**Abstract.** The crucial role that Antarctic sea ice plays in the global climate system is strongly linked to its thickness. While field observations are too sparse in the Southern Ocean Antarctic to determine long-term trends of the Antarctic sea ice thickness (SIT) on a hemispheric scale, satellite radar altimetry data can be applied with a promising prospect. European Space Agency Climate Change Initiative – Sea Ice Project (ESA SICCI) ~~includes sea ice freeboard and generates~~ sea ice thickness derived from Envisat, covering the entire Southern Ocean Antarctic year-round from 2002 to 2012. In this study, the SICCI Envisat Antarctic SIT ~~in the Antarctic~~ is first compared with an conceptually new ICESat SIT product retrieved with a from ~~an algorithm employing~~ modified ice density algorithm. Both data sets are compared to SIT estimates from upward-looking sonar (ULS) in the Weddell Sea, showing mean differences (MD) and standard deviations (SD) of 1.29 (0.65) m for Envisat-ULS (- denotes 'minus' and same as below), while we find 1.11 (0.81) m for ICESat-ULS, respectively. The inter-comparisons are conducted for three seasons except for winter, based on the ICESat operating periods. According to the results, the differences between Envisat and ICESat SIT reveal significant temporal and spatial variations. More specifically, the smallest seasonal SIT MD (with SD shown in brackets) of 0.00 m (0.39 m) for Envisat-ICESat ~~for the entire Antarctic~~ is found in spring (October-November), while larger MD (SD) of 0.52 m (0.68 m) and 0.57 m (0.45 m) exist in summer (February-March) and autumn (May-June), respectively. It is also shown that from autumn to spring, mean Envisat SIT decreases while mean ICESat SIT increases. Our findings suggest that both overestimation of Envisat sea ice freeboard, potentially caused by radar backscatter originating from inside the snow layer, and AMSR-E snow depth biases can possibly primarily ~~accounts~~ for the differences between Envisat and ICESat SIT ~~in summer and autumn, while the uncertainties of snow depth product are not the dominant cause of the differences.~~

## 1 Introduction

Antarctic sea ice plays an important role in the global climate system by reflecting the solar energy and modulating the surface water salinity (Goosse and Zunz, 2014; Massom et al., 2018; Maksym, 2019). In the context of global warming and the

30 significant declines of Arctic sea ice cover, [the](#) Antarctic sea ice [area](#)~~extent~~ has unexpectedly increased over recent decades (Zhang, 2007; Parkinson and Cavalieri, 2012; Comiso et al., 2017), but dropped to a historic low in 2017 (Turner and Comiso, 2017). However, it is still unclear if the recent increase in [the](#) Antarctic sea ice [extent](#)~~area~~ is also [accompanied by associated](#)  
35 [with](#) a similar change in sea ice thickness. Sea ice thickness combined with sea ice [a](#)~~extent~~~~area~~ is necessary to quantify the sea ice volume and sea ice mass (e.g., Kurtz and Markus, 2012; Massonnet et al., 2013). Changes in sea ice volume can influence  
the fresh water input into the Southern Ocean. Moreover, sea ice thickness is also necessary for assessing sea ice mass balance,  
[and](#)~~the~~ surface energy budget, and predicting changes in the polar climate system. Compared to the Arctic, knowledge about  
Antarctic sea ice thickness is still sparse. More accurate estimations are needed to monitor and quantify global sea ice volume  
more precisely (Connor et al., 2009), and improve sea ice components in model simulations (e.g., McLaren et al., 2006).

However, Antarctic sea ice thickness information is difficult to obtain. [One type of observation data is in-in](#)-situ measurements  
40 [providing sea ice thickness information at one fixed locations and some allowing to check the consistency over time. ~~He~~For](#)  
[example](#), drilling data (e.g., Meiners et al., 2012) are accurate but extremely limited in temporal and spatial coverage, and  
hence they cannot be used to [obtain an](#)-understanding of large-scale Antarctic sea ice thickness [processes](#)~~distributions~~. [Upward-](#)  
[looking sonars \(ULS\), located at 13 different sites in the Weddell Sea, provide valuable temporal evolutions of sea ice draft](#)  
[\(Harms et al., 2001; Behrendt et al., 2013a; Behrendt et al., 2013b\), but a basin-wide spatial distribution cannot be derived.](#)  
45 [The other type of data sets has a short durations but with high resolutions, covering comparably large regions and hence](#)  
[allowing to check the spatial variability of the sea ice thickness retrieved from satellite data.](#) Ship-based observations collected  
[by the Antarctic Sea Ice Processes and Climate \(ASPeCt\) expert group from the Antarctic Sea Ice Processes and Climate](#)  
[\(ASPeCt\)](#) (Worby et al., 2008a) can provide more spatial information than drilling, but they tend to underestimate the actual  
thickness because of visual interpretation limitations and biases due to ship routing preferably through thinner ice (Giles et al.,  
50 2008; Williams et al., 2015). In addition, airborne electromagnetic (AEM) data which [provide measure](#)-total freeboard (sea ice  
freeboard plus snow depth) were collected during expeditions like ISPOL (2004/05) (El Naggar et al., 2007), WWOS (2006)  
(Lemke, 2009) and AWECS (2013) (Lemke, 2014). Yet, the Antarctic AEM data [are](#)~~is~~ still sparse and [have](#)~~s~~ mostly been  
obtained in the Weddell Sea. The airborne remote sensing program NASA Operation IceBridge provides along-track data of  
total freeboard and snow depth estimations in the Weddell Sea and Amundsen-Bellinghshausen Sea (Koenig et al., 2010), which  
55 have been investigated in some valuable studies previously (e.g., Kwok and Maksym, 2014; Kwok and Kacimi, 2018; Wang  
et al., 2020). [Upward looking sonars \(ULS\), located at 13 different sites in the Weddell Sea, provide valuable temporal](#)  
[evolution of sea ice draft \(Harms et al., 2001; Behrendt et al., 2013a; Behrendt et al., 2013b\), but a basin wide spatial](#)  
[distribution cannot be derived. Despite covering limited regions and/or time periods, all these various observational data sets](#)  
[are extremely useful for the evaluation of models and satellite retrieval methods.](#) More recently, satellite remote sensing has  
60 been widely applied to investigate the spatial coverage and long-term trends of sea ice thickness [over](#)~~in~~ the whole [Southern](#)  
[Ocean](#)~~Antarctic~~ (e.g., Kurtz and Markus, 2012; Bernstein et al., 2015; Li et al. 2018). Passive microwave sensors are used to  
obtain thin ice thickness ([basically](#)-below 20 cm) by retrieving the brightness temperature, and are effectively applied in coastal

polynyas (Nihashi and Ohshima, 2015). Satellite altimetry, including radar and laser altimetry, has ~~also~~ been used ~~in the Southern Ocean~~ ~~Antarctic~~ to retrieve sea ice thickness (e.g., Giles et al., 2008; ~~Zwally et al., 2008;~~ Kurtz and Markus, 2012; Kacimi and Kwok, 2020) and has ~~ve~~ proven to currently be the best source for Antarctic-wide sea ice thickness retrieval over the full thickness range.

Within the framework of the Sea Ice Climate Change Initiative (SICCI) project, radar altimeter data collected by European Space Agency (ESA) satellites over the past two decades have been reprocessed and assessed. Based on these data, a new SICCI sea ice thickness data set was released in 2018 ~~as version 2.0~~, including the two radar altimetry satellites, Envisat and ~~CryoSat-2~~ ~~CryoSat-2~~ (Hendricks et al., 2018a; Hendricks et al., 2018b). ~~The SICCI product covers the entire Antarctic sea ice for the complete annual cycle from 2002 to 2017. The SICCI product covers the entire Antarctic sea ice for the complete annual cycle from 2002 to 2017, and it is finally a combined data set of Envisat and CryoSat-2~~ ~~CryoSat-2~~. Thickness-SIT retrieval from radar altimetry is based on the assumption that the dominant source of radar backscatter is the snow/ice interface (Beaven et al., 1995) and sea ice freeboard is measured by differential ranging over sea ice and ocean surfaces, illustrated in Fig. 1.

Snow affects the ~~radar altimetry SIT retrieval~~ ~~radar altimetry SIT retrievals~~ in two ways. ~~Firstly, snow depth is required to correct the radar wave speed in snow and hence to appropriately convert the radar freeboard into the sea ice freeboard, as well as to convert sea ice freeboard into sea ice thickness. Secondly, the presence of snow modifies how the radar signal is reflected by the ice-snow system. Specifically, On the one hand,~~ over Antarctic sea ice, the complex snow stratigraphy and frequent snow flooding associated with the formation of snow ice and superimposed ice affect radar altimetry measurements (Willatt et al., 2010), ~~i.e., the assumption of Beaven et al. (1995) is for DRY snow only. Besides~~ ~~On the other hand~~, the snow depth climatology used in the retrieval of Envisat and CryoSat-2 SIT can cause ~~additional uncertainties~~ ~~biases~~ due to neglecting inter-annual variability in snow depth (Bunzel et al., 2018). The SICCI Antarctic SIT data record has therefore been categorized as experimental data by the data producers compared to a more mature climate data record in the Arctic. Additional uncertainties of the radar altimeter range retrieval arise from the surface type mixing (Schwegmann et al., 2016; Paul et al., 2018; Tilling et al., 2019) and surface roughness (Hendricks et al., 2010; Ricker et al., 2014; Landy et al., 2020). Due to ~~the~~ larger footprints compared ~~with~~ ~~to~~ laser altimeters, radar altimeter measurements can be more affected by surface type mixing and surface roughness, ~~which potentially introduces additional range biases~~.

