,  $h(x, y)$  must be adjusted by the water loss (or gain) per unit area. Therefore,

$$281 \quad h(x, y) = [1 - r_{deg}] \varphi(x, y) - H_{loss} , \quad (25)$$

282 where  $H_{loss}$  (m) is the elevation difference between the current water surface and original ground  
283 surface before lake formation. At the lake center,

$$284 \quad H = [1 - r_{deg}] D - H_{loss} . \quad (26)$$

285 Thus, the thermokarst lake bathymetry is affected by the ice-rich layer thickness, interannual  
286 water balance, lake age, and talik geometry.

### 287 **3. Case study**

#### 288 **3.1 Study area**

289 Peatball Lake (70°42.40N, 153°55.50W; 3 m above sea level) on the ACP of Alaska was chosen  
290 for the demonstrative model application in this study as it has been relatively well documented in  
291 previous studies (Lenz et al. 2016; Creighton et al., 2018; Parsekian et al., 2019). Figure 3 shows  
292 the location of Peatball Lake within the Teshekpuk Lake subregion, as well as other subregions  
293 that will be discussed later.

294 Peatball Lake, named for the abundant submerged peat balls on the lake bed, is a subcircular lake  
295 on the Outer Coastal Plain of Alaska with a surface area of 1.18 km<sup>2</sup>. Permafrost in this area is as  
296 thick as ~400 m (Jorgenson et al., 2008), and the average volumetric ground ice content is about  
297 77% in the near surface to a depth of 4 m (Kanevskiy et al., 2013). A talik has formed under  
298 Peatball Lake because the maximum water depth of 2.5 m exceeds the maximum winter ice  
299 thickness of 1.5 to 2.0 m (Arp et al., 2015; Lenz et al., 2016). The talik depth was estimated as  
300 91 m at the lake center based on noninvasive TEM measurements (Creighton et al., 2018).  
301 However, the talik may not be present beneath the shallow sublittoral shelves on the western  
302 shore determined from the bathymetry (Lenz et al., 2016). Additionally, Lenz et al. (2016)  
303 reported that, based on remote sensing imagery, Peatball Lake has expanded laterally between  
304 0.02 and 1.36 m/year from 1955 to 2002.

### 305 **3.2 Geophysical survey of talik**

306 Geophysical field methods are effective for identifying and visualizing the frozen-unfrozen  
307 interface, which is a key feature in permafrost dynamics (e.g., Pilon et al., 1985; Doolittle et al.,  
308 1990; O’Neill et al., 2020; Rangel et al., 2021). For sub-lake taliks in the continuous permafrost  
309 zone, Schwamborn et al. (2000) analyzed the sedimentary history of Lake Nikolay in the western  
310 Lena River Delta using seismic reflection and ground penetrating radar (GPR). Other  
311 geophysical methods such as surface nuclear magnetic resonance (NMR) can be used to detect  
312 lake taliks (Parsekian et al., 2019) and remnant taliks in drained lake basins (Rangel et al., 2021).  
313 At Peatball Lake, Creighton et al. (2018) estimated the talik depth using transient  
314 electromagnetic (TEM) surveys along transects perpendicular to lakeshores. The dataset at  
315 Peatball Lake is, to our knowledge, the only quasi-3D talik model available under an isolated  
316 lake in the continuous permafrost zone because others are mostly sporadic talik depth  
317 measurements at single drill points.

318 We applied the derived 3D Stefan equation to Peatball Lake based on 27 talik thickness point  
319 measurements across the lake (Figure 4), estimated using TEM soundings (Creighton et al.,  
320 2018) during spring 2016 and 2017. Figure 4 shows the observed talik thicknesses by the TEM  
321 sounding (dots) and the fitted theoretical talik thickness estimates (contour lines) superimposed  
322 over the corresponding lake bathymetry measured by Lenz et al. (2016).

323 The geometric parameters of the semi-ellipsoid model such as the talik center depth ( $D$ ), the  
324 cross-sectional aspect ratios ( $\alpha_x$  &  $\alpha_y$ ), lake orientation azimuth angle and the lake center  
325 location were systematically determined by grid searching to minimize the root mean square  
326 difference (RMSD) between the model and thaw front obtained from the TEM data. The

327 optimum parameters for the smallest RMSD (5.94 m) are shown in Figure 4. Unexpectedly, the  
328 basin orientation angle was found to be 23 degrees east from true north, unlike the orientation of  
329 other surrounding lakes in the region. Comparison between the extrapolated talik geometry and  
330 the lake bathymetry (Lenz et al., 2016) suggests the possibility of coalescence of two basins in  
331 the past; a relatively common occurrence on the ACP of Alaska. However, if we had more TEM  
332 measurement points, particularly in the “possible talik sub-basin”, the fitted talik geometry could  
333 be different as the model was only fitted for the 27 TEM soundings. Lake taliks tend to have a  
334 semi-ellipsoidal shape, at least locally, as indicated by the very good fit of the elliptic model to  
335 the TEM measured talik thicknesses (see Figure 4 with overall RMSD = 5.94 m). The idealized,  
336 thermally optimum model geometry can be used to analyze lake formation history of the  
337 irregular talik associated with multi-generation lakes such as Peatball Lake.

