## Abstract

Thermokarst lake dynamics, which plays an essential role in carbon release due to permafrost thaw, is affected by various geomorphological processes. In this study, we derive a three-dimensional (3D) Stefan equation to characterize talik geometry under a hypothetical thermokarst lake in the continuous permafrost region. Using the Euler equation in the calculus of variations, the lower bounds of the talik were determined as an extremum of the functional describing the phase boundary area with a fixed total talik volume. We demonstrate that the semi-ellipsoid geometry of the talik is optimal for minimizing the total permafrost thaw under the lake for a given annual heat supply. The model predicting ellipsoidal talik geometry was verified by talik thickness observations using transient electromagnetic (TEM) soundings in Peatball Lake on the Arctic Coastal Plain (ACP) of Alaska. The lake width-depth ratio of the elliptic talik can characterize the energy flux anisotropy in the permafrost although the lake bathymetry cross section may not be elliptic due to the presence of near-surface ice-rich permafrost. This theory suggests that talik development stabilizes thermokarst lakes by ground subsidence due to permafrost thaw while wind-induced waves and currents are likely responsible for the elongation and orientation of thermokarst lakes in certain regions such as the ACP of northern Alaska.

The Cryosphere Discussions

# 1. Introduction

Thermokarst lakes are abundant in regions underlain by ice-rich permafrost including the Arctic Coastal Plain (ACP) of northern Alaska, northwestern Canada and Siberia (Grosse et al., 2013). These lakes are formed due to permafrost degradation and their basin evolution is fundamentally different from lakes formed in temperate and tropical regions. Thermokarst lakes affect the thermal regime of the surrounding permafrost, which affects the geomorphology and evolution of the lake basin. If the lake bed has a mean annual temperature greater than 0 ˚C, the sub-lake permafrost will begin to thaw (Burn, 2002; Arp et al., 2016). This typically occurs in lakes deeper than the maximum winter ice thickness, where the ice cover floats above an unfrozen water body. In this case, unfrozen lake bed sediments persist and the thaw front continues to penetrate deeper into the underlying permafrost. This creates a “talik”, or a perpetually unfrozen zone confined by permafrost, beneath the lake depending on local anomalies in thermal, hydrological, hydrogeological, or hydrochemical conditions (van Everdingen, 1998). In ice-rich permafrost, the conversion of ice to water with thaw causes a volumetric reduction in the unconsolidated material and the lake bed consequently subsides. The total depth of subsidence is determined by the depth and distribution of excess-ice content in the permafrost. As the lake expands by lateral thermomechanical erosion (thermal abrasion) of the banks, mineral and organic sediments from retreating shores are delivered to the lake basin (Farquharson et al. 2016). However, thaw-induced ground subsidence effectively deepens the basin, so volumetric capacity can actually increase over time. Over decades and centuries, the talik increases in thickness and lake bed subsidence continues as long as the thawing permafrost is ice-rich.

In certain ice-rich permafrost regions in the Arctic, there is a preferential orientation and elliptic shape to the numerous thermokarst lakes that occur there (Black and Barksdale, 1949; Hinkel et

https://doi.org/10.5194/tc-2021-192
Preprint. Discussion started: 30 August 2021

al., 2005; Grosse et al., 2013). On the ACP of northern Alaska, many elliptical thermokarst lakes have a long axes oriented 10–20 degrees west from true north, which is nearly perpendicular to the prevailing wind direction (Sellmann, 1975; Carter, 1981). Hinkel et al. (2005, 2012) also showed significant correlation between lake orientation and summer wind direction by analyzing the geometric shape metrics of the thermokarst lakes and drained thermokarst lake basins (DTLB) on the ACP of Alaska. It has been proposed that winds at the lake surface cause currents and generate a two-cell circulation pattern which triggers thermomechanical bank erosion, resulting in asymmetrical elliptical orientation (Livingstone, 1954; Rex, 1961; Carson and Hussey, 1962; Mackay, 1992; Arp et al., 2011). The sublittoral shelves and bars typically found in the deeper thermokarst lakes may also be formed by wind-driven currents and waves, and warmer water temperatures (Carson and Hussey, 1962). The axis-oriented sublittoral shelves make the orientation appear more pronounced in larger basins. Other processes also influence the orientation of thermokarst lakes such as historical drained lake geometry, ground ice distribution, and dune ridge orientation by aeolian sand transport (Carter, 1981).

Several numerical models have been proposed and applied that describe permafrost thaw for the purpose of analyzing water and carbon cycles (e.g. Kessler et al., 2012). However, Schuur et al. (2015) stress the need to better represent talik formation and geometries to more effectively parameterize numerical models. Painter et al. (2016) demonstrated a coupled surface/subsurface permafrost thermal hydrology model at the ice-wedge polygon scale. Kessler et al. (2012) simulated carbon mobilization over 10,000 years on two neighboring thaw lakes located on organic-rich Yedoma permafrost terrains in the northern Seward Peninsula, Alaska using a 3D numerical thermal model. They demonstrated the effectiveness of model simulations for methane emission from thermokarst lakes. Ling and Zhang (2003b) provided a numerical parametrization

https://doi.org/10.5194/tc-2021-192
Preprint. Discussion started: 30 August 2021

of lake talik development, and showed that shallow thermokarst lakes are a significant heat source affecting permafrost and talik geometries. Rowland et al. (2011) advanced the technique by including parameter of advective heat transport on talik evolution. West and Plug (2008) and Plug and West (2009) characterized the lake bathymetry including the effects of lake ice and littoral shelves. These thermal models use long-term mean lake temperature as the Dirichlet boundary condition and a uniform annual mean temperature profile as the initial condition. Analytical and numerical models can provide dynamic solutions for the heat transfer equation under quasi-steady state climate conditions. However, the existing models require prescribed lake shapes (circle or ellipse) to obtain information on talik depths as opposed to modeling the likely influence of talik evolution on lake shape – this work, in part, attempts to address this shortcoming.

Direct drilling measurements of taliks below thermokarst lakes are difficult to obtain and only exist in a few rare case studies (Brewer, 1958; Johnston and Brown, 1966; Roy-Leveilee and Burn, 2017; Heslop et al., 2015). Geophysical methods can be used (e.g. Schwamborn et al., 2000; Parsekian et al., 2019; Creighton et al., 2018; Sullivan et al., 2021; O'Neill et al., 2020); however, it is time consuming and laborious to produce 3D subsurface images at the large scale of lakes found in permafrost lowland regions. Since field measurements (coring, geophysics, etc.) are spatiotemporally limited, numerical and analytical modelling is used to gain critical insights into talik evolution. Mackay (1962) obtained the analytical vertical temperature profiles below the water at the center of a circular lake by analytically solving the heat transfer equation. Burn (2002) subsequently extended the solution for an elongated lake. This analytical model has been used for lake process characterization because the quasi-steady state model was able to reasonably quantify the talik thickness. For example, Hinkel and Arp (2015) applied the

https://doi.org/10.5194/tc-2021-192
Preprint. Discussion started: 30 August 2021

temperature profile to 2100 lakes and found that larger, long-lived lakes (more than 66 ha) may have taliks that penetrate through the permafrost (throughgoing talik) to the ground-water system below in a region with permafrost that is up to 600 m thick.

These existing models require the prescribed lake shapes (circle or ellipse) to obtain the talik depth; in fact, no existing studies explicitly provide an answer to the fundamental question: why do thermokarst lakes tend to be elliptical and/or round? Also, in spite of several decades of research focused on the orientation of thermokarst lakes in certain regions, no existing studies explicitly explain why thermokarst lakes in some regions orient perpendicular to the prevailing wind direction. The objective of this work is to implement a novel mathematical framework that concurrently describes both the oriented nature of the thermokarst lakes and the talik depth below the lakes. Previous models have calculated the talik development due to heat flow, though most use some simplifying assumptions to reduce dimensionality. Separately, researchers have hypothesized about elliptical lake morphology by invoking winds, currents, and erosion. Here, we couple both the talik evolution and lake shape questions together in a single mathematical model. Additionally, we intend to use this theory to demonstrate that the thermal gradient could exert control on the depth/width ratio of the talik. In other words, the proposed theory aims to isolate the most important process – sub-lake permafrost thaw and subsidence - from other effects such as wind-wave erosion, thaw slumping, sediment redistribution and incoming radiation imbalance, using thermally optimized lake geometry.