The Geoscience Laser Altimeter System (GLAS) aboard the Ice, Cloud and land Elevation Satellite (ICESat-1, hereinafter called 'ICESat') allows estimating the total freeboard ~~via through the~~ determination of the surface elevation from 2003 to 2009, illustrated in Fig. 1. This data-set has been ~~used in previous studies~~ ~~investigated~~ for many years (e.g., Markus et al., 2011; Yi et al., 2011; Kurtz and Markus, 2012; Xie et al., 2013; Kern and Spreen, 2015). ~~Several freeboard to thickness retrieval algorithms have been compared (Kern et al., 2016)~~. In contrast to radar altimetry, laser altimetry has the advantage of a well-defined reflective horizon, which is the air/snow interface. The main deficiencies of ICESat data are data gaps due to cloud coverage, and more generally the discontinuous and short observation periods. Therefore, ICESat data cannot reflect the

95 current characteristics of the fast-changing Antarctic sea ice. However, ICESat-2, which has been in orbit since 2018, provides a new source of year-round observations of total freeboard ~~and thus better coverage than ICESat~~ (Kwok et al., 2019; [Kacimi and Kwok, 2020](#)).

Both the Envisat and CryoSat-2 SIT in the ~~Antarctic~~[Southern Ocean](#) have already been evaluated with the drilling data, AEM, ULS and ship-based data (Kern et al., 2018). These evaluations are comprehensive but still have their limitations due to small  
100 spatial coverage or short temporal coverage. Thus, ~~we~~ we cannot achieve an overall understanding of the ~~ir~~ data quality ~~in the~~  
~~Antarctic~~[Southern Ocean](#). To get a better understanding of the characteristics of the SICCI product version 2.0, we aim to investigate how the SICCI Envisat ~~retrieval SIT~~ compares ~~with~~ the ICESat ~~sea ice thickness data record~~[SIT](#), also how the different ~~altimeters and~~ retrieval methods are represented in the ~~ice thickness~~[SIT](#) distribution. Based on the former inter-comparison study ([Kern et al., 2016](#)), we choose the ICESat ~~sea ice thickness data~~[SIT](#) derived from the modified ~~ice~~-density  
105 approach ~~suggested by Kern et al. (2016)~~ for comparison, which seems to agree with independent observations and has a reasonable winter-to-spring growth (Kern et al., 2016). Furthermore, in order to evaluate the ICESat and Envisat data ~~records~~ in the Weddell Sea, we also compare both ~~sea ice thickness~~[SIT](#) records with the Weddell Sea ULS data first.

The study is organized as follows. In section 2, we describe the data used in this study in detail. Section 3 presents the results of both the Weddell Sea ULS data validations and the inter-comparisons between the two ~~satellite~~ data sets. Potential reasons  
110 for the spatial and temporal ~~deviations differences~~ are discussed in section 4. The main ~~conclusions results~~ are summarized in section 5 ~~with further discussions~~.

## 2 Data and methods

### 2.1 Sea ice thickness from Envisat / RA-2

~~The ESA CCI Sea Ice Climate Change Initiative (SICCI)~~ provides a set of Antarctic sea ice freeboard and thickness data  
115 (Hendricks et al., 2018b) obtained from the satellite missions Envisat (2002–2012) and CryoSat-2 (2010–2017). With 50-km grid resolution and monthly temporal resolution, there is a successive year-round record for Antarctic sea ice freeboard and thickness on Equal-Area Scalable Earth (EASE) grid. Since only Envisat shares overlapping periods with ICESat, we focus on the ~~measurement~~ characteristics of the Envisat radar altimeter. Envisat was launched on 01 March 2002 and the mission ended on 08 April 2012. The Radar Altimeter 2 (RA-2) aboard ~~on~~ Envisat is a nadir-looking pulse limited sensor operating at  
120 the main frequency of 13.575 GHz (Ku-Band), with a secondary frequency of 3.2 GHz (S-Band) compensating the ionospheric error (Zelli and Aerospazio, 1999). It has an orbit inclination of 98.55° (~~Paul et al., 2017~~), covering the ~~full whole ice covered~~ Southern Ocean and nominal circular footprints of 2–10 km in diameter ([Peacock and Laxon, 2004](#); Connor et al., 2009; ~~early 2000s~~). Because the RA-2 is the only altimeter carried by Envisat, we refer to it as Envisat hereafter.

The Envisat radar freeboard is retrieved based on the radar ranges obtained from RA-2 Level-1 waveform data over ice surface and leads between ice floes. Ideally, the signal will return at the interface between snow and ice based on the experience from laboratory work (Beaven et al., 1995). Then, snow-depth dependent radar signal delay is applied to convert the radar freeboard into the sea ice freeboard. ~~The delay correction is based on a conventional assumption that has been revised (Mallett et al. 2019) since the generation of the SICCI data.~~ The illustration of sea ice freeboard is shown in Fig. 1, which is the sea ice surface elevation relative to the sea surface elevation. Sea ice thickness is retrieved from sea ice freeboard based on the hydrostatic equilibrium approach as first used by Laxon et al. (2003), ~~which who applying this method to on ERS altimetry data, i.e. which is the predecessor of the Envisat RA-2 instrument:~~

$$I = \frac{F\rho_{water} + S\rho_{snow}}{\rho_{water} - \rho_{ice}} \quad (1)$$

where  $F$  represents Envisat sea ice freeboard,  $S$  represents snow depth,  $I$  represents sea ice thickness,  $\rho_{water}$ ,  $\rho_{snow}$ ,  $\rho_{ice}$  refer to the densities of the sea water, snow cover and sea ice, respectively. A snow depth climatology (based on 2002-2011) is employed to retrieve sea ice thickness from sea ice freeboard here (Markus and Cavalieri, 1998; Comiso et al., 2003). This snow depth climatology is derived from the passive microwave sensor Advanced Microwave Scanning Radiometer-EOS (AMSR-E) and AMSR 2 data for the Antarctic and is based on a revised ~~version of the~~ approach with different tie point retrieval plus addition of retrieval errors described by Cavalieri et al. (2014) and provided by the Integrated Climate Data Center (ICDC, ~~https://www.cen.uni-hamburg.de/icedc~~ <http://icedc.cen.uni-hamburg.de>).

In addition, it is noted that Envisat sea ice thickness represents the actual SIT (i.e., ~~ice mean thickness~~ [SIT](#) of the ice-covered fraction of the grid cell area) and values with sea ice concentration ([SIC](#)) less than 70 % have been removed during Envisat SIT retrieval.

## 2.2 Sea ice thickness from ICESat / GLAS

ICESat, operating as part of NASA's Earth Observing System, provides a set of Antarctic total freeboard data from 2003 to 2009. Different from the sea ice freeboard measured by radar altimeters, laser altimeters allow to detect the distance between the snow surface and sea surface, ~~which is called total freeboard~~, as shown in Fig. 1. ICESat measurements are characterized by ~~conducted with~~ laser footprints of ~70 m and sampling distances of 170 m (Kwok et al., 2004). However, the measurements are not continuous due to cloud coverage and each measurement campaign lasted for about 35 days (see Fig. 3 in Kern and Spreen, 2015). There are several ICESat ~~sea ice thickness~~ [SIT](#) data sets derived from different retrieval algorithms. Qualitative inter-comparisons have been done among several ICESat freeboard-to-thickness retrieval approaches (Kern et al., 2016). According to the ~~ir~~ conclusions of Kern et al. (2016), we choose the product derived with the modified ~~ice~~ density approach in this study, because of its reasonable winter-to-spring increase and better agreements with independent data. The data set is provided by ICDC on the polar-stereographic grid. The approach considers the snow-ice layer as one system with a modified

155 density, in order to avoid using a potentially biased snow depth product. According to Kern et al. (2016), the modified density can be derived as follows:

$$\rho_{ice}^* = \frac{R\rho_{ice} + \rho_{snow}^*}{R + 1} \quad (2)$$

where  $R$  is the ratio of sea ice thickness over snow depth, which is a seasonally dependent factor and calculated from ASPeCt observations (Worby et al., 2008a). And ~~sea ice total~~ thickness (~~actually~~ sea ice thickness plus snow depth) can be determined from it:

160

$$I = F \frac{\rho_{water}}{\rho_{water} - \rho_{ice}^*} \quad (3)$$

where  $F$  represents ICESat total freeboard. [Although this method cannot obtain the real SIT, it still extracts the SIT information to a large extent. Meanwhile, we will discuss the biases caused by this method in Sect. 4.](#)

The Antarctic mean gridded ~~sea ice total~~ freeboard and effective sea ice thickness (i.e., mean thickness per grid cell including open water areas) with a grid resolution of 100 km from 2004 to 2008 are provided in this product. Table 1 presents the available time periods of [this data set](#). It is noted that grid cells with ~~sea ice concentration~~ SIC less than 60 % have been removed for the ICESat SIT retrieval.

### 2.3 Sea ice thickness from Weddell Sea ULS

The upward-looking sonars (ULS) located in the Weddell Sea provide long-term and high-frequency sea ice draft at each site (Behrendt et al., 2013a; Behrendt et al., 2013b). The ~~sensors moorings are deployed at more than 900 m underwater,~~ transmitting sound pulses upwards with a footprint of 6–8 m in diameter ~~and~~. The signals are reflected either by the sea ice bottom or the sea surface, yielding two-way ~~distances based on the~~ travel time [which can be converted into distances](#). The sea ice draft, which is the depth of the sea ice underwater, can consequently be derived from the difference of the two distances, shown in Fig.1. The ~~measurement intervals~~ of sea ice draft ~~measurements are between were collected 3 and 15 minutes once several minutes~~ from November 1990 to March 2008. In this study, we use the monthly average sea ice draft [from 2004 to 2008](#) at three sites, corresponding to Envisat and ICESat operating time. According to Behrendt (2013), the uncertainty of sea ice draft ~~varies vary~~ from 5 cm to 12 cm, depending on the seasons. ~~The uncertainty in summer is smaller than in other seasons because open water occurs more frequently in the ULS footprint and with that thus the estimate of the sea surface height is more accurate. The uncertainty in summer is smaller than in other seasons because the frequent leads or open water in summer provides the benchmark for sea surface height calibration.~~ The mooring locations used in this study are shown in Fig. 2. ~~We choose the sea ice draft measured from 2004 to 2008 to cover the ICESat periods in this study.~~ Sea ice thickness ( $z$ ) is converted from the sea ice draft ( $d$ ) through an empirical formula established from drilling data in the Weddell Sea (Harms et al., 2001):

$$z \text{ (m)} = 0.028 + 1.012d \text{ (m)}. \quad (4)$$

This empirical equation is based on the assumption that the snow depth values from drillings and ULS are comparable. But it still bears the uncertainties from the production of slush and snow ice caused by flooding (Harms et al., 2001). All the SIT data used in this study have been summarized in Table 2.