338 Additionally, the gaps between the shoreline and the modeled talik extent located along north  
339 and east shores occur where lake expansion is most rapid (Lenz et al., 2016). It has been  
340 reported that thaw lake banks continuously retreat through a combination of thermal and  
341 mechanical processes, although there is significant variability in rate of bank retreat depending  
342 on region (Hopkins, 1949; Hopkins et al., 1955; Tomirdiaro, 1982; Rampton, 1982; Burn and  
343 Smith, 1990; Jones et al. 2011, Lenz et al., 2016). Cross-sectional numerical thermal models  
344 demonstrated that the expansion rates are affected by the talik thickness (Plug and West, 2009)  
345 and seasonal snow cover (Ling and Zhang, 2003a). The disagreement between the lake and talik  
346 extents on the north and east shores of Peatball Lake implies that rapid horizontal lake expansion  
347 can locally dominate permafrost thaw and subsidence processes even in a lake with a talik.

348 Figure 5 compares the observed lakebed and talik profiles in Peatball Lake along the north-south  
349 center line and along transects (b) – (c), respectively. Note that the TEM transects for the talik is

350 not a straight line (See Figure 4); therefore, the fitted theoretical line shows irregularity. Figure  
 351 5A illustrates that the lakebed profile is characterized by flatter trapezoidal geometry compared  
 352 to the elliptic talik. In fact, there is a clear inflection in the linear regression line at a talik depth  
 353 of ~50 m in Figure 5B. From the slopes of the regression lines, the permafrost degradation rates  
 354  $r_{deg}$  are computed as 97.3 % and 99.7 % for the shallow talik section (50 m or less) and the deep  
 355 section (50 m or more), respectively. This analysis suggests that the subsidence due to  
 356 permafrost thaw continues even after the shallow ice-rich part of the permafrost (about 4 meters,  
 357 Kanevskiy, 2013) is thawed while it has diminished around the depth of 50 meter under Peatball  
 358 Lake. This case study demonstrates a link between lake bathymetry and talik thickness  
 359 associated with a layered permafrost structure.

### 360 **3.3 Depth-width ratio and temperature gradient**

361 The analysis (Equations 22 & 23) suggests the proportional relationship between lake/talik  
 362 geometry and thaw energy. That is,

$$363 \quad a : b : D = \alpha_x : \alpha_y : 1 = \xi : \eta : \zeta = q_{f,x} : q_{f,y} : q_{f,z} \quad . \quad (27)$$

364 Combining Equations (27), (1) and (4), the depth-width (radius) ratio of the talik may be written  
 365 as follows:

$$366 \quad a : D = \left( q_{in,x} + k_p \frac{dT}{dr} \right) : \left( q_{in,z} + k_p \frac{dT}{dn} \right) \quad (28)$$

367 where  $r$  and  $n$  are the horizontal and vertical distances from the original permafrost surface  
 368 center, respectively, and  $a$  is the representative horizontal radius of the lake. This expression  
 369 states that the anisotropic top-down permafrost thaw is caused by anisotropy of the thermal  
 370 gradient for uniform incoming energy and uniform thermal properties of near surface

371 permafrost. For example, since the vertical thermal gradient is typically steeper than the  
 372 horizontal gradient during the critical summer months (Carson and Hussey, 1962; illustration in  
 373 Figure 1), the heat energy in the vertical direction is used more for heat conduction rather than  
 374 permafrost thawing. The vertical temperature gradient is always negative near the talik  
 375 boundary in the permafrost ( $\frac{dT}{dn} < 0$ ) at the center of the lake while the inter-seasonal average  
 376 of the horizontal thermal gradient may be negligible ( $\frac{dT}{dr} \approx 0$ ) (McClymont et al., 2013; Devoie  
 377 et al., 2021). Assuming the normal heat flux to the phase boundary is uniform throughout the  
 378 phase boundary surface ( $q_{in,x} = q_{in,z} = q_{in}$ ), Equation (28) can be simplified as follows:

$$379 \quad \frac{D}{a} = 1 + \frac{k_p}{q_{in}} \frac{dT}{dn} \quad , \text{ or } \quad q_{in} = -\frac{ak_p}{a-D} \frac{dT}{dn} \quad . \quad (29)$$

380 This simple expression may be a useful tool to link the lake depth-width ratio, the lake average  
 381 heat flux  $q_{in}$ , and the vertical temperature gradient  $\frac{dT}{dn}$  at the base of the talik. Since  $\frac{dT}{dn} < 0$  in  
 382 the permafrost near the talik boundary, the  $D/a$  is always less than 1 (flatter than a semi-sphere).  
 383 However, the depth-width ratio of the talik depends on the vertical temperature slope near the  
 384 talik boundary, which is likely affected by talik age. For instance, Mackay's analytical model  
 385 (1962) suggests that the vertical temperature gradient below the lake center begins steeply at the  
 386 talik initiation, and then over time it approaches a lower slope at equilibrium. Therefore, the  
 387 formula in Equation (29) suggests that a younger talik should be flatter while an older talik  
 388 approaches a deeper semi-spheric shape ( $D/a \rightarrow 1$ ).

389 Table 1 shows the estimated incoming heat flux with the key parameters using the proposed  
 390 formula (Equation (29)). Creighton et al. (2018) applied the CRYOGRID2 model (Westerman et  
 391 al., 2013) to Peatball Lake. The temperature slope at the talik bottom at the lake center was

392 estimated by the Mackay's analytical model assuming the lake age of 1400 years since the talik  
393 initiation with the same model configuration Creighton et al. (2018) adopted. Creighton et al.  
394 (2018) estimated the interannual mean heat flux  $q_{in}$  to be 0.070 (W/m<sup>2</sup>), which is very close to  
395 our estimate. As this simplified formula is consistent with the well-configured modeling result,  
396 the horizontal thermal gradient contribution to the vertical aspect ratio of the talik seems to be  
397 very small in Peatball Lake.