# 2. Theory

## 2.1 Basin integrated energy equation

Heat energy collected by a waterbody is used for phase boundary expansion as well as heat conduction into the adjacent permafrost (e.g. French, 1996). From the energy balance equation around the phase boundary, the energy for permafrost thaw is expressed as the subtraction of heat conduction from the input energy at the phase boundary (Carslaw and Jaeger, 1959; Patel, 1968; Lunardini, 1981). Therefore, the energy conservation equation at the phase boundary can be expressed as,

$$q_f = q_{in} - q_c \ , \tag{1}$$

where $q_f$ is heat for fusion or thawing (W/m$^2$); $q_{in}$ is heat input at the phase boundary (W/m$^2$); and $q_c$ is heat conduction to the permafrost (W/m$^2$). These heat fluxes can be evaluated by the following formulas:

$$q_f = \phi v \rho L \quad , \tag{2}$$

$$q_{in} = q_{suf} - k_L \frac{dT}{dn} \quad \text{, and} \tag{3}$$

$$q_c = -k_p \frac{dT}{dn} \quad . \tag{4}$$

where $\phi$ is volumetric water content; $v$ is thaw rate or advancement of talik boundary (m/s); $\rho$ is density of water (kg/m$^3$); $L$ is latent heat for fusion (liquid-solid) of water (J kg$^{-1}$); $q_{suf}$ is additional heat input from ground surface around the lake shore (W/m$^2$); $k_L$ is thermal conductivity of unfrozen soil or lake water; and $k_p$is thermal conductivity of frozen soil (permafrost); $T$ is temperature (̊C); and $n$ is outward normal from the interface into the soil (m).

https://doi.org/10.5194/tc-2021-192
Preprint. Discussion started: 30 August 2021

When heat input from the surface is consumed for phase change without any loss ($q_c = q_{suf} = 0$), the well-known Stefan equation can be obtained from Equations (1) through (4) under the quasi-steady state approximation (Stefan, 1891; Kurylyk & Hayashi, 2016). This study also adopts the quasi-steady state approximation for the talik shape characterization.

As the thawing process is direction-dependent, it is convenient to use vector notation (Figure 1). That is,

$$\boldsymbol{q}_f = \boldsymbol{q}_{in} - \boldsymbol{q}_c. \tag{5}$$

The letter in bold denotes a vector. The fusion heat flux vector corresponds to thaw direction, which is affected by the other two heat fluxes. Figure 1 also illustrates the thermal profiles around the thaw lake in warm and cold seasons. The horizontal near-surface heat conduction is influenced by the seasonality of the surface heat budget while the vertical heat conduction under the lake remains unidirectional throughout the years. Clearly, the presence of the thaw lake considerably alters the heat environment of the permafrost while the temperature slope at the bottom of the permafrost may be approximated by the geothermal gradient in regions with thick continuous permafrost such as the ACP. This directionality in the heat environment around the lake may cause anisotropic talik expansion. Here, the phase change heat vector is expressed as proportional to the normal heat input $q_{in}$, as follows:

$$\boldsymbol{q}_f = \left(q_{f,x},\, q_{f,y},\, q_{f,z}\right) = \left(\xi q_{in},\, \eta q_{in},\, \zeta q_{in}\right) = q_{in}(\xi, \eta, \zeta) \tag{6}$$

where $q_{in}$ is the input heat normal to the phase boundary, $\xi, \eta$, and $\zeta$ are the fusion energy fractions of the heat input normal to the phase boundary with respect to x, y, and z directions, respectively. The depth of the phase boundary, $z = \varphi(x, y)$, may be expressed as an arbitrary 3D surface as,

https://doi.org/10.5194/tc-2021-192
Preprint. Discussion started: 30 August 2021

$$g(x, y, z) = \varphi(x, y) - z = 0. \tag{7}$$

Hence, the normal vector $\boldsymbol{n}$ at any location on the phase boundary $g$ can be written as follows:

$$\boldsymbol{n} = \frac{\nabla g}{|\nabla g|} = \frac{1}{|\nabla g|}\left(g_x, g_y, g_z\right) = \frac{1}{\sqrt{\varphi_x{}^2+\varphi_y{}^2+1}}\left(\varphi_x, \varphi_y, -1\right) \tag{8}$$

where the subscript in this expression denotes partial derivative (e.g. $\varphi_x = \partial\varphi/\partial x$) and $\nabla$ is a vector differential operator $(\partial/\partial x\,, \partial/\partial y\,, \partial/\partial z)$. As such, the vector of the input heat to the phase boundary $\varphi$ is

$$\boldsymbol{q}_{in} = |\boldsymbol{q}_{in}|\boldsymbol{n} = q_{in}\boldsymbol{n} = \frac{q_{in}}{\sqrt{\varphi_x{}^2+\varphi_y{}^2+1}}\left(\varphi_x, \varphi_y, -1\right), \tag{9}$$

and the corresponding fusion heat vector is,

$$\boldsymbol{q}_f = \frac{q_{in}}{\sqrt{\varphi_x{}^2+\varphi_y{}^2+1}}\left(\xi\varphi_x, \eta\varphi_y, -\zeta\right). \tag{10}$$

Next, the fusion heat magnitude can be evaluated using a Euclidian norm as,

$$\left|\boldsymbol{q}_f\right| = \frac{q_{in}}{\sqrt{\varphi_x{}^2+\varphi_y{}^2+1}}\sqrt{\xi^2\varphi_x{}^2 + \eta^2\varphi_y{}^2 + \zeta^2} = \frac{\zeta q_{in}}{\sqrt{\varphi_x{}^2+\varphi_y{}^2+1}}\sqrt{\alpha_x{}^2\varphi_x{}^2 + \alpha_y{}^2\varphi_y{}^2 + 1} \tag{11}$$

where

$$\alpha_x = \frac{\xi}{\zeta}, \quad \alpha_y = \frac{\eta}{\zeta} \quad . \tag{12}$$

The parameters $\alpha_x$ and $\alpha_y$ describe the anisotropic thermal condition between horizontal and vertical directions. The parameters $\alpha_x$ and $\alpha_y$ are greater than one when the vertical temperature gradient is steeper than in horizontal direction. The total fusion energy over the lake can be computed by the area integral on the phase boundary $\Gamma$. That is,

https://doi.org/10.5194/tc-2021-192
Preprint. Discussion started: 30 August 2021

$$\int_{\Gamma} |\boldsymbol{q}_f| \, d\Gamma = \iint_B |\boldsymbol{q}_f| \sqrt{{\varphi_x}^2 + {\varphi_y}^2 + 1} \, dxdy$$

$$= \zeta q_{in} \iint_B \sqrt{{\alpha_x}^2 {\varphi_x}^2 + {\alpha_y}^2 {\varphi_y}^2 + 1} \, dxdy. \quad (13)$$

This expression indicates that the heat required for lake expansion is proportional to the weighted phase boundary area.