#### 2.4 Dynamic freezing-degree-days (FDD) Meteorological data

In this study, we use 2-m air temperature data ~~derived~~ from ERA-5 reanalysis (Hersbach et al., 2019) to generate the accumulative ~~freezing degree days~~ (FDD). FDD is calculated by daily degrees below freezing summed over the total number of days when the temperature was below freezing point. Here the freezing point is set to -1.8 degrees Celsius for ocean water.

Since FDD only accounts for the thermodynamic thickening and neglects SIT changes from snowfall, freezing rain or ridging, we add sea ice motion data and convert it to a dynamic FDD. The NSIDC Polar Pathfinder daily 25 km EASE-grid sea ice motion data (Tschudi et al., 2019) are applied to produce the forward tracking on daily FDD and generate a more realistic FDD field.

We compare the dynamic FDD with the SIT variations ~~from summer to autumn~~ February/March to May/June ~~during (MJ-FM)~~ (FM-MJ) and ~~from May/June-October/November~~ ~~autumn to spring~~ (ON-MJ) (MJ-ON) represented by Envisat and ICESat SIT. Specifically, MJ-FMFMJ represents the differences between that mean FDD/Envisat SIT/ICESat SIT in MJ minus that and mean FDD in FM following consistent with ICESat operating periods and so does ON-MJMJON. Note that FDD only accounts for the thermodynamic thickening and neglects SIT variations ice growth from snowfall, freezing rain or ridging.

#### 2.5 Spatial and seasonal divisions

The comparisons are realized in different seasons and different sectors by considering the differences between the two sea ice thickness SIT data sets in different seasons and different sectors. The seasonal classification is based on the ICESat operating periods presented in Table 1 following Kurtz and Markus (2012). For each ICESat operating period, we choose the corresponding time period during which Envisat monthly data are used, also given in Table 1. We employ a time-weighted average of the monthly Envisat data to match the ICESat period. For example, considering the ON04 period from Oct 3 to Nov 8 in 2004, which is 37 days long – 29 days in October and 8 days in November. ~~So~~ we calculate the corresponding Envisat SIT as:  $SIT_{ON04} = (29/37) * (SIT_{October}) + (8/37) * (SIT_{November})$ . The weighting has taken into account periods where only Envisat SIT of one month are present, i.e., w We use this weighing equation only for grid cells where we have valid Envisat SIT data from exist in both months, while the weighing is not conducted we only use the Envisat SIT of the respective month without weighing for those grid cells where we valid data only exist in either one month have valid data from either month. It is noted that this approach can lead to considerably larger coverage with of Envisat SIT data than ICESat when Envisat SIT maps show

~~data of the entire month into which an ICESat period overlaps, e.g., summer 2005 (Ross Sea) or 2007 (several regions) in Fig. 5.~~

215 ~~Besides,~~ Antarctic sea ice characteristics differ remarkably in different areas in the Southern Ocean. Therefore, we divide it into six sectors (Fig. 2) following Worby et al. (2008a) and discuss the differences for each of them.

### 3 Results and discussion

#### 3.1 Comparisons with Weddell Sea ULS

220 Before the inter-comparison between Envisat and ICESat SIT, both of them are compared with ULS observations ~~first~~. The ULS sea ice draft has been converted into monthly sea ice thickness data with Eq. (4) in Sect. 2.3. Both Envisat and ICESat SIT have been interpolated onto each ULS location in the nearest neighbour way. We here compare Envisat and ICESat actual SIT with ULS observations. ~~Therefore, thus,~~ we ~~exclude zero thickness measured by ULS in the statistical calculations and~~ divide ICESat SIT by ~~the sea ice concentration~~ SIC contained in the data for each grid. The ~~sea ice concentration~~ SIC data are derived from Special Sensor Microwave/Imager (SSM/I) and Special Sensor Microwave/Imager Sounder (SSM/IS) ~~based on~~ ASI algorithm provided by ICDC (Kaleschke et al., 2001; ~~https://www.cen.uni-~~ [https://www.cen.uni-](https://www.cen.uni-hamburg.de/en/icdc/data/cryosphere/seaiceconcentration-asi-ssmi.html) ~~http://icedc.zmaw.de/~~ [hamburg.de/en/icdc/data/cryosphere/seaiceconcentration-asi-ssmi.html](https://www.cen.uni-hamburg.de/en/icdc/data/cryosphere/seaiceconcentration-asi-ssmi.html) with ~~25~~ 12.5 km spatial resolution, interpolated to 100 km grid NSIDC polar-stereographic grid and averaged over respective ICESat measurement periods.

230 During ICESat operating periods, there are only three sites with valid data for the comparison: 207, 229 and 231 (~~see also shown in~~ Fig. 2). The sites can be divided into two regions. Site 207 is near the coast of the Antarctic Peninsula, mostly characterized by perennial ice, while the others belong to the eastern Weddell Sea, predominantly characterized by first-year ice. The corresponding time periods of each SIT product ~~during the comparison~~ are listed in Table 3.

235 Figure 3 presents the time series of sea ice thickness for Weddell Sea ULS, Envisat and ICESat at each site. Due to the operating period gaps and lack of valid data along the coast, ICESat only provides a limited number of measurements for comparison. The ~~gaps of~~ Envisat ~~SIT gaps~~ originate from grid cells with ~~sea ice concentration~~ SIC below 70%, or missing data caused by failure of retrieval or instrument. ~~The error bars show the uncertainty estimates from the SIT products. We provide error bars of uncertainty information contained in both SIT products. The~~ Envisat SIT uncertainties ~~are is~~ computed as the error propagation of all input uncertainties with the assumption that the sea water density is negligible (see Section 2.9.8 in Paul et al., 2017). ICESat SIT uncertainties are ~~also~~ calculated based on the uncertainties of ~~sea ice density and snow density~~ densities and freeboard, ~~also neglecting the uncertainty of water density (see Eq. (6) in Li et al., 2018 Kern et al., 2016).~~ ~~We also add the~~ ULS uncertainty of  $\pm 0.05$  m following Belter et al. (2020). ~~It is noted that the corresponding time of each ICESat SIT point is placed between the two months that each period covers in Fig. 3.~~ We find that ~~both either~~ Envisat ~~and or~~ ICESat SIT ~~are is~~ not

consistent with the sea ice thickness observed from ULS. In the western Weddell Sea, along the coast of the Antarctic Peninsula (at site 207), the ULS thickness ranges between 0 and 1.5 m, without a clear seasonal cycle. Envisat thickness exceeds ULS, with a maximum value larger than 5 m, and ~~the~~ the relatively large error bars ~~only~~ cover ~~part of the few~~ observations. In comparison, ICESat thickness also exceeds ULS and the smaller error bars of ICESat also ~~do not~~ cannot cover the observations. In the eastern Weddell Sea (at sites 229 and 231), ICESat has a few overestimations while Envisat has larger overestimations, but the Envisat error bars cover almost all the observations. The ~~large~~ differences in the error bars between Envisat and ICESat mainly result from the inclusion of ~~uncertainties of sea ice freeboard and~~ snow depth ~~uncertainty in Envisat SIT, and lack of adequate regards for potential correlations between the error contribution in Envisat SIT while these this is~~ are not considered for ICESat SIT uncertainties. In the eastern Weddell Sea (at sites 229 and 231), ICESat does not capture grid cells where the ULS ice thickness is smaller than 0.5 m, while having a few overestimations on thicker ice. In comparison, Envisat has larger overestimations, but the error bars can cover almost all the observations. However, since many contributions are not well characterized and quantified, it is difficult to estimate realistic uncertainties. Table 4 shows the MDs, SDs ~~and~~, root mean square deviations (RMSDs) for Envisat-ULS and ICESat-ULS, and the numbers of comparison pairs. The Envisat and ULS SIT are all time-weighted processed and the calculations are conducted when all three products have valid data. The statistics show that both MDs are largest at site 207 ~~the mean differences of ICESat-ULS and Envisat-ULS are all large at three sites. At site 207, the differences are~~ (1.63 m for Envisat-ULS and 1.73 m for ICESat-ULS) and smallest at site 229. The respective differences are (0.72 m for Envisat-ULS and 0.42 m for ICESat-ULS at site 229), ~~while at site 231 are 1.11 m and 0.55 m.~~ However, the numbers of valid data are too small to derive a reliable conclusion on the accuracy of ~~both products~~ ICESat. The comparison is based on more data pairs for Envisat, but the agreement of the seasonal cycle between ULS and satellite data sets is bad qualitatively (Fig. 3).

The uncertainties of such comparisons cannot be ignored. The ULS measurements are recorded at fixed locations with approximately 6–8 m footprint in diameter, while Envisat (ICESat) has a footprint of 2–10 km (70 m) and the SIT data used in the comparison represents mean values over 50 km (100 km) grid cells. ~~The~~ The large resolution differences can increase the selection biases. When the ULS measures a single point like a ridge or the edge of thin ice, satellites will survey a large area, ~~which is represented in the SIT retrieval.~~ In addition, though the ULS SIT and satellite SIT are all monthly mean values, one ~~satellite~~ ICESat SIT grid cell is scanned ~~only~~ once or twice on most occasions through a measurement period month (see Fig. 3 in Kern and Spreen, 2015). Averages based on such a small number of measurements ~~population~~ has a limited representation of the mean SIT throughout the whole month. Theoretically, the more valid measurements exist in one grid cell, the more accurate the mean SIT is. In general, uncertainties from both spatial interpolation and temporal representation can affect the comparisons. However, considering the typical sea ice motion (Drucker et al., 2011) in the Weddell Sea, monthly average ULS SIT could be referred to as a spatial average value, representing 100 km around the fixed ULS positions. According to With the sea ice motion data from NSIDC introduced in Sect. 2.4, the 30-day origins of the sea ice passing the three ULS sites in

July 2011 sea ice drift is shown in Fig. S1 and it proves the heterogeneity of sea ice measured by each ULS and the validity of ULS data usage in comparison with satellite products.