398 Moreover, this relationship may be useful to incorporate the three-dimensional talik expansion  
399 effect in a simple analysis without fully integrated permafrost thermal modeling. For example, if  
400 the mean energy flux increases 10 percent from current climate conditions (e.g., shorter lake  
401 freeze period), assuming all other properties and horizontal thermal gradient variation are equal,  
402 the talik depth-width ratio  $D/a$  would shift from 0.171 to 0.234 toward the new equilibrium state.  
403 Therefore, this analysis suggests that a warmer climate may promote permafrost thaw in the  
404 vertical direction more than in the horizontal direction. Hence, it is important to quantify the  
405 vertical thawing as well as the visible lake horizontal expansion in order to evaluate the impact  
406 of the climate change on permafrost thaw beneath thermokarst lakes.

## 407 **4. Discussion**

### 408 **4.1 Relationship between hypothetical models**

409 To illustrate the applicability of the thermal model presented here, the available hypothetical  
410 models of thermokarst lake growth are compiled in Figure 6. This diagram focuses on the  
411 physical processes after the lake initiation stage assuming the bio-ecological effects are  
412 negligible.

413 Figure 6 illustrates the evolution of the talik in ice-rich permafrost over time, with driving  
414 processes shown in the right panel. In Stage A, the mechanical processes of wave erosion and  
415 thaw slumping along lake margins dominate lake expansion in summer, and shallow water favors  
416 grounded lake ice in the winter. In time (Stage B), the lake deepens from thaw subsidence  
417 beneath the older lake center. Winter ice may freeze to the lake bed, but heat loss is insufficient  
418 to freeze the underlying thawed lake bed sediments. A shallow talik develops as thermal  
419 processes work in tandem with mechanical processes, the latter now enhanced by more vigorous  
420 lake circulation. By Stage C, the talik is well developed beneath the entire lake basin as ground  
421 subsidence continues. Eventually (Stage D), the winter ice cover no longer extends to the lake  
422 bed, but instead floats atop a residual pool of lake water, while milder vertical temperature  
423 gradient beneath the lake deepens the talik as the lake matures. Thermomechanical erosion of  
424 lake margins, especially if there are prominent banks in hilly terrain, promotes sedimentation on  
425 near-shore shelves, and the underlying talik may begin refreezing. If the lake hasn't drained by  
426 this point (Stage E), the talik beneath the lake center extends deeper into the permafrost although  
427 subsidence may cease as the excess ice content diminishes with depth. Where many large, old  
428 lakes exist, the permafrost may be riddled with deep taliks, and some may eventually penetrate to  
429 the permafrost base to create an open talik.

430 Talik development is affected by climatic and local conditions that favor talik initiation and  
431 growth including:

- 432 • Deepening lake waters triggered by greater precipitation and/or reduced evaporation,  
433 which promotes a floating ice regime
- 434 • Presence of ice-rich sediments (e.g., Yedoma) beneath lakes
- 435 • Warmer lake water induced by regional warming or by longer ice-free summers

436 • Thinner winter ice cover due to warmer winter temperatures and/or deeper snow

437 Conversely, talik growth cessation or contraction can occur when the same drivers are reversed,  
438 if the lake partially or completely drains, or when the lake basin is filled with sediments. The  
439 latter scenario is more likely in hilly terrain when the expanding lake erodes high banks and lake  
440 currents redistribute sediments.

## 441 4.2 Thermal process and preferential expansion

### 442 4.2.1 Lake geometry and heat balance

443 The analytical expression of the lake geometry may be useful to analyze horizontally oriented  
444 lakes with direction dependent elongation as well. From Equation (27) and (1), we have,

$$445 \quad a: b = q_{f,x}: q_{f,y} = (q_{in,x} - q_{c,x}): (q_{in,y} - q_{c,y}), \quad (30)$$

446 where  $a$  and  $b$  are the semi-major and -minor axes of the elongated lake, respectively. When  
447 horizontal heat conduction into the tundra is negligible, ( $q_{c,r} = k_p \frac{dT}{dr} \approx 0$ ), this equation can be  
448 reduced to,

$$449 \quad a: b = q_{in,x}: q_{in,y}. \quad (31)$$

450 Hence, the aspect ratio of elliptic lakes can be explained by heat supply inequality if the lake  
451 geomorphology process is dominated by thermal process. As expressed in Equation (3), there are  
452 two different components in the incoming heat flux to the lake banks: surface energy flux and  
453 heat conduction from the lake water body. Thus, the lake aspect ratio may be written as,

$$454 \quad a: b = \left( q_{suf,x} - k_L \frac{dT}{dx} \right) : \left( q_{suf,y} - k_L \frac{dT}{dy} \right) \quad (32)$$

#### 455 **4.2.2 Incoming radiation imbalance effect**

456 One of the incoming surface energy flux inequalities  $q_{surf}$  may be caused by shortwave radiation  
457 along the lake shoreline. The daily potential solar irradiation on a sloping surface can be  
458 computed by the trigonometric function (e.g., Equation B.11 in DeWalle and Rango, 2008). The  
459 total daily radiation is a function of latitude and bank slope angle, which depends on the  
460 permafrost degradation rate, the maturity of the talik, and ground ice distribution.