## 2.2 Optimum phase boundary shape as extremum

The calculus of variation, often referred to as a functional analysis, is the mathematical technique to find an extremum (minimum or maximum) of the system in terms of a function type instead of a variable (e.g. Courant and Hilbert, 1954; Gelfand and Fomin, 1963). Here, we present the thermally optimum function type $\varphi(x, y)$ of the phase boundary using this method. As presented in the previous section, the heat consumption rate for talik expansion is represented by the weighted phase boundary area while the time-integrated heat supply is equivalent to the thawed permafrost volume. Assuming heat thaws the most susceptible region of the permafrost near the heat source first, the shape of a talik may minimize the total permafrost thaw with a given amount of incoming energy. Hence, this variational principle states that the optimum talik shape should minimize the phase boundary area for the total talik expansion. The weighted phase boundary area A and its volume V can be expressed as follows:

$$\begin{cases} V[\varphi] = \iint_B \varphi \, dxdy \\ A[\varphi] = \iint_B \sqrt{{\alpha_x}^2 {\varphi_x}^2 + {\alpha_y}^2 {\varphi_y}^2 + 1} \, dxdy \end{cases}. \quad (14)$$

The functional $F$ is defined as

$$F[\varphi] = \lambda V[\varphi] + A[\varphi] = \iint_B \left(\lambda \varphi + \sqrt{{\alpha_x}^2 {\varphi_x}^2 + {\alpha_y}^2 {\varphi_y}^2 + 1}\right) dxdy \quad (15)$$

https://doi.org/10.5194/tc-2021-192
Preprint. Discussion started: 30 August 2021

where $\lambda$ is a constant. Extremum of the functional $F$ can be determined for $\lambda < 0$ because both $V$ and $A$ are monotonic functions. Let

$$f(\varphi, \varphi_x, \varphi_y) = \lambda\, \varphi + \sqrt{{\alpha_x}^2{\varphi_x}^2 + {\alpha_y}^2{\varphi_y}^2 + 1}\,. \tag{16}$$

Equation (15) becomes,

$$F[\varphi] = \lambda\, V[\varphi] + A[\varphi] = \iint_B f(\varphi, \varphi_x, \varphi_y)\, dxdy. \tag{17}$$

To find the extremal phase-boundary shape $\varphi$ that minimizes the functional $F[\varphi]$, the Euler's Equation can be formulated as,

$$\frac{\partial f(\varphi,\varphi_x,\varphi_y)}{\partial \varphi} - \frac{\partial}{\partial x}\left(\frac{\partial f(\varphi,\varphi_x,\varphi_y)}{\partial \varphi_x}\right) - \frac{\partial}{\partial y}\left(\frac{\partial f(\varphi,\varphi_x,\varphi_y)}{\partial \varphi_y}\right) = 0. \tag{18}$$

Substituting Equation (16) to (18) yields,

$$\lambda - \frac{\partial}{\partial x}\left(\frac{{\alpha_x}^2\, \varphi_x}{\sqrt{1+{\alpha_x}^2\, {\varphi_x}^2+{\alpha_y}^2{\varphi_y}^2}}\right) - \frac{\partial}{\partial y}\left(\frac{{\alpha_y}^2\, \varphi_y}{\sqrt{1+{\alpha_x}^2{\varphi_x}^2+{\alpha_y}^2{\varphi_y}^2}}\right) = 0. \tag{19}$$

By analogy to two-dimensional application in Ohara and Yamatani (2019), an ellipsoid is one of the solutions of Equation (19), as follows:

$$z = -\varphi = -\sqrt{\frac{4}{\lambda^2} - \frac{x^2}{{\alpha_x}^2} - \frac{y^2}{{\alpha_y}^2}} + d, \text{ or} \tag{20}$$

$$\left(\frac{x}{\frac{2\alpha_x}{|\lambda|}}\right)^2 + \left(\frac{y}{\frac{2\alpha_y}{|\lambda|}}\right)^2 + \left(\frac{z-d}{\frac{2}{|\lambda|}}\right)^2 = 1. \tag{21}$$

Detailed alternative derivation using isoperimetric inequality is available in the Appendix A. The coefficients $d$ and $\lambda$ can be determined by further variational analysis explained in Appendix B. As such, Equations (20) and (21) become

https://doi.org/10.5194/tc-2021-192
Preprint. Discussion started: 30 August 2021

$$\varphi = \sqrt{D^2 - \frac{x^2}{{\alpha_x}^2} - \frac{y^2}{{\alpha_y}^2}} \text{, and} \tag{22}$$

$$\left(\frac{x}{\alpha_x D}\right)^2 + \left(\frac{y}{\alpha_y D}\right)^2 + \left(\frac{z}{D}\right)^2 = 1\text{, respectively.} \tag{23}$$

*D* is the talik center depth, $\alpha_x$ & $\alpha_y$ are the cross-sectional aspect ratios. Hence, the semi-ellipsoidal geometry of the phase boundary (i.e., the boundary between the permafrost and talik) was explicitly derived as a thermally optimum shape based on the variational principle using the thermal quasi-steady state approximation; this is the 3D Stefan Equation for the talik beneath a thermokarst lake.

## 2.3 Thermokarst lake bathymetry and phase boundary geometry

When top-down permafrost thaw dominates the process, the thermokarst lake bottom shape $\psi(x,y)$ may be similar to the phase boundary shape, as illustrated in Figure 2. However, the lake bathymetry can be related to the permafrost degradation rate defined as,

$$r_{deg} = \frac{D_{thaw}}{D_{frzn}} \sim 1 - \frac{\psi(x,y)}{\varphi(x,y)} \sim 1 - \frac{H}{D} \quad , \tag{24}$$

where *H* and *D* denote the water depth and the talik thickness at the lake center, respectively. $D_{frzn}$ is the frozen soil thickness (m) and $D_{thaw}$ is the corresponding thawed soil thickness depth (m), which is strongly dependent on the excess ground ice content; excess ice is defined as the volume of ice in the ground which exceeds the total pore (van Everdingen, 1998; Kanevskiy et al., 2013). Therefore, thaw settlement is typically computed from wedge-ice volume content and the thickness of the layer with excess ground ice. However, as the consolidation settlement effect, which is a function of void ratio and effective stress, may not be separated, we use the simple permafrost degradation rate (Equation 24) in this study.

https://doi.org/10.5194/tc-2021-192
Preprint. Discussion started: 30 August 2021

If the permafrost degradation rate is uniform and constant throughout the basin (Panel A: uniform permafrost in Figure 2), the lake bathymetry tends to be an ellipsoid shape. However, as the ice-rich layer (ice wedges) is typically developed near the surface on the ACP (e.g. Kanevskiy et al., 2013, 2016), the bathymetry may have a flatter bottom like a rectangular cross section (Panel B: layered permafrost in Figure 2) because the ice-rich layer is characterized by much higher thaw settlement than the ice-poor permafrost at depth. Therefore, proportionality between talik thickness and lake water depth or uniform permafrost is unlikely reasonable assumption due to the ice rich layer presence. Indeed, Hinkel et al. (2012) showed many flat-bottomed lakes through the extensive bathymetry surveys across the ACP of Alaska using a GPS-enabled sonar from a boat.

Additionally, as hydrology also affects the lake water level, the apparent lake bathymetry or lake water depth, $h(x,y)$ must be adjusted by the water loss (or gain) per unit area. Therefore,

$$h(x,y) = [1 - r_{sub}]\varphi(x,y) - H_{loss} \ , \tag{25}$$

where $H_{loss}$ (m) is the elevation difference between the current water surface and original ground surface before lake formation. At the lake center,

$$H = [1 - r_{sub}]D - H_{loss} \quad . \tag{26}$$

Thus, the thermokarst lake bathymetry is affected by the ice-rich layer thickness, interannual water balance, lake age, and talik geometry.

https://doi.org/10.5194/tc-2021-192
Preprint. Discussion started: 30 August 2021

# 3. Case study

## 3.1 Study area

Peatball Lake (70°42.40N, 153°55.50W; 3 m above sea level) on the ACP of Alaska was chosen for the demonstrative model application in this study as it has been relatively well-documented. Figure 3 shows the location of Peatball Lake as well as the subregions that will be presented later.