### 3.2 Inter-comparisons between Envisat and ICESat

We first conduct an overall comparison between Envisat and ICESat effective SIT for each ICESat operating period in each season, as shown in Fig. 4–6. The effective Envisat SIT is calculated by multiplying the SIC contained in the data for each grid from OSI-SAF Global Sea Ice Concentration (OSI-409) and the OSI-SAF Global Sea Ice Concentration continuous reprocessing offline product (OSI-430) (<http://osisaf.met.no>). The inter-comparisons are carried out by linearly interpolating Envisat SIT onto the ICESat polar-stereographic grid with 100 km grid resolution. The figures results suggest that there are substantial inter-seasonal and interannual differences between the two SIT data sets.

In spring (ON), both positive and negative differences exist between Envisat and ICESat SIT (Env-ICE), shown in Fig. 4. Envisat and ICESat SIT are both able to capture the thick ice located in the western Weddell Sea and the Bellingshausen and Amundsen Sea. Deformed sea ice near along the coast of the western Pacific Ocean is also detected by both sensors, but is thicker than the ship-based observations (Worby et al., 2008a). Thin ice in the Ross Sea is not captured by Envisat. Envisat does not show the young ice in the Ross Sea (Kern et al., 2018) while the Ross Ice Shelf polynya (which is indicated in Fig. 2) is present in the ICESat maps. The same feature is found for Similarly, the Ronne Ice Shelf polynya in the Weddell Sea in 2007, with the polynya appearing only on the ICESat map in 2007 but not on Envisat map. ICESat map has There is a fringe with no data along most of the East Antarctic coast, which indicates that the 100 km ICESat product possibly fails to see the sea ice close to the coast. This can be attributed to a different land mask used in the ICESat product and consideration of less accurate total freeboard there. Using a 100 km grid naturally results in a land mask at the same grid resolution and it is very likely that the land mask used in the ICESat product extends further into the open ocean than the landmask which is used in the Envisat product. Besides, as stated in Kern and Spreen (2015), it is not overly bad to not take ICESat freeboard estimates close to the coast not into account because there the freeboard often is less accurate here compared to the open ocean due to various issues, mostly because of a lack of enough open leads detected by ICESat and hence a less accurate approximation of the local sea surface height and with that less accurate total freeboard. Table 5 provides the respective SIT and their SDs, differences, RMSDs, correlation coefficients (CCs) and the numbers of comparison pairs. In general, the difference between Envisat and ICESat spring SIT is close to zero, ranging from -0.16 m in 2006 to +0.10 m in 2007. However, these differences have to be seen in the light of the standard deviations large SDs of (~0.6 m) some of the differences between Envisat and ICESat SIT may not be significant, because the SDs are ~0.6 m while the differences are near zero. The RMSD for seasonal average comparison is the smallest by 0.39 m among three seasons and the correlation coefficient CC is 0.68, with the significance larger than 95%. Note that we calculate the seasonal mean values only with valid data that are available for at least three years and from the average map.

305 At the end of summer melt (FM), the ice coverage is limited to the western Weddell Sea, Bellingshausen-~~and~~ Amundsen Sea along the coast and southern Ross Sea (Fig. 5). In the western Weddell Sea, Envisat shows that thick ice still exists and remains at least 3 m, while ICESat shows thinner ice. As for the Ross Ice Shelf polynya, ICESat displays thin ice lower than 1 m ~~there~~ in 2004, 2007 and 2008, while in 2005 and 2006 the data is missing due to low ~~ice concentration~~ SIC. Envisat detects sea ice in the Ross Sea all the years, but with thickness estimates of up to 1.5 m, much larger than expectant seasonal ice thickness.

310 According to Table 5, the numbers of comparison pairs are small. Generally, Envisat SIT exceeds ICESat SIT by 0.52 m in summer, with the largest RMSD by 0.68 m and the smallest correlation values by 0.40 among the three seasons.

In autumn (MJ), ~~the thickness~~ SIT patterns of the two data sets are comparable, shown in Fig. 6. The differences between Envisat and ICESat SIT are consistently positive over all regions except some regions in the Eastern Antarctic, ~~probably inferring that ICESat is more sensitive to thick ice than Envisat, i.e., higher spatial resolution is better able to resolve thick ice~~.

315 Compared ~~to~~ with summer, the positive differences in the western Weddell Sea ~~spread~~ expand to positive differences over the whole Weddell Sea sector, and the differences decrease from west to east. In addition, ~~the~~ positive differences in the Ross Ice Shelf polynya still exist, mostly due to Envisat's inability to capture the thin ice there (Comiso et al., 2011; Tian et al., 2020), which has been pointed out in Kern et al. (2018) identifying a substantial SIT difference between Envisat and CryoSat-2 in that region. According to Table 5, ~~despite the largest the~~ mean difference ~~in autumn is the largest by of~~ (0.57 m), ~~with and large~~ RMSD ~~by of~~ (0.47 m), ~~the correlation in autumn is actually the highest of the three seasons investigated and the largest CC of by~~ (0.71).

320

To investigate the development of ~~sea ice thickness from two satellites~~ two SIT data from the end of melting to end of freezing, we provide the probability distribution of the Envisat SIT and the ICESat SIT for all the valid individual comparison pairs, shown in Fig. 7. The mean and modal ~~ice thickness~~ SIT of both data sets are marked beside. In summer, the agreement between Envisat ~~has a positive difference with respect to~~ SIT and ICESat SIT is not good, mainly due to their different performances ~~on towards~~ thick ice above 3 m. Envisat still presents a larger mean and modal thickness than ICESat in autumn ~~with similar distributions~~. In spring, the two data sets ~~coincide with each other~~ have similar distributions, represented by ~~closer~~ similar mean and modal thicknesses. ~~In addition, We~~ find that ICESat mean SIT increases while Envisat mean SIT decreases from autumn to spring. For Envisat SIT, the distribution indicates that more thin ice is present in spring than autumn, while for ICESat SIT more thick ice is found. Therefore, we further compare the SIT variations from summer (FM) to spring (ON) with the dynamic FDD results in 2004, 2005 and 2006, shown in Fig. 8 and Table 6. We conduct the forward tracking on daily FDD with the NSIDC sea ice motion data to add the dynamic effects on the purely thermodynamic growth pattern. We use FDD rather than converted SIT with an empirical equation because they represent the same mechanism and we cannot constrain the uncertainties sufficiently caused by additional assumptions. As introduced in Sect. 2.4, this indicator only represents thermodynamic growth and neglects any dynamic contributions to sea ice thickness. We calculate the period-average SIT from the model corresponding to ICESat operating periods for the same spatial coverage. The results show that As both satellite

325

330

335

products present decreasing SIT in the southern Weddell Sea and increasing SIT in the northwest Weddell Sea during FMMJ. Envisat SIT ~~has~~ shows more thinning all around the Southern Ocean and ICESat SIT generally shows more thickening ~~opposite~~ developments from ICESat and FDD during MJ-ON, ~~while shares similar variations during FM-MJ. Both products present~~ decreasing SIT in Ronne Ice Shelf polynya and increasing SIT in the northwest Weddell Sea from FM to MJ. This pattern is probably formed through thin ice produced in the Ronne Ice Shelf polynya combined with the typical sea ice drift in the Weddell Sea (Drucker et al., 2011). The thick ice found in the southwestern Weddell Sea at the end of summer is advected northward and the thick old ice is replaced by the thin younger ice formed in the polynya and other comparably thin ice that is recirculated from the Eastern Weddell Sea in winter. The adverse patterns from MJ to ON infer that a lot of SIT changes during this time are caused by deformation processes and snow ice formation, and both products have different abilities to reveal them. Since the dynamic FDD cannot reproduce these patterns, more mechanisms like snowfall/flooding, ridging/crack and some ice-ocean feedbacks should be examined for further study. However, one thing we can give a speculation based on the analyses in autumn and the regular rule during freezing seasons is that the main reason for Envisat SIT overall decrease during MJON is the overestimation of Envisat SIT in autumn.

Figure 9 presents scatterplots of the individual data-comparison pairs between Envisat SIT and ICESat SIT for each region and each season. ~~The r~~Respective ~~correlation coefficient~~CCs and RMSDs are indicated in the panels. Due to the limited measurements in the Indian Ocean and western Pacific Ocean, we combine them into the whole Eastern Antarctic. For all five ~~panels~~sectors, ~~the regression lines have large positive intercepts in all three seasons, indicating that~~ Envisat SIT tends to exceed ICESat SIT ~~for on~~ thin ice. From Fig. 9a, we can see that in the western Weddell Sea, the summer and autumn ~~sea-ice thickness~~SIT ~~splashes~~cloudsdots exceed the spring ones. This reveals that ~~mean~~ICESat SIT are nearly constant through all three seasons in the western Weddell Sea, while ~~mean~~Envisat SIT are noticeably larger in summer and autumn, ~~which can also be seen from the statistical results~~ shown in Table 7. From FM to ON, Envisat SIT changes from 3.01 m to 3.18 m to 2.23 m, while ICESat SIT changes from 2.04 m to 2.28 m to 2.23 m. ~~The numbers in the last column of the table are the weighted average, taking into account the actual number of values per season.~~ Considering the regional average differences between Envisat and ICESat SIT, the largest (0.63 m) is found in the western Weddell Sea and the smallest is in the Bellingshausen- and Amundsen Sea (0.09 m). Differences are small in spring for ~~most all~~ regions except Eastern Antarctic, ~~just as the seasonal results shown in Table 5. Regarding the spatial correlation,~~ the largest ~~coefficients~~CC are ~~is~~ found in autumn Bellingshausen- and Amundsen Sea (0.5458) and the smallest is in the western Weddell Sea and autumn Ross Sea by 0.36(0.1).