461 Figure 7 shows the computed mean daily potential solar irradiation on the sloping lakeshore ( $I'_q$ )  
462 relative to a flat surface ( $I_q$ ) during the summer period (June-August) at three different latitudes.  
463 The shape of this diagram may correspond to the shape of a thermokarst lake as the enhanced  
464 radiation results in more permafrost thaw. The difference in relative incoming radiation will  
465 diminish as bank slope angle lessens. In general, the south facing slope along the northern shore  
466 tends to receive more radiation than the north facing slope (e.g., Séjourné et al., 2015). This  
467 tendency is more pronounced in lower latitude zones due to the higher mid-day sun angle.

468 It is interesting that at 65 and 60 degree latitude the north and south facing banks receive slightly  
469 less radiation than east and west facing slopes, while an opposite result occurs at 70 degree  
470 latitude (Figure 7). Therefore, the radiation imbalance may partially explain the north-south  
471 elongation along the 70 degree latitude line and the west-east elongation of lower latitude (60-65  
472 degrees) of lowland thermokarst lakes shown by Grosse et al. (2013, Figure 19). However,  
473 because these small differences in incoming radiation imbalance alone are insufficient to result  
474 in the distinctive lake elongation in the ACP, they likely introduce rather minor additional  
475 complexities in lake spatial shape.

### 476 **4.3 Wind wave erosion and preferential expansion**

477 Wind wave erosion plays an important role in horizontal expansion of shallow lakes because  
478 waves can undercut the vegetated bank (Hopkins, 1949). Wind waves make the water bodies  
479 (e.g., lakes and bays) round by local net sediment flux even in low latitude regions (e.g., Ashton  
480 et al., 2009). The effect of waves on shoreline morphology has been analyzed in the coastal  
481 engineering field: for example, Silvester (1974) investigated the equilibrium shape of bays under  
482 different wave conditions using laboratory wave experiments and found that the stable beach in  
483 the bay adapted a half-heart or cardioid shape for a fixed wave direction in the absence of  
484 sediment supply. Reeve et al. (2018) showed theoretically that the equilibrium coastline shape  
485 can be expressed as a diffusion type equation through incorporating the wave diffraction effect,  
486 which makes the wave crest line nearly parallel to the shore. However, according to the shallow  
487 water wave theory, which is applicable for small fetch distances on lakes in the ACP, water  
488 waves do not cause any sediment transport without current, although wave motion is a key factor  
489 for the mobilization of the sediment (e.g., Carson and Hussey, 1962).

490 Wind-induced water circulation in a shallow, oval lake was perhaps first analyzed by  
491 Livingstone (1954) who showed theoretically that the current around the lake ends may be  
492 accelerated efficiently by wind-induced return rip currents. However, the lake water circulation  
493 pattern assumed in his study (shown in the left side of Figure 8) was less common than the  
494 pattern described by Carson and Hussey (1962), who observed reverse circulation patterns near  
495 the lake ends, as shown in the right side of Figure 8. For convenience, we refer to two distinctive  
496 current patterns: the Livingstone type and the Carson & Hussey (C&H) type. C&H type  
497 circulation can indeed explain the commonly observed peat and sediment bars near the leeward  
498 lake side shores. Carson and Hussey (1962) noted that sedimentation on the leeward lake side

499 can provide protection from mechanical wave erosion as well as insulation from permafrost  
500 thaw, which result in lake elongation. They also observed that preferential bank erosion is  
501 typically focused in zones oriented 50 degrees to wave approach. The return flow was found to  
502 concentrate around the windward lake side, which accelerates the mechanical erosion and  
503 sediment transport at the lake ends. However, the Livingstone type circulation might occur  
504 depending on the local wind field as it can explain the sublittoral shelf formation on the  
505 windward shore. In either case, the wind-induced current effect on lake elongation can be  
506 supported by Livingstone's theory (1954) which should be valid for both circulation types. Thus,  
507 the combination of wind wave mobilization and lake water circulation is the most accepted  
508 hypothesis for lake elongation during the relatively young shallow lake expansion stage (Carson,  
509 1968; Arp et al., 2011, Hinkel et al., 2012).

510 The shallow wave theory states that the sediment mobilization due to wind wave only occurs in  
511 shallow water (wave height  $>4\%$  of water depth, e.g., Reeve et al., 2018). Therefore, the  
512 contribution of the wind wave effect to lake elongation may be reduced as the lake deepens.  
513 Figure 9 shows a plot of lake length:width ratios versus the percent of lakes with a bedfast ice  
514 regime in seven study regions in Alaska determined with satellite-based synthetic aperture radar  
515 imagery (Engram et al., 2018). The study regions represent differences in permafrost  
516 characteristics and climate that appear to be reflected in this comparison of length:width ratio  
517 and the percent of lakes in a region that freeze to their bed and thus likely do not have a sub-lake  
518 talik. For example, lakes in the Teshekpuk Lake and Kuparuk study areas have a shape that is  
519 nearly twice as long as it is wide. In both of these regions, more than 80% of the lakes freeze to  
520 their bed and likely do not have a talik. This is contrast to lakes located near Umiat and on the  
521 Seward Peninsula, that have primarily developed in Yedoma permafrost deposits. Lakes near

522 Umiat and on the Seward Peninsula tend to be more circular ( $L:W = 1.3$  to  $1.4$ ) and more than  
523 90% likely have a talik since they do not freeze to their bed in the winter. The differences  
524 observed here relative to elongation of lakes and whether the region primarily has lakes that  
525 freeze to their bed or not likely demonstrates a key aspect related to the role of wind-wave  
526 erosion. In general, the shallower lakes common in coastal areas, such as Teshekpuk, Barrow,  
527 and Kuparuk, are more elongated likely due to wind wave erosion. Whereas lakes in Umiat (ice-  
528 rich permafrost), Seward Peninsula (ice-rich permafrost), and Inigok (ice-poor permafrost) tend  
529 to be rounder because of talik development and the presence of deeper lakes (on the order of 10-  
530 20 m in some instances). This remote-sensing based evidence implies that the wind effect seems  
531 to be limited by the lake thermal subsidence due to sub-lake talik development, while shallow  
532 lakes with the bedfast ice may continue elongating by wind erosion.