Peatball Lake, named for the abundant submerged peat balls on the lake bed, is a subcircular lake on the Outer Coastal Plain of Alaska with a surface area of 1.18 $km^2$. Permafrost in this area is as thick as 410 m (Jorgenson et al., 2007), and the average volumetric ground ice content is about 77% in the near surface to a depth of 4 m (Kanevskiy et al., 2011). A talik has formed under Peatball Lake because the maximum water depth of 2.5 m exceeds the maximum winter ice thickness of 1.5 to 2.0 m (Arp et al., 2015; Lenz et al., 2016). The talik depth was estimated as 91 m at the lake center based on noninvasive TEM measurements (Creighton et al., 2018). However, the talik may not be present beneath the sublittoral shelves on the western shore from the bathymetry (Lenz et al., 2016). Additionally, Lenz et al. (2016) reported that, based on remote sensing imagery, Peatball lake has expanded laterally between 0.02 m/year and 1.36 m/year between 1955 and 2002.

## 3.2 Geophysical survey of talik

Geophysical field methods are effective for identifying and visualizing the frozen-unfrozen interface, which is a key feature in permafrost dynamics (e.g. Pilon et al., 1985; Doolittle et al., 1990; O'Neill et al., 2020; Rangel et al., 2021). For lake taliks in the continuous permafrost zone, Schwamborn et al. (2002) analyzed the sedimentary history of Lake Nikolay in the western Lena River Delta using seismic reflection and ground penetrating radar (GPR). Other geophysical

https://doi.org/10.5194/tc-2021-192
Preprint. Discussion started: 30 August 2021

methods such as surface nuclear magnetic resonance (NMR) can be used to detect lake taliks (Parsekian et al., 2019) and remnant taliks in drained lake basins (Rangel et al., 2021). At Peatball Lake, Creighton et al. (2018) estimated the talik depth using transient electromagnetic (TEM) surveys along transects perpendicular to lakeshores.

We applied the derived 3D Stefan equation to Peatball Lake based on the 27 talik thickness point measurements across the lake (Figure 4), estimated using TEM soundings (Creighton et al., 2018) during spring 2016 and 2017. Figure 4 shows the observed talik thicknesses by the TEM sounding (dots) and the fitted theoretical talik thickness estimates (contour lines) superimposed over the corresponding lake bathymetry measured by Lenz et al., 2016.

The geometric parameters of the semi-ellipsoid model such as the talik center depth (*D*), the cross-sectional aspect ratios ($\alpha_x$ & $\alpha_y$), lake orientation azimuth angle and the lake center location were systematically determined by grid searching to minimize the root mean square difference (RMSD) between the model and thaw front obtained from the TEM data. The optimum parameters for the smallest RMSD (5.94 m) are shown in Figure 4. Unexpectedly, the basin orientation angle was found to be 23 degrees east from true north, unlike the orientation of other surrounding lakes in the region. Comparison between the extrapolated talik geometry and the lake bathymetry (Lenz et al., 2016) suggests the possibility of coalescence of two basins in the past; a relatively common occurrence on the ACP of Alaska. However, if we had more TEM measurement points, particularly in the "possible talik sub-basin", the fitted talik geometry could be different as the model was only fitted for the 27 TEM soundings. Lake taliks tend to have a semi-ellipsoidal shape, at least locally, as indicated by the very good fit of the elliptic model to the TEM measured talik thicknesses (see Figure 4 with overall RMSD = 5.94 m). The idealized,

https://doi.org/10.5194/tc-2021-192
Preprint. Discussion started: 30 August 2021

thermally optimum geometry model can be used to analyze lake formation history of the irregular talik associated with multi-generation lakes such as Peatball Lake.

Additionally, the gaps between the shoreline and the modeled talik extent located along north and east shores occur where lake expansion is occurring most rapidly (Lenz et al., 2016). It has been reported that thaw lake banks continuously retreat through a combination of thermal and mechanical processes, although there is significant variability in rate of bank retreat depending on region (Hopkins, 1949; Hopkins et al., 1955; Tomirdiaro, 1982; Rampton, 1982; Burn and Smith, 1990; Jones et al. 2011, Lenz et al., 2016). Cross-sectional numerical thermal models demonstrated that the expansion rates are affected by the talik thickness (Plug and West, 2009) and seasonal snow cover (Ling and Zhang, 2003a). The disagreement between the lake and talik extents on the north and east shores of Peatball lake implies that rapid horizontal lake expansion can locally dominate permafrost thaw and subsidence processes even in a lake with a talik.

Figure 5 compares the observed lakebed and talik profiles in Peatball Lake along the north-south center line and along transects (b) –(c), respectively. Note that the TEM transects for the talik is not a straight line (See figure 4); therefore, the fitted theoretical line shows irregularity. Figure 5A illustrates that the lakebed profile is characterized by flatter trapezoidal geometry compared to the elliptic talik. In fact, there is a clear inflection in the linear regression line at a talik depth of ~50 m in Figure 5B. From the slopes of the regression lines, the permafrost degradation rates $r_{deg}$ are computed as 97.3 % and 99.7 % for the shallow talik section (50 m or less) and the deep section (50 m or more), respectively. This analysis suggests that the subsidence due to permafrost thaw continues even after the shallow ice-rich part of the permafrost (about 4 meters, Kanevskiy, 2011) is thawed while it has diminished around the depth of 50 meter under Peatball

https://doi.org/10.5194/tc-2021-192
Preprint. Discussion started: 30 August 2021

lake. This case study demonstrates a link between lake bathymetry and talik thickness associated with a layered permafrost structure and the wind erosion effect.

### 3.3 Depth-width ratio and temperature gradient

The analysis (Equations 22 & 23) suggests the proportional relationship between lake/talik geometry and thaw energy. That is,

$$a : b : D = \alpha_x : \alpha_y : 1 = \xi : \eta : \zeta = q_{f,x} : q_{f,y} : q_{f,z} \quad . \tag{27}$$

Combining Equations (27), (1) and (4), the depth-width (radius) ratio of the talik may be written as follows:

$$a : D = \left(q_{in,x} + k_p \frac{dT}{dr}\right) : \left(q_{in,z} + k_p \frac{dT}{dn}\right) \tag{28}$$

where *r* and *n* are the horizontal and vertical distances from the original permafrost surface center, respectively, and *a* is the representative horizontal radius of the lake. This expression states that the anisotropic top-down permafrost thaw is caused by anisotropy of the thermal gradient for uniform incoming energy and uniform thermal properties of near surface permafrost. For example, since the vertical thermal gradient is typically steeper than the horizontal gradient during the critical summer months (Carson and Hussey, 1962; illustration in Figure 1), the heat energy in the vertical direction is used more for heat conduction rather than permafrost thawing. The vertical temperature gradient is always negative near the talik boundary in the permafrost $\left(\frac{dT}{dn} < 0\right)$ at the center of the lake while the inter-seasonal average of the horizontal thermal gradient may be negligible $\left(\frac{dT}{dr} \approx 0\right)$. Assuming the normal heat flux to the phase boundary is uniform throughout the phase boundary surface ($q_{in,x} = q_{in,z} = q_{in}$), Equation (28) can be simplified as follows:

https://doi.org/10.5194/tc-2021-192
Preprint. Discussion started: 30 August 2021

The Cryosphere Discussions
Open Access
EGU

$$\frac{D}{a} = 1 + \frac{k_p}{q_{in}}\frac{dT}{dn} \quad \text{, or} \quad q_{in} = -\frac{ak_p}{a-D}\frac{dT}{dn} \quad . \tag{29}$$

This simple expression may be a useful tool to link the lake depth-width ratio, the lake average heat flux $q_{in}$, and the vertical temperature gradient $\frac{dT}{dn}$ at the base of the talik. Since $\frac{dT}{dn} < 0$ in the permafrost near the talik boundary, the *D/a* is always less than 1 (flatter than a semi-sphere). However, the depth-width ratio of the talik depends on the vertical temperature slope near the talik boundary, which is likely affected by talik age. For instance, Mackay's analytical model (1962) suggests that the vertical temperature gradient below the lake center begins steeply at the talik initiation, and then over time it approaches a lower slope at equilibrium. Therefore, the formula in Equation (29) suggests that a younger talik should be flatter while an older talik approaches a deeper semi-spheric shape (*D/a* → 1).