#### 4 Potential reasons for the differences

There are two main differences between the two data sets. One is the different ~~altimeter~~sensors to determine surface elevation and freeboard. Envisat is equipped with a Ku-Band radar altimeter (RA-2), whose backscatter is assumed to originate from the snow/ice interface, ~~though~~ it is known that this assumption is flawed for snow that is ~~not drywet~~, not cold and without a

homogeneous stratigraphy (Willatt et al., 2010). Instead, ICESat is equipped with a laser altimeter (GLAS) whose signals are reflected from the air/snow interface. In addition, considering the Envisat large pulse-limited footprint of the radar altimeter of about 2–10 km and smaller footprint of ICESat laser beams of about 70 m, there are very likely differences in the ability to resolve leads or open water required for an adequate representation of the local sea-surface height during the freeboard retrieval, as well as in the accurate representation of heterogeneous sea ice surfaces. The other difference is that they apply different retrieval algorithms to convert freeboard into thickness. Envisat directly uses the hydrostatic equilibrium with an extra AMSR-E snow depth climatology product, while ICESat also uses the hydrostatic equilibrium but accompanied with a modified snow-ice density method to reduce the influence of the often regionally biased snow depth product. The effects of these differences between both products are discussed in the following.

#### 4.1 Differences due to sensors

It is assumed that the dominant backscatter horizon for a Ku-Band radar altimeter is the snow/ice interface for cold and dry snow (Beaven et al., 1995). However, this would not always be the case in the Antarctic Southern Ocean, according to the field investigations conducted by Willatt et al. (2010). They demonstrate that the dominant scattering surface of the Ku-Band radar lies within the snowpack, usually half of the mean snow depth, when the snow cover is not cold and dry. Wet conditions can affect the dielectric properties of snow and then decrease-weaken the penetration of radar altimeter signals into the snow. Another common property of snow in the southern hemisphere occurs when snow cover gets thicker and depresses sea ice below the sea surface, seawater intrudes towards the base of the snow layer and before the slush freezes, the existence of wet snow will cause the extinction of signals from ice layer (Massom et al., 2001). Consequently, RA-2 range measurements could be biased high when the main scattering horizon is located within the snow pack, above the snow/ice interface, which will lead to larger sea ice freeboard and larger sea ice thickness. The salinity of the basal snow layer also contributes to this effect (Nandan et al., 2017). Such The existence of this biases are also shown by Kwok and Kacimi (2018), where they find that radar freeboards from CryoSat-2 are consistently higher than those computed using Operation Ice Bridge (OIB) measurements. Other studies that utilize CryoSat-2 radar data in the southern hemisphere have thus explicitly incorporated radar backscatter from the snow layer into their freeboard retrieval method (Fons and Kurtz, 2019).

Assuming the total freeboard derived from ICESat and the snow depth product used in the retrieval of Envisat SIT as a reference, we can calculate the sensitivity of Envisat SIT ( $I$ ) to the sea ice freeboard ( $F$ ) caused solely by the offset of the radar main reflecting horizon can be calculated from Eq. (1):

$$\frac{dI}{dF} = \frac{\rho_{\text{water}}}{\rho_{\text{water}} - \rho_{\text{ice}}} \quad (5)$$

We set  $\rho_{\text{water}}$  to  $1024 \text{ kg m}^{-3}$  and use  $\rho_{\text{ice}}$  between  $880$  and  $916.740 \text{ kg m}^{-3}$  to cover all mixed types of sea ice. Table 8 Figure 10a illustrates the sensitivity of the sea ice thickness changes in response to sea ice density and sea ice freeboard biases between 2 and 10 cm in steps of 2 cm. We can see that SIT changes range from 14 cm to 122 cm with different freeboard biases and

density in our experiment. With the increase of freeboard biases/sea ice density, SIT changes become larger. Under larger  
400 freeboard bias conditions, SIT changes climb faster as density rises. For typical sea ice freeboard biases (7 cm for the Arctic  
nominal adjustment suggested by Nandan et al. (2017, 2020)), the sea ice density variations induce the thickness changes  
ranging from ~0.5 m to ~0.8 m. This could potentially account for the differences between Envisat and ICESat SIT in summer  
(0.52 m) and autumn (0.57 m). Therefore, we assume that in summer and autumn freeboard-biases-induced SIT changes  
happen frequently. However, we cannot exclude the possible occurrences in spring since the SDs are large. Detailed  
405 sensitivity discussions are limited due to lack of the seasonal and regional sea ice density and adjustments to sea ice freeboard.

In addition to the different penetration depths, the two sensors have different footprints. Envisat is a pulse-limited radar  
altimeter with a large footprint of 2–10 km and ICESat is a laser altimeter with a small footprint of about 70 m. This makes  
them sensitive to a relative selection bias, primarily on the side of the altimeters with the lower resolution in the case of surface-  
type mixing within the footprint, especially if the different surface types vary in their backscatter properties. Higher spatial  
410 resolution will mitigate this issue and subsequently allow a better classification of lead and sea surface height retrieval in  
principle. Several studies have pointed that Envisat freeboard and thickness uncertainties are elevated with respect to other  
sensors due to sub-footprint scale surface type mixing (Schwegmann et al., 2016; Paul et al., 2018; Tilling et al., 2019). While  
this is also directly applicable to radar altimeters with different footprints, the difference of lead detection skill between laser  
(ICESat) and radar (Envisat) altimeters is not directly a function of footprint size but also of altimeter concept. Leads amplify  
415 radar backscatter and thus cause over-representation, while the laser backscatter is a function of the surface albedo thus leads  
return lower laser backscatter power. For different ice surfaces, however, the smaller footprint of ICESat has the capability to  
provide more detailed observations in areas with heterogeneous ice conditions than the pulse-limited Envisat footprint.

#### 4.2 Differences due to ~~AMSR-E~~ snow depth

~~According to the retrieval algorithms applied by the two data sets described in Sect. 2, one of the largest uncertainties may~~  
420 ~~come from~~ Another source of the differences is the ~~biased~~ AMSR-E snow depth. AMSR-E snow depth is retrieved from  
brightness temperature based on the linear relation between brightness temperatures and ~~in-~~in-situ observations (Markus and  
Cavalieri, 1998; Comiso et al., 2003). According to Markus and Cavalieri (1998), their AMSR-E snow depth product masks  
out perennial ice and is limited to the maximal retrieval value being around 50 cm because of the similar radiometric signature  
of deep snow and multiyear ice (Comiso et al., 2003). Previous studies ~~reveals show~~ that AMSR-E snow depth tends to  
425 considerably underestimate the actual value over deformed sea ice, which usually occurs in the Eastern Antarctic (Worby et  
al., 2008b; Ozsoy-Cicek et al., 2011). According to Frost et al. (2014), ~~the differences that~~ AMSR-E snow depths minus the  
ASPeCt observations ~~is are~~ positive for snow below 15 cm and negative for snow above 30 cm. Environmental conditions have  
great effects on the snow physical properties such as density, wetness and salinity, and ~~the satellite~~ passive microwave snow  
depth is sensitive to ice concentration errors, weather effects, grain size, thaw and refreezing (Markus and Cavalieri, 1998).

430 Especially, wet snow caused by melting or flooding could lead to underestimations of snow depth while refreezing of wet snow could lead to overestimations. All of the above biases can affect the differences between Envisat and ICESat SIT.

~~Assuming the sea ice freeboard derived from Envisat as a reference, we can calculate the required snow depth  $\Delta S$  for compensating the difference between Envisat and ICESat SIT ( $\Delta I$ ). According to Eq. (1), we can derive the sensitivity of Envisat SIT ( $I$ ) to snow depth ( $S$ ) that:~~

435 
$$\frac{dI}{dS} = \frac{\rho_{\text{snow}}}{\rho_{\text{water}} - \rho_{\text{ice}}} \quad (6)$$

Setting  $\rho_{\text{snow}} = 300 \text{ kg m}^{-3}$ , and taking the same values for water and sea-ice density as in Eq. 5, we can see how SIT change in response to sea ice density and snow depth biases between 5 cm and 30 cm in steps of 5 cm, shown in Fig. 10b. Thickness changes rise as snow biases get larger and also with larger sea ice density. However, compared with Fig. 10a, SIT changes are more sensitive to freeboard biases than to snow biases. For  $880 \text{ kg m}^{-3}$  density, SIT only changes 0.1 m every 5 cm snow bias but 0.14 m every 2 cm freeboard bias. With typical snow depth biases (20 cm for the monthly mean retrieval uncertainty in Kern and Ozsoy-Cicek (2016)), the thickness changes from  $\sim 0.4 \text{ m}$  to  $\sim 0.7 \text{ m}$ . Therefore, snow depth bias is also a critical factor contributing to the difference between Envisat and ICESat SIT, ~~one of the causes of differences is the bias of snow depth products, albeit not the dominating one.~~ In general, passive microwave snow depth is valid over level ice. During FM, snow is deep, potentially wet and/or metamorphous on thick ice, causing substantial difficulties for radar altimeters. And for the same reasons, passive microwave snow depth is possibly underestimated on thick ice during FM but also during the other ICESat periods. These snow depths also underestimate actual snow depth over deformed ice mostly during ON in Eastern Antarctic, Bellingshausen and Amundsen Seas (Kwok and Maksym, 2014; Kacimi and Kwok, 2020).