#### 533 **4.4 Applicability of the 3D Stefan equation**

534 The limitations of the derived 3D Stefan Equation (Equation 22) are summarized in this section  
535 along with Figure 6. Once a seasonal pond is formed on the permafrost, it primarily expands  
536 horizontally by wind wave erosion and the thaw slump process (Livingstone, 1954; Carson &  
537 Hussey, 1962; Rex, 1961; Hinkel et al., 2012, Grosse et al., 2013) because the active layer  
538 beneath the pond likely freezes every year. On the flat ACP of Alaska, lake thaw slumps tend to  
539 be the result of topography (e.g., slope and aspect of the ground surface) while lake elongation is  
540 likely caused by wind wave erosion. As described above, preferential bank thaw at the lake ends  
541 can be explained by the insulation effect of the sediments carried by the water current (likely, the  
542 C&H type circulation) because the sublittoral shelf may be initiated at this stage.

543 When seasonal thawing penetrates more deeply than the annual freezing depth, a talik may be  
544 initiated, typically around the deepest point near the center of the lake (Lachenbruch et al. 1962).  
545 Sellmann (1975) described this process, which is one of the mechanisms for shelf formation in a  
546 thermokarst lake. For the horizontal expansion stage, A in Figure 6, the proposed quasi-steady  
547 state thermal model may not be appropriate because the lakeshore expansion imbalance occurs at  
548 least minimally throughout the lake expansion process. However, the 3D Stefan equation may  
549 be able to characterize the talik in the initiation stage B in Figure 6.

550 Once the talik is established, the 3D Stefan's thermal model proposed here suggests that the talik  
551 may begin to influence lake geometry. Since sediment mobilization due to wind-driven waves  
552 occurs in shallow water, lake elongation by waves may diminish as the lake deepens via ground  
553 subsidence (Figure 9). Lake water effectively collects energy from the surface during summer  
554 and the talik stores the excess heat throughout the winter. Arp et al. (2010, 2011) and Jefferies et  
555 al. (1999) discussed the difference in heat conduction between a grounded ice lake and a floating  
556 ice lake. Their observations are generally consistent with the proposed theory because a deeper  
557 talik under a floating ice lake should have a greater heat capacity. Since lake elongation likely  
558 occurs before talik formation, the horizontal lake characterization derived in this study may not  
559 be fully applicable to the analysis of thaw lakes on the ACP. In fact, the disagreement of the  
560 talik and lake extents in Peatball Lake application illustrates the multiple effects on the lake  
561 bathymetry and orientation. Clearly, however, talik expansion and concurrent subsidence  
562 stabilizes lake geometry and contributes to lake roundness.

563 The applicability of the proposed 3D Stefan equation is limited for lakes with high sediment  
564 influx and for lakes with through talik. The paired sublittoral shelves on both lake sides are  
565 commonly found in the sand dune areas of the southern ACP. The talik shape is likely altered by

566 uneven sediment deposition that affects the temperature gradient normal to the phase boundary  
567 as mentioned by several researchers (Hunter et al., 1981; Mackay, 1992; West and Plug, 2008).  
568 The shelves created by sediment redistribution due to lake water circulation adds complexity to  
569 the ellipsoidal talik shape described in this study. Finally, if the talik penetrates through the  
570 permafrost and becomes a throughgoing talik (Hinkel and Arp, 2015), the proposed thermal  
571 theory herein is no longer applicable for thermokarst lake and talik characterization.

## 572 **5. Conclusions**

573 The theory presented here addresses the origin of the thermokarst lake ellipticity on the ACP.  
574 Elliptic lake geometry results from minimizing overall thawing energy consumption for a given  
575 incoming energy load. This is particularly applicable for mature, deep thermokarst lakes with  
576 well-developed taliks. Additionally, existing hypothetical models were reviewed to illuminate  
577 the thermal effect (e.g., ellipsoidal talik geometry) on the thermokarst lake morphology.

578 The derived ellipsoid talik model integrates the atmospheric forcing (or incoming energy), the  
579 vertical thermal gradient, the thermal diffusivity of the permafrost, and the talik geometry. Heat  
580 flux by conduction into the permafrost depends on the heat gradient of the underlying permafrost  
581 (Fourier's law). As the vertical temperature slope diminishes with talik maturation, the depth-  
582 width ratio of the talik becomes larger creating a deeper talik; thus, much of incoming energy is  
583 likely consumed for vertical rather than horizontal expansion. Conversely, during the early  
584 stages, thermo-mechanical processes such as wind-driven wave erosion dominates horizontal  
585 expansion and elongation of the lake. Consequently, this theory elucidates how talik expansion  
586 and concurrent permafrost degradation stabilizes the shape of thermokarst lake to one that is  
587 more round rather than elliptical.