Table 1 shows the estimated incoming heat flux with the key parameters using the proposed formula (Equation (29)). Creighton et al. (2018) applied the CRYOGRID2 model (Westerman et al., 2013) to Peatball Lake. The temperature slope at the talik bottom at the lake center was estimated by the Mackay's analytical model assuming the lake age of 1400 years since the talik initiation with the same model configuration Creighton et al. (2018) adopted. Creighton et al. (2018) estimated the interannual mean heat flux $q_{in}$ to be 0.070 (W/m$^2$), which is very close to our estimate. As this simplified formula is consistent with the well-configured modeling result, the horizontal thermal gradient contribution to the vertical aspect ratio of the talik seems to be very small in Peatball Lake.

Moreover, this relationship may be useful to incorporate the three-dimensional talik expansion effect in a simple analysis without fully integrated permafrost thermal modeling. For example, if the mean energy flux increases 10 percent from current climate conditions (e.g. shorter lake

https://doi.org/10.5194/tc-2021-192
Preprint. Discussion started: 30 August 2021

freeze period), assuming all other properties are equal, the talik depth-width ratio *D/a* would shift from 0.171 to 0.234 toward the new equilibrium state. Therefore, this analysis suggests that the warmer climate may promote permafrost thaw in the vertical direction more than in the horizontal direction. Hence, it is important to quantify the vertical thawing as well as the visible lake horizontal expansion in order to evaluate the impact of the climate change on permafrost thaw beneath thermokarst lakes.

# 4. Discussion

## 4.1 Relationship between hypothetical models

To illustrate the applicability of the thermal model presented here, the available hypothetical models of thermokarst lake growth are compiled in Figure 6. This diagram focuses on the physical processes after the lake initiation stage assuming the bio-ecological effects are negligible.

Figure 6 illustrates the evolution of the talik in ice-rich permafrost over time, with driving processes shown in the right panel. In Stage A, the mechanical processes of wave erosion and thaw slumping along lake margins dominate lake expansion in summer, and shallow water favors grounded lake ice in the winter. In time (Stage B), the lake deepens from thaw subsidence beneath the older lake center. Winter ice may freeze to the lake bed, but heat loss is insufficient to freeze the underlying thawed lake bed sediments. A shallow talik develops as thermal processes work in tandem with mechanical processes, the latter now enhanced by more vigorous lake circulation. By Stage C, the talik is well developed beneath the entire lake basin as ground subsidence continues. Eventually (Stage D), the winter ice cover no longer extends to the lake bed, but instead floats atop a residual pool of lake water, while milder vertical temperature

https://doi.org/10.5194/tc-2021-192
Preprint. Discussion started: 30 August 2021

gradient beneath the lake deepens the talik as the lake matures. Thermomechanical erosion of lake margins, especially if there are prominent banks in hilly terrain, promotes sedimentation on near-shore shelves, and the underlying talik may begin refreezing. If the lake hasn't drained by this point (Stage E), the talik beneath the lake center extends deeper into the permafrost although subsidence may cease as the excess ice content diminishes with depth. Where many large, old lakes exist, the permafrost may be riddled with deep taliks, and some may eventually penetrate to the permafrost base to create a through-going talik.

Talik development is a natural processes governed by local conditions, but can be impacted by direct and indirect human activities. Conditions that favor talik initiation and growth include:

- Deepening lake waters triggered by greater precipitation and/or reduced evaporation, which promotes a floating ice regime
- Presence of ice-rich sediments (e.g., Yedoma) beneath lakes
- Warmer lake water induced by regional warming or by longer ice-free summers
- Thinner winter ice cover due to warmer winter temperatures and/or deeper snow

Conversely, talik growth cessation or contraction can occur when these same drivers are reversed, if the lake partially or completely drains, or when the lake basin is filled with sediments. The latter scenario is more likely in hilly terrain when the expanding lake erodes high banks and lake currents redistribute sediments.

Preprint. Discussion started: 30 August 2021

## 4.2 Thermal process and preferential expansion

### 4.2.1 Lake geometry and heat balance

The analytical expression of the lake geometry may be useful to analyze the horizontally oriented lakes as well. From Equation (27) and (1), we have,

$$a:b = q_{f,x}:q_{f,y} = \left(q_{in,x} - q_{c,x}\right):\left(q_{in,y} - q_{c,y}\right), \tag{30}$$

where *a* and *b* are the semi-major and -minor axes of the elongated lake, respectively. When horizontal heat conduction into the tundra is negligible, ($q_{c,r} = k_p \frac{dT}{dr} \approx 0$), this equation can be reduced to,

$$a:b = q_{in,x}:q_{in,y}. \tag{31}$$

Hence, the aspect ratio of elliptic lakes can be explained by heat supply inequality if the lake geomorphology process is dominated by thermal process. As expressed in Equation (3), there are two different components in the incoming heat flux to the lake banks: surface energy flux and heat conduction from the lake water body. Thus, the lake aspect ratio may be written as,

$$a:b = \left(q_{suf,x} - k_L \frac{dT}{dx}\right):\left(q_{suf,y} - k_L \frac{dT}{dy}\right) \tag{32}$$

### 4.2.2 Incoming radiation imbalance effect

One of the incoming surface energy flux inequalities $q_{suf}$ may be caused by shortwave radiation along the lake shoreline. The daily potential solar irradiation on a sloping surface can be computed by the trigonometric function (e.g. Equation B.11 in DeWalle and Rango, 2008). The total daily radiation is a function of latitude and bank slope angle, which depends on the permafrost degradation rate, the maturity of the talik, and ground ice distribution.

https://doi.org/10.5194/tc-2021-192
Preprint. Discussion started: 30 August 2021

Figure 7 shows the computed mean daily potential solar irradiation on the sloping lakeshore ($I'_q$) relative to a flat surface ($I_q$) during the summer period (June-August) at three different latitudes. The shape of this diagram may correspond to the shape of a thermokarst lake as the enhanced radiation results in more permafrost thaw. The difference in relative incoming radiation will diminish as bank slope angle lessens. In general, the south facing slope along the northern shore tends to receive more radiation than the north facing slope (e.g. Séjourné et al., 2015). This tendency is more pronounced in lower latitude zones due to the higher mid-day sun angle.

It is interesting that at 65 and 60 degree latitude the north and south facing banks receive slightly less radiation than east and west facing slopes, while an opposite result occurs at 70 degree latitude (Figure 7). Therefore, the radiation imbalance may partially explain the north-south elongation along the 70 degree latitude line and the west-east elongation of lower latitude (60-65 degrees) of lowland thermokarst lakes shown by Grosse et al. (2013, Figure 19). However, because these small differences in incoming radiation imbalance alone are insufficient to result in the distinctive lake elongation in the ACP, they likely introduce rather minor additional complexities in lake spatial shape.

### 4.3 Wind wave erosion and preferential expansion

Wind wave erosion plays an important role in horizontal expansion of shallow lakes because waves can undercut the vegetated bank (Hopkins, 1949). Wind wave asymptotically makes the water bodies (e.g. lakes and bays) round by local net sediment flux even in low latitude regions (e.g. Ashton et al., 2009). The effect of waves on shoreline morphology has been analyzed in the coastal engineering field: for example, Silvester (1974) investigated the equilibrium shape of bays under different wave conditions using laboratory wave experiments and found that the

https://doi.org/10.5194/tc-2021-192
Preprint. Discussion started: 30 August 2021

stable beach in the bay adapted a half-heart or cardioid shape for a fixed wave direction in the absence of sediment supply. Reeve et al. (2018) showed theoretically that the equilibrium coastline shape can be expressed as a diffusion type equation through incorporating the wave diffraction effect, which makes the wave crest line nearly parallel to the shore. However, according to the shallow water wave theory, which is applicable for small fetch distances on lakes in the ACP, water waves do not cause any sediment transport without current, although wave motion is a key factor for the mobilization of the sediment (e.g. Carson and Hussey, 1962).