445 ~~Additionally, more significant~~The largest effects might come from ~~not come from the impact of ice deformation on the snow depth retrieval but might be due to the differences~~ between actual snow depth from that represented by the climatology. In this study ~~During the Envisat SIT retrieval, the snow depth climatology is employed during Envisat SIT retrieval processes, which neglects the inter-annual snow variability. According to Bunzel et al. (2018), the impact of using a snow depth climatology is small when the snow depth is thin. The usage of snow depth climatology allows reducing the relative uncertainties compared with using the actual snow depth values. The latter ones are affected by many factors as discussed above and have large uncertainties. While a snow climatology allows reducing relative uncertainties. However, it can also have an adverse effect when being constructed from biased snow depth data, as is the case for the climatology used for the Envisat SIT data. The SIT differences between different summer seasons might, to a large extent, also simply be the result that the climatology does not match the actual conditions.~~ To further quantify the differences between snow depth climatology and actual snow depth contributions, we conduct the retrieval of Envisat SIT by replacing the snow depth climatology with SICCI AMSR-E snow depth on Envisat level-3 sea ice freeboard data and keeping remainder the same values. The new Envisat SIT is compared with ICESat SIT and the variations of their differences are shown in Fig. S2. This figure reveals that the impacts of snow depth

climatology are larger in the Amundsen-Bellingshausen Sea and the Western Weddell Sea compared to other sectors. Among the three seasons, the variations are larger in summer, partly accounting for the differences between Envisat and ICESat SIT.

~~In addition~~ Moreover, snow-depth dependent radar signal delay is applied to convert the radar freeboard into the sea-ice freeboard, but the delay correction is based on a conventional assumption that has been revised (Mallett et al. 2019) since the generation of the SICCI data.

~~In general, passive microwave snow depth is valid over level ice. During FM, snow is deep, potentially wet and/or metamorphous on thick ice, causing substantial difficulties for radar altimeters. And for the same reasons, passive microwave snow depth is possibly underestimated on thick ice during FM but also during the other ICESat periods. These snow depths also underestimate actual snow depth over deformed ice mostly during ON in Eastern Antarctic, Bellingshausen and Amundsen Seas (Kwok and Maksym, 2014; Kacimi and Kwok, 2020).~~

### 4.3 Differences due to ICESat ~~biases~~ uncertainties

~~Although we mainly discuss the possible biases of Envisat and AMSR-E above, it must be taken into account that also estimates from ICESat are subject to uncertainties. ICESat freeboard can be biased at the locations where the geoid or the sea surface height are inaccurate or where the elevation measurements are affected by ocean swell (Kern et al., 2016). Consequently, the total freeboard retrieved from ICESat has an uncertainty up to 0.1 m (Kern and Spreen, 2015). In addition, the approach by Kern et al. (2016) is actually providing the total (sea ice plus snow depth) thickness. Taking this into account, the actual 1-layer sea ice thickness values shown in this paper would possibly even be a bit smaller. In addition, the modified density used in the Worby retrieval algorithm. The modified density method used by Kern et al. (2016) does not consider the small-scale or regional variability of the snow depth. Instead, only a seasonal constant density derived from the ASPeCt observations is given.~~

Therefore, the largest uncertainty of ICESat comes from the potential underestimations of the ~~ship-based~~ sea ice ~~thickness~~ and snow ~~depth~~ observations for the computation of the ~~apparent ice density, representing the~~ bulk density of the ice-snow column (Kern et al., 2016). This bias has been modified in Li et al. (2018), who derived first guess values of snow depth and sea ice thickness directly from ICESat data with empirical approaches, instead of the observation climatology used by Kern et al. (2016). ~~Besides, this method is actually providing the total (sea ice plus snow depth) thickness. Taking this into account, the actual ICESat SIT shown in this paper would possibly even be a bit smaller. To examine this issue, we compare the Envisat total thickness (SIT plus AMSR-E snow depth) using the snow depth climatology product and the ICESat SIT derived by Kern et al. (2016). The changes to the differences are shown in Fig. S3. Larger variations exist in the Western Weddell Sea, especially in summer and autumn. The general variations are smaller than 0.5 m, yet leading to larger positive differences between Envisat and ICESat SIT. More realistic SIT data are derived in Xu et al. (2021) by subtracting the snow depth. This product has been demonstrated to be more reasonable than ICESat SIT used in this study because it takes into account local conditions. However, it is noted that the empirical approaches used by Li et al. (2018) were developed from a suite of historic in-situ observations~~

of freeboard, snow depth and sea ice thickness which in a way have the character of a climatology as well. In addition, the approach by Kern et al. (2016) is actually providing the total (sea ice plus snow depth) thickness. Taking this into account, the actual 1-layer sea ice thickness values shown in this paper would possibly even be a bit smaller. However, we do not aim to choose the best ICESat SIT product with the most real SIT, but investigate the causes of the differences between Envisat and ICESat SIT, and how different sensors and retrieval methods are represented in the SIT fields. In addition, the empirical approaches used by Li et al. (2018) and Xu et al. (2021) were developed from a suite of historic in-situ observations of freeboard, snow depth and sea-ice thickness which in a way have the character of climatology as well. ~~the empirical approaches used by Li et al. (2018) were developed from a suite of historic in-situ observations of freeboard, snow depth and sea ice thickness which in a way have the character of a climatology as well.~~

As for the uncertainties of ICESat, its total freeboard can be biased at the locations where the geoid or the sea surface height are inaccurate or where the elevation measurements are affected by ocean swell (Kern et al., 2016). Consequently, the total freeboard retrieved from ICESat has an uncertainty of up to 0.1 m (Kern and Spreen, 2015).

## 5 Summary

In this study, we compare SIT estimates of the sea-ice thickness obtained from satellite altimeter observations by Envisat RA-2 (radar) and ICESat GLAS (laser) in the Southern Ocean. ~~Antarctic sea ice thickness derived from Envisat RA-2 is firstly compared with ICESat sea ice thickness retrieved from a modified ice density algorithm. Envisat and ICESat sea ice thickness SIT are has been~~ compared with ULS SIT in the Weddell Sea, with the ~~mean differences MDs (SDs) and the standard deviations~~ of 1.29 (0.65) m for Envisat-ULS while 1.11 (0.81) m for ICESat-ULS, respectively. ~~The results show that both Envisat and ICESat measurements are not comparable to the ULS sea ice thickness.~~ Then a systematic comparison between the two data sets ~~has been~~ carried out for three seasons except winter, based on the ICESat operating periods. According to the results, the differences between Envisat and ICESat ~~sea ice thickness SIT vary are different in each season, year and region considering different seasons, years and regions.~~ More specifically, ~~we find~~ the smallest monthly average difference (SD in brackets) ~~for Envisat SIT minus ICESat SIT exists in spring~~ of 0.00 m (0.39 m) ~~between Envisat SIT minus ICESat SIT in spring~~, while larger differences (SD) exist in summer and autumn by 0.52 m (0.68 m) and 0.57 m (0.45 m), respectively. In spring, ICESat SIT maps reveal the Ross Ice Shelf polynya, while it is not present in the Envisat data. In summer, Envisat shows that thick ice still exists in the western Weddell Sea and remains at least 3 m thick ~~through all the year every year~~, while ICESat shows thinner ice. Compared to summer, the positive differences in the western Weddell Sea ~~spread expand~~ to the whole Weddell Sea sector and slightly decrease from west to east in autumn. From the probability distribution, it is noted that Envisat and ICESat have different SIT variations from autumn to spring, i.e., ICESat SIT increases while Envisat SIT does not, but share similar SIT growth from summer to autumn. Compared to the dynamic FDD results in 2004, 2005 and 2006, we find that the Envisat SIT decrease during MJON cannot be explained simply by freezing and dynamic processes and we assume

525 ~~the main reason of the SIT decrease is the overestimation of Envisat SIT in autumn. we infer that thermodynamic growth dominates during FM MJ and deformation processes dominate during MJ ON.~~ With respect to different sea-sectors, the regional ~~mean difference~~MDs (SD ~~in brackets~~) are 0.63 m (0.91 m) in the Western Weddell Sea, 0.34 m (0.58 m) in the Eastern Weddell Sea, 0.31 m (0.57 m) in the Ross Sea, -0.12 m (0.69 m) in the Eastern Antarctic, and 0.09 m (0.71 m) in the Bellingshausen ~~and~~ Amundsen Sea. ~~Through the sensitivity experiments, we find that Envisat SIT changes are more sensitive to sea ice freeboard biases than to snow depth biases. Besides, with the increase of sea ice density, the SIT changes become larger. Usage of snow depth climatology has moderate impacts on SIT estimates in summer Amundsen-Bellingshausen Sea and Western Weddell Sea.~~The potential overestimation of sea ice freeboard caused by range biases accounts for much of the differences between Envisat and ICESat SIT in summer and autumn, while the biases of snow depth are not the dominant cause of the differences.

530  
535 Through the study, we acknowledge that there are differences between Envisat and ICESat sea ice thickness, which potentially result from the ~~uncertainties~~biases of both data sets. There is still more work to be done in the future to make better use of remote-sensed ~~sea ice thickness~~SIT data, such as assimilating the Antarctic sea ice thickness observations and analyzing the sea ice volume variations.

540 *Data availability.* ~~The~~ Envisat sea ice thickness data are available at <https://dx.doi.org/10.5285/b1f1ac03077b4aa784c5a413a2210bf5> (Hendricks et al., 2018b). ~~The~~ ICESat-1 sea ice thickness data are available at <http://icdc.cen.uni-hamburg.de/1/projekte/esa-cci-sea-ice-ecv0/esa-cci-data-access-form-antarctic-sea-ice-thickness.html> (Kern et al., 2016). The Weddell Sea upward looking sonar data are available at <http://doi.pangaea.de/10.1594/PANGAEA.785565> (Behrendt et al., 2013a; Behrendt et al., 2013b). ~~The 2-2-~~meter air temperature data are available at <https://www.ecmwf.int/en/forecasts/datasets/reanalysis-datasets/era5> (Hersbach et al., 2019). ~~NSIDC sea ice motion data are accessible at https://nsidc.org/data/nsidc-0116 (Tschudi et al., 2019). AMSR-E snow depth data are accessible at https://www.cen.uni-hamburg.de/icdc (Markus and Cavalieri, 1998).~~

545 *Author contributions.* JW, QY and QS developed the concept of the paper. JW analyzed the data and wrote the manuscript. CM, RR, QY, QS, BH ~~and~~, SH ~~and~~ RW assisted during the writing process.