588 The semi-ellipsoidal 3D Stefan equation is, to our knowledge, the first geometric model  
589 explicitly derived only from the energy conservation equation at the phase boundary. The vector  
590 form of the energy conservation equation (Equation 5) in a 3D anisotropic thermal field was  
591 integrated at the phase boundary area under the isolated general-shaped lake to quantify the total  
592 energy balance. It was shown that the basin total thaw energy or talik expansion rate is  
593 equivalent to the weighted phase boundary area. The optimum talik shape function was  
594 determined by the variational principle as an extremum of the functional that minimizes the total  
595 thawing energy consumption (the stationary action principle). Thus, the resultant semi-ellipsoid  
596 equation (Equation 22) can be considered the 3D Stefan equation because it describes the  
597 optimum geometry of phase boundary.

598 The derived semi-ellipsoid function was applied to Peatball Lake, ACP of Alaska, where the  
599 talik was extensively surveyed using TEM soundings. The pure geometric fitting exercise met  
600 the 27 measured TEM data point well with RMSD of 5.94 m, although the talik orientation  
601 disagreed with orientation of Peatball Lake and other surrounding lakes. This may be induced by  
602 the irregularity due to the rapid and uneven horizontal lake expansion, or possibly by basin  
603 coalescence. Comparing the observed talik thickness to the observed lake bathymetry indicated  
604 two distinctive permafrost degradation scenarios: significant subsidence by near-surface ice-rich  
605 layer thaw and minor contribution of subsidence due to ice-poor permafrost thaw at depth.  
606 Consequently, lake water depth is affected by uneven subsidence of thawing permafrost, the  
607 interannual water balance; the spatial lake shape irregularity was determined during earlier stage  
608 of development. Therefore, careful consideration is required for the analysis of the relationship  
609 between lake bathymetry and talik thickness. Nevertheless, this theoretical technique can be  
610 used as guidance to partition various effects such as talik development and thaw subsidence,

611 wind wave erosion, lake ice thickness, surficial geology type, and sediment transport by lake  
 612 water current. Moreover, the analytical expression of the 3D Stefan Equation can be potentially  
 613 incorporated in the global or regional scale Earth system model to describe missing sub-grid  
 614 scale processes such as lake dynamics with minimal additional computational resources.

## 615 **Appendix A: Alternative derivation using isoperimetric inequality**

616 Alternative derivation may provide the thermally optimum talik shape minimizing the phase  
 617 boundary area  $A$  with a fixed talik volume  $V$ . Equation (14) establishes talik volume and phase  
 618 boundary area under the thermokarst lake by a general function of the phase boundary  $\varphi$ . The  
 619 horizontal coordinate system may be transformed by  $(u, v) = \left(\frac{x}{\alpha_x}, \frac{y}{\alpha_y}\right)$ . Then, the phase  
 620 boundary can be expressed as a scaled function,

$$621 \quad \hat{\varphi}(u, v) = \varphi(x, y) = \varphi(\alpha_x u, \alpha_y v), \quad (u, v) \in \hat{B}. \quad (\text{A1})$$

622 According to,

$$623 \quad \begin{cases} \frac{du}{dx} = \frac{1}{\alpha_x}, \\ \frac{dv}{dy} = \frac{1}{\alpha_y}, \\ \frac{\partial}{\partial u} \hat{\varphi}(u, v) = \frac{\partial}{\partial u} \varphi(\alpha_x u, \alpha_y v) = \alpha_x \varphi_x, \\ \frac{\partial}{\partial v} \hat{\varphi}(u, v) = \frac{\partial}{\partial v} \varphi(\alpha_x u, \alpha_y v) = \alpha_y \varphi_y \end{cases} \quad (\text{A2})$$

624 the talik volume and the phase boundary area can be written as,

$$625 \quad \begin{cases} V[\varphi] = \alpha_x \alpha_y \iint_{\hat{B}} \hat{\varphi} \, dudv \\ A[\varphi] = \alpha_x \alpha_y \iint_{\hat{B}} \sqrt{\hat{\varphi}_u^2 + \hat{\varphi}_v^2 + 1} \, dudv = \alpha_x \alpha_y \int_{\hat{S}} d\hat{S} \end{cases} \quad (\text{A3})$$

626 where  $\hat{B}$  denotes the extent of  $\hat{\varphi}(u, v)$  on the  $uv$  plane, and  $\hat{S}$  is the surface on  $z = \hat{\varphi}(u, v)$  as,

627 
$$\hat{S} = \{ (u, v, z) \in \mathbb{R}^3 \mid (u, v) \in \hat{B}, z = \hat{\varphi}(u, v) \}. \quad (\text{A4})$$

628 The horizontal scaling transform makes it a symmetric closed surface on  $z = 0$ ,

629 
$$S^* = \{ (u, v, z) \in \mathbb{R}^3 \mid (u, v) \in \hat{B}, z = \pm \hat{\varphi}(u, v) \} . \quad (\text{A5})$$

630 It is known that volume  $U$  enclosed by the ovaloid surface  $S^*$  and its surface area satisfy the  
631 isoperimetric inequality for an ovaloid surface, which can be written as,

632 
$$\left( \int_{S^*} dS^* \right)^3 \geq 36\pi U^2 . \quad (\text{A6})$$

633 As the volume and the surface area of the convex closed surface  $S^*$  can be expressed as

634 
$$U = 2 \left| \iint_{\hat{B}} \hat{\varphi} \, dudv \right| = \frac{2}{\alpha_x \alpha_y} |V[\varphi]| , \text{ and} \quad (\text{A7})$$

635 
$$\int_{S^*} dS^* = 2 \int_{\hat{S}} d\hat{S} = \frac{2}{\alpha_x \alpha_y} A[\varphi] , \text{ respectively,} \quad (\text{A8})$$