Wind-induced water circulation in a shallow, oval lake was perhaps first analyzed by Livingstone (1954) who showed theoretically that the current around the lake ends may be accelerated efficiently by wind-induced return rip currents. However, the lake water circulation pattern assumed in his study (shown in the left side of Figure 8) was less common than the pattern described by Carson and Hussey (1962), who observed reverse circulation patterns near the lake ends, as shown in the right side of Figure 8. For convenience, we refer to two distinctive current patterns: the Livingstone type and the Carson & Hussey (C&H) type. C&H type circulation can indeed explain the commonly observed peat and sediment bars near the leeward lake side shores. Carson and Hussey (1962) noted that sedimentation on the leeward lake side can provide protection from mechanical wave erosion as well as insulation from permafrost thaw, which result in lake elongation. They also observed that preferential bank erosion is typically focused in zones oriented 50 degrees to wave approach. The return flow was found to concentrate around the windward lake side, which accelerates the mechanical erosion and sediment transport at the lake ends. However, the Livingstone type circulation might occur depending on the local wind field as it can explain the sublittoral shelf formation on the windward shore. In either case, the wind-induced current effect on lake elongation can be

https://doi.org/10.5194/tc-2021-192
Preprint. Discussion started: 30 August 2021

supported by Livingstone's theory (1954) which should be valid for both circulation types. Thus, the combination of wind wave mobilization and lake water circulation is the most accepted hypothesis for lake elongation during the relatively young shallow lake expansion stage (Carson, 1968; Arp et al., 2011, Hinkel et al., 2012).

The shallow wave theory states that the sediment mobilization due to wind wave only occurs in shallow water (wave height >4 % of water depth, e.g. Reeve et al., 2018). Therefore, the contribution of the wind wave effect to lake elongation may be reduced as the lake deepens. Figure 9 shows a plot of lake length:width ratios versus the percent of lakes with a bedfast ice regime in seven study regions in Alaska determined with satellite-based synthetic aperture radar imagery (Engram et al., 2018). The study regions represent differences in permafrost characteristics and climate that appear to be reflected in this comparison of length:width ratio and the percent of lakes in a region that freeze to their bed and thus likely do not have a sub-lake talik. For example, lakes in the Teshekpuk Lake and Kuparuk study areas have a shape that is nearly twice as long as it is wide. In both of these regions, more than 80% of the lakes freeze to their bed and likely do not have a talik. This is contrast to lakes located near Umiat and on the Seward Peninsula, that have primarily developed in Yedoma permafrost deposits. Lakes near Umiat and on the Seward Peninsula tend to be more circular (L:W = 1.3 to 1.4) and more than 90% likely have a talik since they do not freeze to their bed in the winter. The differences observed here relative to elongation of lakes and whether the region primarily has lakes that freeze to their bed or not likely demonstrates a key aspect related to the role of wind-wave erosion. In general, the shallower lakes common in coastal areas, such as Teshekpuk, Barrow, and Kuparuk, are more elongated likely due to wind wave erosion. Whereas lakes in Umiat and Inigok with a thicker ice-rich permafrost layer tends to rounder because of more rapid talik

https://doi.org/10.5194/tc-2021-192
Preprint. Discussion started: 30 August 2021

development and more subsequent subsidence. This remote-sensing based evidence implies that the wind effect seems to be limited by the lake thermal subsidence due to talik development underneath while the lake with the bedfast ice may continue elongating by the wind erosion.

## 4.4 Applicability of the 3D Stefan equation

The limitations of the derived 3D Stefan Equation (Equation 22) are summarized in this section along with Figure 6. Once a seasonal pond is formed on the permafrost, it primarily expands horizontally by wind wave erosion and the thaw slump process (Carson & Hussey, 1962; Livingstone, 1954; Rex, 1961; Hinkel et al., 2012, Grosse et al., 2013) because the active layer beneath the pond likely freezes every year. On the flat ACP of Alaska, lake thaw slump tends to be the result of topography (e.g. slope and aspect of the ground surface) while lake elongation is likely caused by wind wave erosion. As described above, preferential bank thaw at the lake ends can be explained by the insulation effect of the sediments carried by the water current (likely, the C&H type circulation) because the sublittoral shelf may be initiated at this stage.

When seasonal thawing penetrates more deeply than the annual freezing depth, a talik may be initiated, typically around the deepest point near the center of the lake (Lachenbruch et al. 1962). Sellmann (1975) described this process, which is one of the mechanisms for shelf formation in a thermokarst lake. For the horizontal expansion stage A in Figure 6, the proposed quasi-steady state thermal model may not be appropriate because the lakeshore expansion imbalance occurs at least minimally throughout the lake expansion process. However, the 3D Stefan equation may be able to characterize the talik in the initiation stage B in Figure 6.

Once the talik is established, the 3D Stefan's thermal model proposed here suggests that the talik may begin to influence lake geometry. Since sediment mobilization due to wind-driven waves

https://doi.org/10.5194/tc-2021-192
Preprint. Discussion started: 30 August 2021

The Cryosphere Discussions

occurs in shallow water, lake elongation by waves may diminish as the lake deepens via ground subsidence (Figure 9). Lake water effectively collects energy from the surface during summer and the talik stores the excess heat throughout the winter. Arp et al. (2010, 2011) and Jefferies et al. (1999) discussed the difference in heat conduction between a grounded ice lake and a floating ice lake. Their observations are generally consistent with the proposed theory because a deeper talik under a floating ice lake should have a greater heat capacity. Since lake elongation likely occurs before talik formation, the horizontal lake characterization derived in this study may not be fully applicable to the analysis of thaw lakes on the ACP. In fact, the disagreement of the talik and lake extents in Peatball Lake application illustrates the multiple effects on the lake bathymetry and orientation. Clearly, however, talik expansion and concurrent subsidence stabilizes lake geometry and contributes to lake roundness.

The applicability of the proposed 3D Stefan equation must be limited for lakes with high sediment influx and for lakes with through talik. The paired sublittoral shelves on both lake sides are commonly found in the sand dune areas of the southern ACP. The talik shape is likely altered by uneven sediment deposition that affects the temperature gradient normal to the phase boundary as mentioned by several researchers (Mackay, 1992; Hunter et al., 1981; West and Plug, 2008). The shelves created by sediment redistribution due to lake water circulation adds complexity to the ellipsoidal talik shape described in this study. Finally, if the talik penetrates through the permafrost and becomes a throughgoing talik (Hinkel and Arp, 2015), the proposed thermal theory herein is no longer applicable for thermokarst lake and talik characterization.

https://doi.org/10.5194/tc-2021-192
Preprint. Discussion started: 30 August 2021

## 5. Conclusions

The theory presented here addresses the origin of the thermokarst lake ellipticity on the ACP. Elliptic lake geometry results from minimizing overall thawing energy consumption for a given incoming energy load. This is particularly applicable for mature, deep thermokarst lakes with well-developed taliks. Additionally, existing hypothetical models were reviewed to illuminate the thermal effect on the thermokarst lake morphology.

The derived ellipsoid talik model integrates the atmospheric forcing (or incoming energy), the vertical thermal gradient, the thermal diffusivity of the permafrost, and the talik geometry. Heat flux by conduction into the permafrost depends on the heat gradient of the underlying permafrost (Fourier's law). As the vertical temperature slope diminishes with talik maturation, the depth-width ratio of the talik becomes larger creating a deeper talik; thus, much of incoming energy is likely consumed for vertical rather than horizontal expansion. Conversely, during the early stages, thermo-mechanical processes such as wind-driven wave erosion dominates horizontal expansion and elongation of the lake. Consequently, this theory elucidates how talik expansion and concurrent permafrost degradation stabilizes the shape of thermokarst lake to one that is more round rather than elliptical.