*Competing interests.* The authors declare that they have no conflict of interest.

*Acknowledgments.* This study is supported by the National Key R&D Program of China (Grant No. 2019YFC1509102), the National Natural Science Foundation of China (No. 41941009, 41922044), the Fundamental Research Funds for the Central Universities (No. 19lgzd07). The authors would like to thank Alfred Wegener Institute Helmholtz Centre for Polar and Marine Research for providing the Weddell Sea upward looking sonar data, the Integrated Climate Data Center at the University of Hamburg for providing the ICESat-1 sea ice thickness data and European Centre for Medium-Range Weather Forecasts for providing ERA-5 2 meter air temperature data.

740

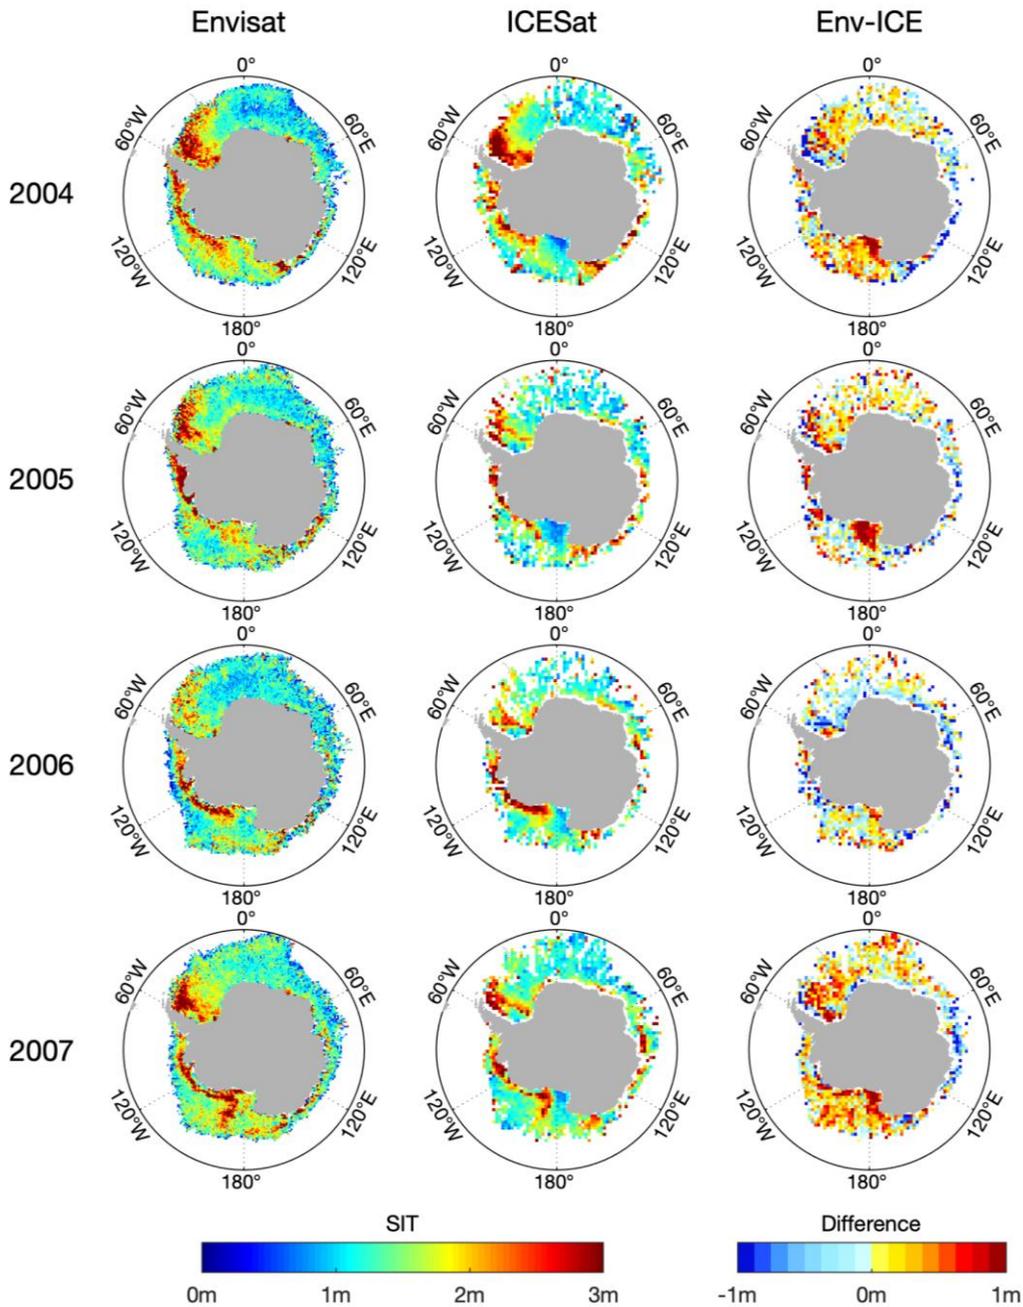

**Figure 1:** An illustration of measuring freeboard using ICESat and Envisat, and the ULS measurement principle.

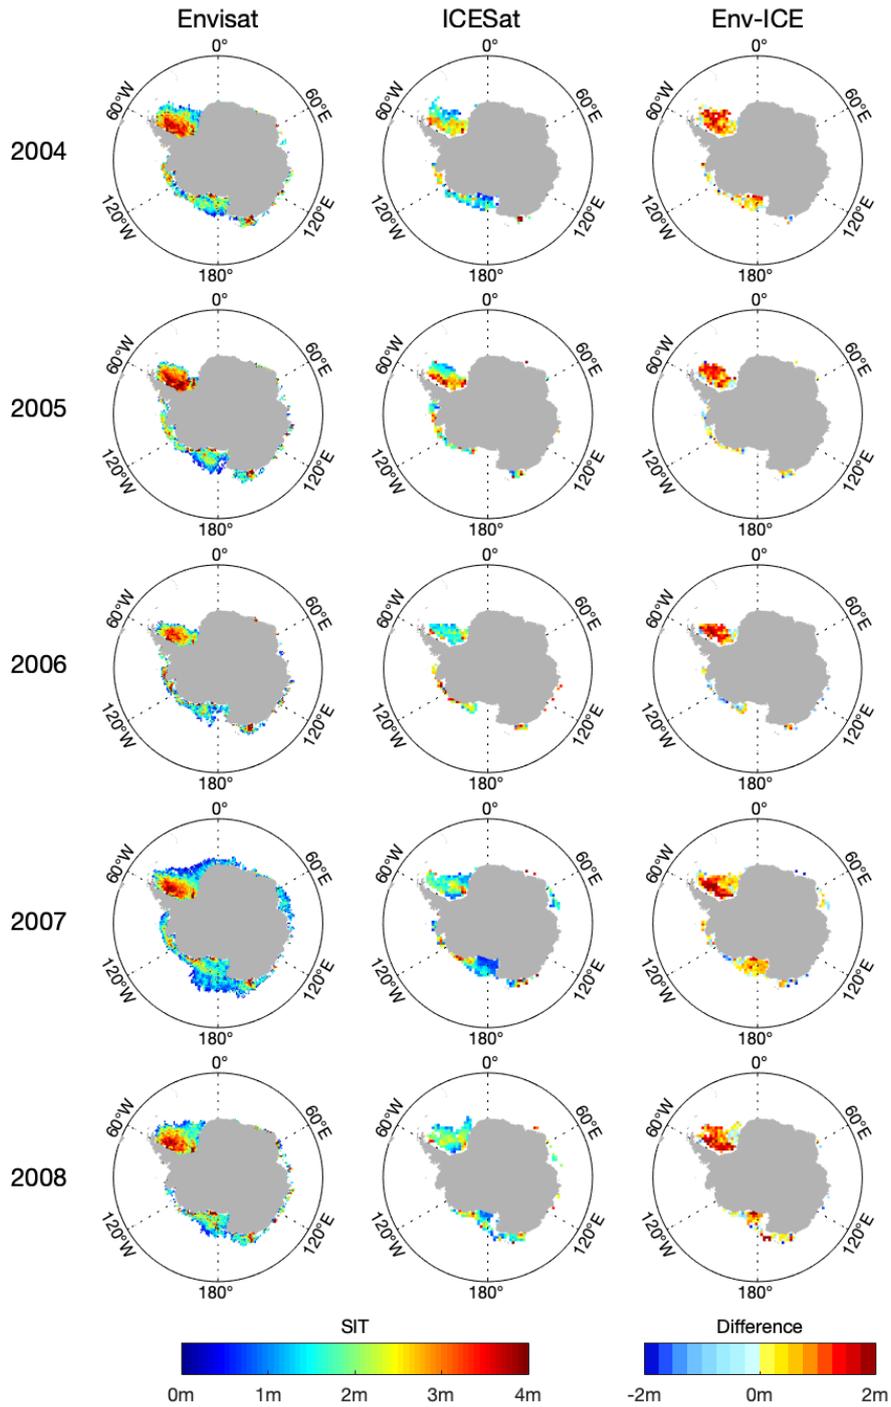

745 **Figure 2:** Map of the different sectors referred to in the study. The background is the average of the September sea ice thickness from Envisat during 2003-2011 with 50 km grid size. Each sector and the two ice shelf polynyas are indicated in the figure. The circles and the corresponding numbers refer to the sites of the ULS. The white grid cells stand for area with sea ice concentration less than 70% or missing data.