636 we have,

637 
$$\left( \frac{2}{\alpha_x \alpha_y} A[\varphi] \right)^3 \geq 36\pi \left( \frac{2}{\alpha_x \alpha_y} V[\varphi] \right)^2 , \text{ or}$$

638 
$$A[\varphi] \geq \sqrt[3]{18\pi \alpha_x \alpha_y (V[\varphi])^2} . \quad (\text{A9})$$

639 The equality in Equation (A9) holds only if the surface  $S^*$  is a sphere, which maximizes the  
640 volume. Let the radius of this sphere,

641 
$$D = \sqrt[3]{\frac{3}{4\pi} V} = \sqrt[3]{\frac{3|A[\varphi]|}{2\pi \alpha_x \alpha_y}} . \quad (\text{A10})$$

642 From the symmetricity to the plane  $z = 0$ , we can obtain,

643 
$$\hat{\varphi}(u, v) = -D \sqrt{1 - \left(\frac{u}{D}\right)^2 - \left(\frac{v}{D}\right)^2}, \quad (u, v) \in \hat{B}. \quad (\text{A11})$$

644 Inverse scaling coordinate transformation yields the ellipsoid phase boundary function as  
 645 follows:

646 
$$\varphi(x, y) = -D \sqrt{1 - \left(\frac{x}{\alpha_x D}\right)^2 - \left(\frac{y}{\alpha_y D}\right)^2}, \quad (x, y) \in B, \quad (\text{A12})$$

647 where  $D$  is the depth of the talik at the center. The ellipsoid, the three-dimensional Stefan  
 648 Equation for talik, can be obtained by the isoperimetric inequality as well as the functional  
 649 analysis.

## 650 **Appendix B: Determination of the coefficients $d$ and $\lambda$**

651 We can determine two coefficients in the ellipsoid (Equation 21) by further application of the  
 652 variational principle. Let

653 
$$D = \frac{2}{|\lambda|}. \quad (\text{B1})$$

654 Also, let the intersect  $d$  proportional to the vertical radius of the ellipsoid, as follows:

655 
$$d = tD \quad (-1 \leq t < 1), \quad (\text{B2})$$

656 where  $t$  is a parameter describing the relative elevation of the basin to the original ground  
 657 surface. Then, Equations (20) and (21) can be rewritten as,

658 
$$z = -\varphi = -\sqrt{D^2 - \frac{x^2}{\alpha_x^2} - \frac{y^2}{\alpha_y^2}} + tD, \quad \text{and} \quad (\text{B3})$$

659 
$$\left(\frac{x}{\alpha_x D}\right)^2 + \left(\frac{y}{\alpha_y D}\right)^2 + \left(\frac{z-tD}{D}\right)^2 = 1, \quad \text{respectively.} \quad (\text{B4})$$

660 Now, the phase boundary area and volume can be evaluated as functions of the parameter  $t$ :

$$\begin{aligned}
 V[\varphi] &= \iint_B \varphi \, dx dy = \iint_B \left( -\sqrt{D^2 - \frac{x^2}{\alpha_x^2} - \frac{y^2}{\alpha_y^2}} + tD \right) \, dx dy \\
 &= \pi \alpha_x \alpha_y \int_{-(1-t)D}^0 \{D^2 - (tD - z)^2\} dz \\
 &= \frac{\pi}{3} \alpha_x \alpha_y D^3 (t^3 - 3t + 2)
 \end{aligned}
 \tag{B5}$$

$$\begin{aligned}
 A[\varphi] &= \iint_B \sqrt{\alpha_x^2 \varphi_x^2 + \alpha_y^2 \varphi_y^2 + 1} \, dx dy \\
 &= \iint_B \frac{1}{\sqrt{1 - \left(\frac{x}{\alpha_x D}\right)^2 - \left(\frac{y}{\alpha_y D}\right)^2}} \, dx dy \\
 &= \pi \alpha_x \alpha_y D^2 \left\{ (1 - t^2) + \int_1^{\frac{1}{t}} \left( \frac{1}{z^2} - t^2 \right) dz \right\} \\
 &= 2\pi \alpha_x \alpha_y D^2 (1 - t)
 \end{aligned}
 \tag{B6}$$

663 Eliminating  $D$  from these expressions yields,

$$A[\varphi]^3 = M \frac{(1-t)^3}{(t^3 - 3t + 2)^2}
 \tag{B7}$$

665 where  $M$  is a positive constant. Therefore, as

$$\frac{d}{dt} (A[\varphi]^3) = M \frac{3t}{(1-t)^2 (t+2)^3} > 0 \quad (-1 \leq t < 1),
 \tag{B8}$$

667 the phase boundary area  $A[\varphi]$  is the minimum at  $t = 0$ . Hence,  $d = 0$  that corresponds to a semi-  
 668 ellipsoid with depth  $D$  at the center.

## 669 **Author contribution**

670 Ohara and Yamatani developed the theory, and all other co-authors, especially Hinkel, Jones,  
 671 Parsekian, and Kanevskiy, offered crucial advice in interpretation. Jones and Parsekian provided  
 672 the field observed data for the case study of Peatball Lake. Jones performed the statistical

673 analysis on the oriented lakes based on SAR-satellite remote-sensing data. Ohara prepared the  
674 manuscript with contributions from all co-authors.