The semi-ellipsoidal 3D Stefan equation is, to our knowledge, the first geometric model explicitly derived only from the energy conservation equation at the phase boundary. The vector form of the energy conservation equation (Equation 5) in a 3D anisotropic thermal field was integrated at the phase boundary area under the isolated general-shaped lake to quantify the total energy balance. It was shown that the total lake fusion energy or lake expansion rate is equivalent to the weighted phase boundary area. The optimum talik shape function was

https://doi.org/10.5194/tc-2021-192
Preprint. Discussion started: 30 August 2021

determined by the variational principle as an extremum of the functional that minimizes the total thawing energy consumption. Thus, the resultant semi-ellipsoid equation (Equation 22) can be considered the 3D Stefan equation because it describes the optimum geometry of phase boundary.

The derived semi-ellipsoid function was applied to Peatball Lake, ACP of Alaska, where the talik was extensively surveyed using TEM soundings. The pure geometric fitting exercise met the 27 measured TEM data point well with RMSD of 5.94 m, although the talik orientation disagreed with orientation of Peatball Lake and other surrounding lakes. This may be induced by the irregularity due to the rapid and uneven horizontal lake expansion, or possibly by basin coalescence. Comparing the observed talik thickness to the observed lake bathymetry indicated two distinctive permafrost degradation scenarios: significant subsidence by near-surface ice-rich layer thaw and minor contribution of subsidence due to ice-poor permafrost thaw at depth. Consequently, lake water depth is affected by uneven subsidence of thawing permafrost, the interannual water balance; the spatial lake shape irregularity was determined during earlier stage of development. Therefore, careful consideration is required for the analysis of the relationship between lake bathymetry and talik thickness. Nevertheless, this theoretical technique can be used as guidance to partition various effects such as talik development and thaw subsidence, wind wave erosion, lake ice thickness, surficial geology type, and sediment transport by lake water current.

# Appendix A: Alternative derivation using isoperimetric inequality

Alternative derivation may provide the thermally optimum talik shape minimizing the phase boundary area A with a fixed talik volume V. Equation (14) establishes talik volume and phase boundary area under the thermokarst lake by a general function of the phase boundary $\varphi$. The

https://doi.org/10.5194/tc-2021-192
Preprint. Discussion started: 30 August 2021

horizontal coordinate system may be transformed by $(u, v) = \left(\frac{x}{\alpha_x}, \frac{y}{\alpha_y}\right)$. Then, the phase boundary can be expressed as a scaled function,

$$\hat{\varphi}(u, v) = \varphi(x, y) = \varphi(\alpha_x u, \alpha_y v), \qquad (u, v) \in \hat{B}. \tag{A1}$$

According to,

$$\begin{cases} \frac{du}{dx} = \frac{1}{\alpha_x}, \\ \frac{dv}{dy} = \frac{1}{\alpha_y}, \\ \frac{\partial}{\partial u}\hat{\varphi}(u, v) = \frac{\partial}{\partial u}\varphi(\alpha_x u, \alpha_y v) = \alpha_x \varphi_x, \\ \frac{\partial}{\partial v}\hat{\varphi}(u, v) = \frac{\partial}{\partial v}\varphi(\alpha_x u, \alpha_y v) = \alpha_y \varphi_y \end{cases} \tag{A2}$$

the talik volume and the phase boundary area can be written as,

$$\begin{cases} V[\varphi] = \alpha_x \alpha_y \iint_{\hat{B}} \hat{\varphi}\, du dv \\ A[\varphi] = \alpha_x \alpha_y \iint_{\hat{B}} \sqrt{\hat{\varphi}_u{}^2 + \hat{\varphi}_v{}^2 + 1}\, du dv = \alpha_x \alpha_y \int_{\hat{S}} d\hat{S} \end{cases}, \tag{A3}$$

where $\hat{B}$ denotes the extent of $\hat{\varphi}(u, v)$ on the $uv$ plane, and $\hat{S}$ is the surface on $z = \hat{\varphi}(u, v)$ as,

$$\hat{S} = \left\{ (u, v, z) \in \mathbb{R}^3 \,\middle|\, (u, v) \in \hat{B},\ z = \hat{\varphi}(u, v) \right\}. \tag{A4}$$

The horizontal scaling transform makes it a symmetric closed surface on $z = 0$,

$$S^* = \left\{ (u, v, z) \in \mathbb{R}^3 \,\middle|\, (u, v) \in \hat{B},\ z = \pm\hat{\varphi}(u, v) \right\}. \tag{A5}$$

It is known that volume $U$ enclosed by the ovaloid surface $S^*$ and its surface area satisfy the isoperimetric inequality for an ovaloid surface, which can be written as,

$$\left(\int_{S^*} dS^*\right)^3 \geq 36\pi U^2 . \tag{A6}$$

https://doi.org/10.5194/tc-2021-192
Preprint. Discussion started: 30 August 2021

As the volume and the surface area of the convex closed surface $S^*$ can be expressed as

$$U = 2\left|\iint_{\hat{B}} \hat{\varphi}\, dudv\right| = \frac{2}{\alpha_x \alpha_y} |V[\varphi]| \text{ , and} \tag{A7}$$

$$\int_{S^*} dS^* = 2\int_{\hat{S}} d\hat{S} = \frac{2}{\alpha_x \alpha_y} A[\varphi] \text{ , respectively,} \tag{A8}$$

we have,

$$\left(\frac{2}{\alpha_x \alpha_y} A[\varphi]\right)^3 \geq 36\pi \left(\frac{2}{\alpha_x \alpha_y} V[\varphi]\right)^2 \text{, or}$$

$$A[\varphi] \geq \sqrt[3]{18\pi \alpha_x \alpha_y (V[\varphi])^2} \text{ .} \tag{A9}$$

The equality in Equation (A9) holds only if the surface S* is a sphere, which maximizes the volume. Let the radius of this sphere,

$$D = \sqrt[3]{\frac{3}{4\pi} V} = \sqrt[3]{\frac{3|A[\varphi]|}{2\pi \alpha_x \alpha_y}} \text{ .} \tag{A10}$$

From the symmetricity to the plane $z = 0$, we can obtain,

$$\hat{\varphi}(u, v) = -D\sqrt{1 - \left(\frac{u}{D}\right)^2 - \left(\frac{v}{D}\right)^2}, \qquad (u, v) \in \hat{B} \text{ .} \tag{A11}$$

Inverse scaling coordinate transformation yields the ellipsoid phase boundary function as follows:

$$\varphi(x, y) = -D\sqrt{1 - \left(\frac{x}{\alpha_x D}\right)^2 - \left(\frac{y}{\alpha_y D}\right)^2}, \qquad (x, y) \in B \text{ ,} \tag{A12}$$

https://doi.org/10.5194/tc-2021-192
Preprint. Discussion started: 30 August 2021

where D is the depth of the talik at the center. The ellipsoid, the three-dimensional Stefan Equation for talik, can be obtained by the isoperimetric inequality as well as the functional analysis.