## 675 **Acknowledgements**

676 This study was supported by the National Science Foundation (NSF) under awards OPP-  
677 1806287, 1806213, and 1806202. The authors thank UIC Science and CH2MHill Polar Field  
678 Services (now Battelle Arctic Research Operations) for logistical field support. Datasets and  
679 sources code for this research are available in these in-text data citation references. Louise  
680 Farquharson and Benjamin Gaglioti provided helpful comments improving the manuscript.

903 Table 1: Computed incoming heat flux with the estimated parameters

Parameter	Estimates	Unit	Note
Porosity	0.18		Sandstone >15 m deep; Creighton et al., 2018
Thermal conductivity of permafrost	2.20	W/(m·K)	From porosity and typical thermal properties of ice and mineral in this region
Talik depth, D	88.0	m	Fitted ellipsoid
Talik width (radius), a	514.8	m	Fitted ellipsoid
Aspect ratio, D/a	0.1709		Fitted ellipsoid
Geothermal gradient	0.0250	K/m	Kessler et al., 2012
dT/dz at the talik bottom	-0.0259	K/m	From Mackay model (1962)
Basin average heat flux, $q_{in}$	0.0689	W/m <sup>2</sup>	Computed from Equation (29)

Figure 1: Definitions of variables associating with the overall shape of phase boundary  $\varphi$  during warm (Upper left panel) and cold seasons (Lower left panel) and incoming and outgoing heat transfers on  $\varphi(x, y)$  (Right panel). Incoming heat (red colored vector) is perpendicular to the phase boundary  $\varphi(x, y)$  while thaw direction (blue colored vector) is modified by the anisotropic heat conduction (green colored vector) in the permafrost.

913

914 Figure 2: Lake bathymetry models for a thermokarst lake and the talik underneath based on the quasi-  
 915 steady state. (A) The lake bathymetry is proportional to the talik geometry with uniform ice distribution.

916 (B) The lake bathymetry tends to have a flat bottom due to the widespread ice-rich layer near the surface.

917

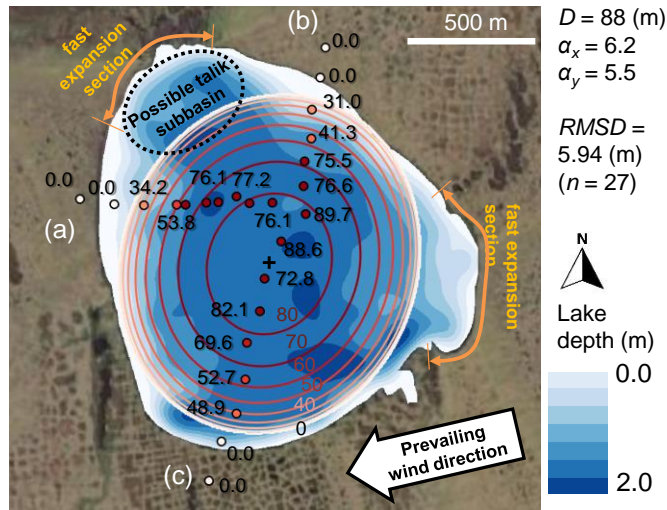

918

920

921

922 Figure 4: The theoretically extrapolated talik thickness map (contour lines) based on 27 TEM soundings  
 923 (dots) in Peatball Lake, ACP of Alaska. The red contour lines and the observation points are consistent.  
 924 The corresponding observed lake bathymetry (adopted from Lenz et al., 2016) is also included in blue  
 925 gradation. The TEM sounding transects start on the lakeshore and end near the center of the lake.

926

927

928 Figure 5: Cross sectional comparisons of the lakebed and the talik profiles along two TEM transects (b)  
 929 through (c) (Lenz et al., 2016) in Peatball Lake. Panel (B) displays the cross plot of the observed talik  
 930 and lake depths at all 27 TEM data points.

940

941

Figure 6: Combined hypothetical models of thermokarst lake evolution and diagram of major influencing factors through time. The left column represents summer conditions, the center column represents winter conditions, and the right column indicates the corresponding importance of mechanical vs. thermal processes through time as the lake ages (top is younger, bottom is older). Row (A) indicates the early processes under bedfast ice conditions before talik initiation. Row (B) shows the onset of vertical thaw and subsidence as talik begins to develop. Row (C) shows early, shallow talik growth conditions. Row (D) indicates later stage processes on deepened talik due to vertical thaw. Row (E) is the mature stage of development when complex bathymetry has set in as a result of sediment transport.

942

943 Figure 7: Computed mean daily potential solar radiation on sloping lakeshore relative to the flat surface  
 944 during summer period (June-August) with respect to latitude.  $I_q$  is the potential solar radiation on a flat  
 945 surface, and  $I'_q$  is radiation on sloping lakeshore.

946

947

948 Figure 8: Two distinctive lake water circulation patterns created by unidirectional wind. Livingstone type  
 949 circulation (Left) and Carson & Hussey type circulation (Right) cause opposite flow directions around  
 950 lake ends. This also results in difference in sediment and peat deposition patterns.

951

952

953 Figure 9: Comparison of Length to Width ratio versus the percent of a particular region exhibiting a  
 954 bedfast lake ice regime for seven study areas in Arctic Alaska. This analysis is based on SAR-satellite  
 955 remote-sensing data presented in Engram et al. (2018). Lakes that are more elliptical in shape tend to  
 956 occur where the majority of the lakes in the area freeze to their bed and thus likely do not have a talik.  
 957 Lakes that are more circular in shape tend to occur where the majority of lakes in an area do not freeze to  
 958 their bed and thus likely have a sub-lake talik.

959