## Appendix B: Determination of the coefficients d and λ

We can determine two coefficients in the ellipsoid (Equation 21) by further application of the variational principle. Let

$$D = \frac{2}{|\lambda|}. \tag{B1}$$

Also, let the intersect *d* proportional to the vertical radius of the ellipsoid, as follows:

$$d = tD \quad (-1 \le t < 1), \tag{B2}$$

where *t* is a parameter describing the relative elevation of the basin to the original ground surface. Then, Equations (20) and (21) can be rewritten as,

$$z = -\varphi = -\sqrt{D^2 - \frac{x^2}{{\alpha_x}^2} - \frac{y^2}{{\alpha_y}^2}} + tD \quad \text{, and} \tag{B3}$$

$$\left(\frac{x}{\alpha_x D}\right)^2 + \left(\frac{y}{\alpha_y D}\right)^2 + \left(\frac{z-tD}{D}\right)^2 = 1\text{, respectively.} \tag{B4}$$

Now, the phase boundary area and volume can be evaluated as functions of the parameter *t*:

$$\begin{aligned} V[\varphi] &= \iint_B \varphi \, dxdy = \iint_B \left(-\sqrt{D^2 - \frac{x^2}{{\alpha_x}^2} - \frac{y^2}{{\alpha_y}^2}} + tD\right) dxdy \\ &= \pi\alpha_x\alpha_y \int_{-(1-t)D}^{0} \{D^2 - (tD - z)^2\} dz \\ &= \frac{\pi}{3}\alpha_x\alpha_y D^3 (t^3 - 3t + 2) \end{aligned} \tag{B5}$$

https://doi.org/10.5194/tc-2021-192
Preprint. Discussion started: 30 August 2021

The Cryosphere Discussions
Open Access

$$\begin{aligned} A[\varphi] &= \iint_B \sqrt{{\alpha_x}^2{\varphi_x}^2 + {\alpha_y}^2{\varphi_y}^2 + 1}\, dxdy \\ &= \iint_B \frac{1}{\sqrt{1-\left(\frac{x}{\alpha_x D}\right)^2 - \left(\frac{y}{\alpha_y D}\right)^2}}\, dxdy \\ &= \pi\alpha_x\alpha_y D^2\left\{(1-t^2) + \int_1^{\frac{1}{t}}\left(\frac{1}{z^2} - t^2\right) dz\right\} \\ &= 2\pi\alpha_x\alpha_y D^2(1-t) \end{aligned} \quad . \tag{B6}$$

Eliminating $D$ from these expressions yields,

$$A[\varphi]^3 = M\frac{(1-t)^3}{(t^3-3t+2)^2} \tag{B7}$$

where $M$ is a positive constant. Therefore, as

$$\frac{d}{dt}(A[\varphi]^3) = M\frac{3t}{(1-t)^2(t+2)^3} > 0 \qquad (-1 \le t < 1), \tag{B8}$$

the phase boundary area $A[\varphi]$ is the minimum at $t = 0$. Hence, $d = 0$ that corresponds to a semi-ellipsoid with depth $D$ at the center.

# Author contribution

Ohara and Yamatani developed the theory, and all other co-authors, especially Hinkel, Jones, Parsekian, and Kanevskiy, offered crucial advice in interpretation. Jones and Parsekian provided the field observed data for the case study of Peatball Lake. Jones performed the statistical analysis on the oriented lakes based on SAR-satellite remote-sensing data. Ohara prepared the manuscript with contributions from all co-authors.

833 Table 1: Computed incoming heat flux with the estimated parameters

| Parameter | Estimates | Unit | Note |
|---|---|---|---|
| Porosity | 0.18 | | Sandstone >15 m deep; Creighton et al., 2018 |
| Thermal conductivity of permafrost | 2.20 | W/(m·K) | From porosity and typical thermal properties of ice and mineral in this region |
| Talik depth, D | 88.0 | m | Fitted ellipsoid |
| Talik width (radius), a | 514.8 | m | Fitted ellipsoid |
| Aspect ratio, D/a | 0.1709 | | Fitted ellipsoid |
| Geothermal gradient | 0.0250 | K/m | Kessler et al., 2012 |
| dT/dz at the talik bottom | -0.0259 | K/m | From Mackay model (1962) |
| Basin average heat flux, $q_{in}$ | 0.0689 | $W/m^2$ | Computed from Equation (29) |

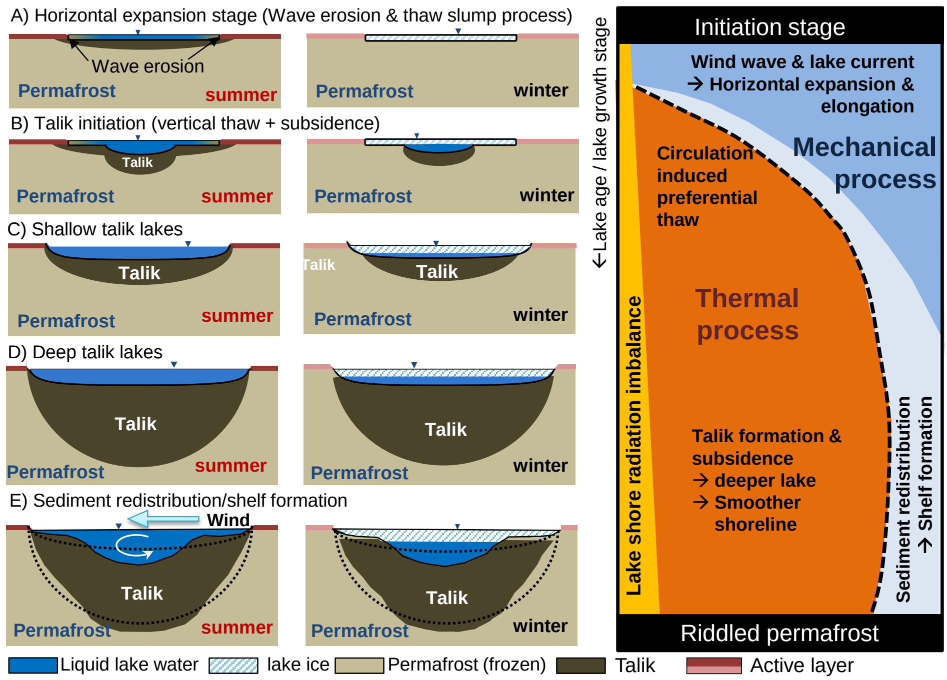

Figure 6: Combined hypothetical models of thermokarst lake evolution and diagram of major influencing factors through time. The left column represents summer conditions, the center column represents winter conditions, and the right column indicates the corresponding importance of mechanical vs. thermal processes through time as the lake ages (top is younger, bottom is older). Row (A) indicates the early processes under bedfast ice conditions before talik initiation. Row (B) shows the onset of vertical thaw and subsidence as talik begins to develop. Row (C) shows early, shallow talik growth conditions. Row (D) indicates later stage processes on deepened talik due to vertical thaw. Row (E) is the mature stage of development when complex bathymetry has set in as a result of sediment transport.

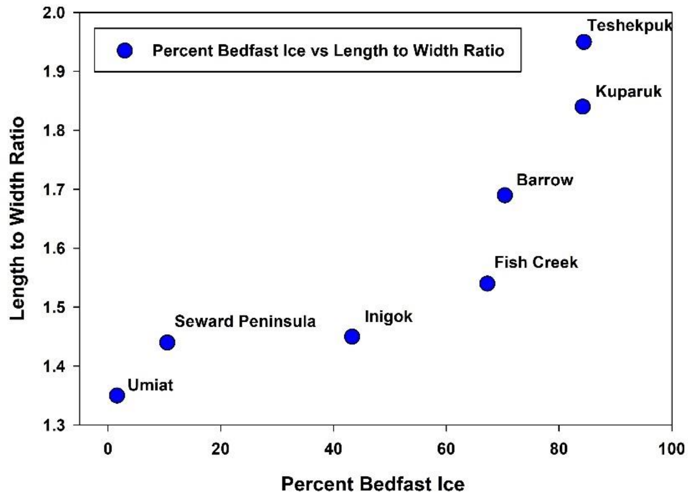

Figure 9: Comparison of Length to Width ratio versus the percent of a particular region exhibiting a bedfast lake ice regime for seven study areas in Arctic Alaska. This analysis is based on SAR-satellite remote-sensing data presented in Engram et al., 2018. Lakes that are more elliptical in shape tend to occur where the majority of the lakes in the area freeze to their bed and thus likely do not have a talik. Lakes that are more circular in shape tend to occur where the majority of lakes in an area do not freeze to their bed and thus likely have a sub-lake talik.