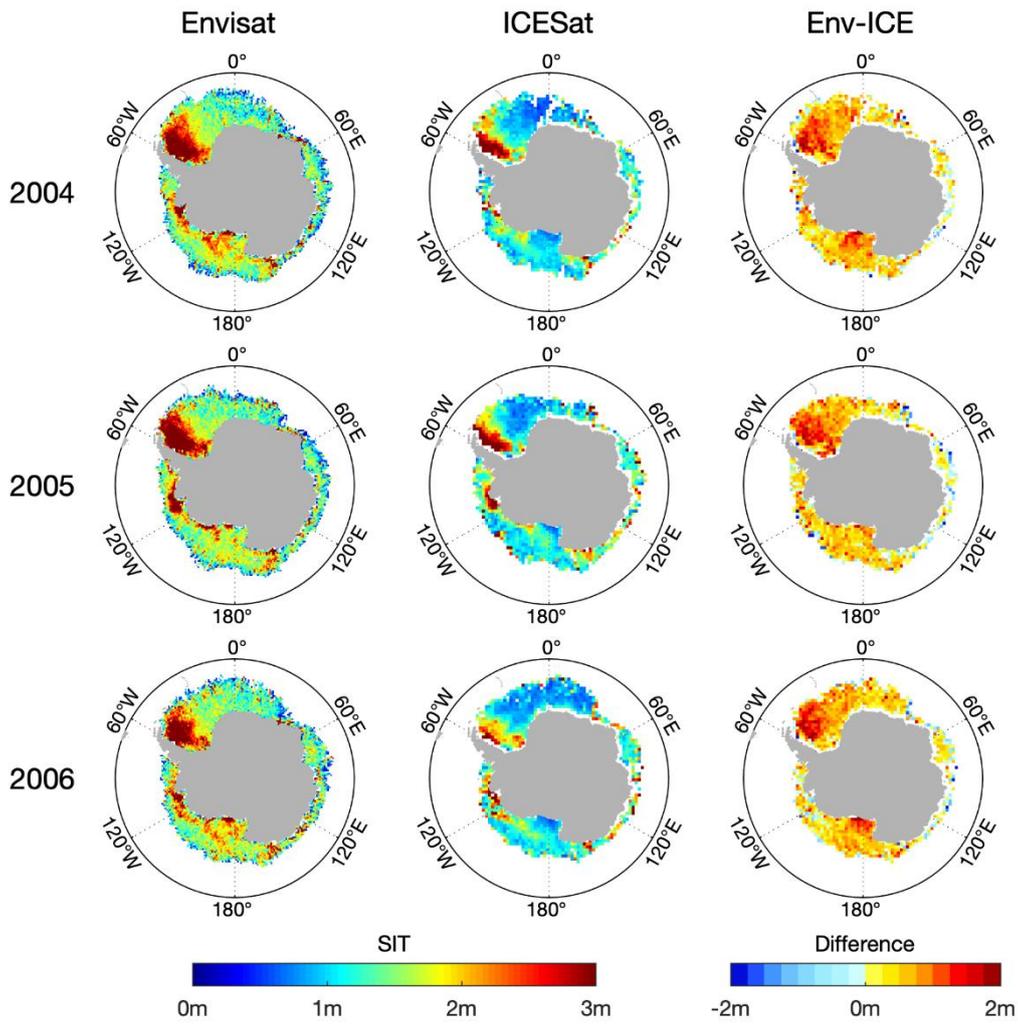

750 **Figure 3:** Time series of sea ice thickness [and their uncertainties](#) for the Weddell Sea ULS data, Envisat and ICESat. The numbers on the top represent the location of each site for the comparisons. The site locations can be searched in Fig. 2. ICESat SIT values are placed between the two months that each period covers. The mean differences ( $MD_s$ ) and their standard deviations ( $SD_s$ ) are shown in the figures.

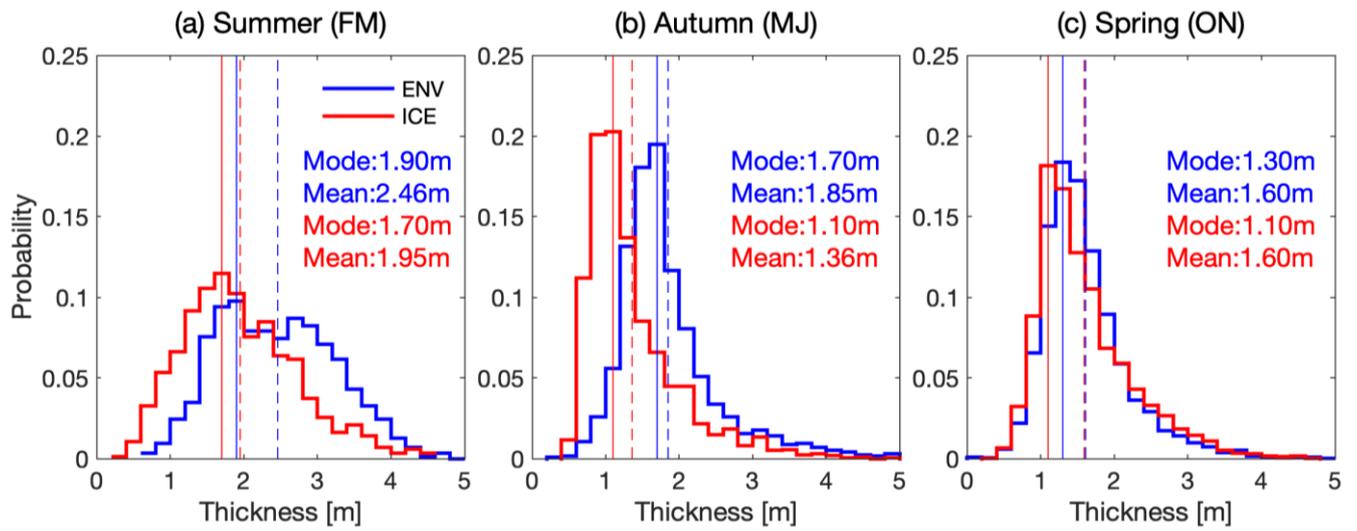

755 **Figure 4:** Comparisons of Envisat versus ICESat sea ice thickness for each ICESat operating period in spring (October & November). The first and second columns show the sea ice thickness distribution of Envisat and ICESat respectively, and the last column shows the difference map (Envisat minus ICESat) of sea ice thickness. Each row represents a year from 2004 to 2007. The sea ice thickness maps are at their native grid resolution while the difference map is interpolated onto the polar-stereographic grid of the ICESat product. The white cells denote sea ice concentration less than threshold or missing data.

760 **Figure 5:** Same as Fig. 4 but for summer (February & March).

**Figure 6:** Same as Fig. 4 but for autumn (May & June).

765 **Figure 7:** Probability of the Envisat SIT and the ICESat SIT for all the individual comparison pairs. The blue stairs represent Envisat ice thickness and the red stairs represent ICESat ice thickness. The solid lines indicate the modal ice thickness and the dashed lines indicate the mean ice thickness of both data sets.

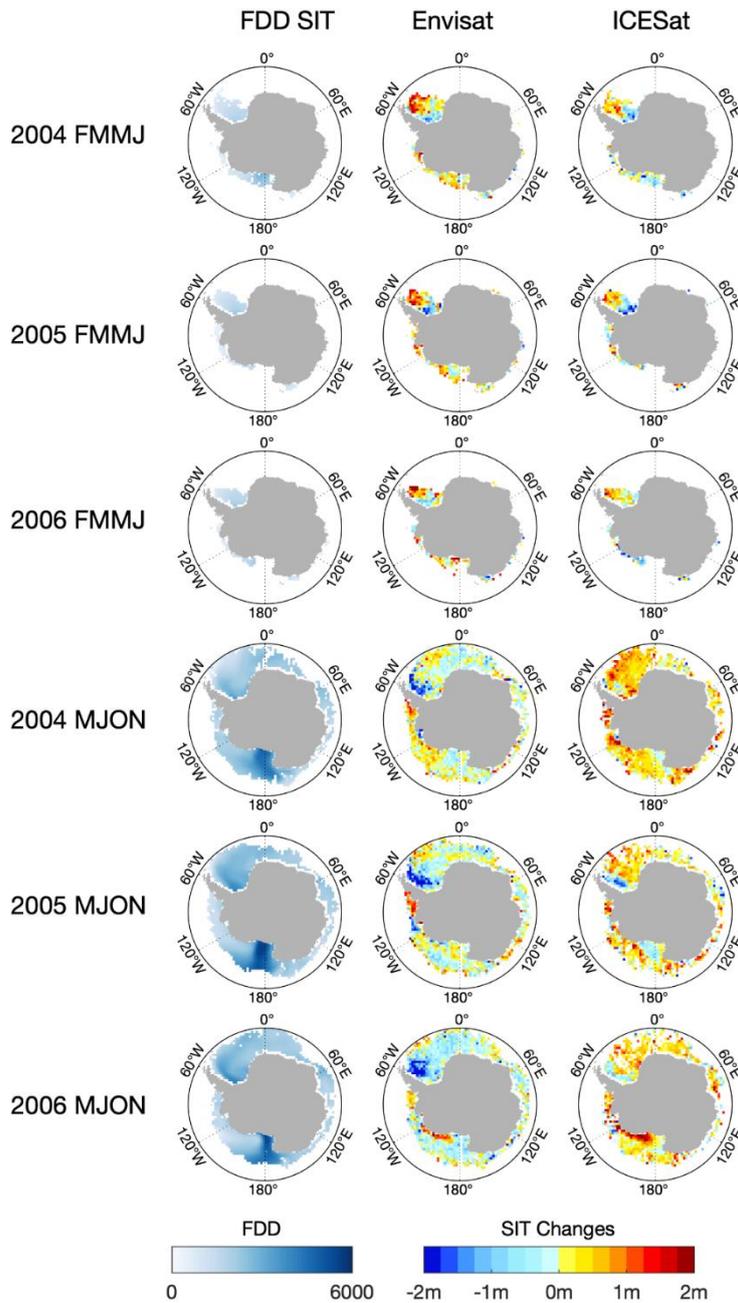

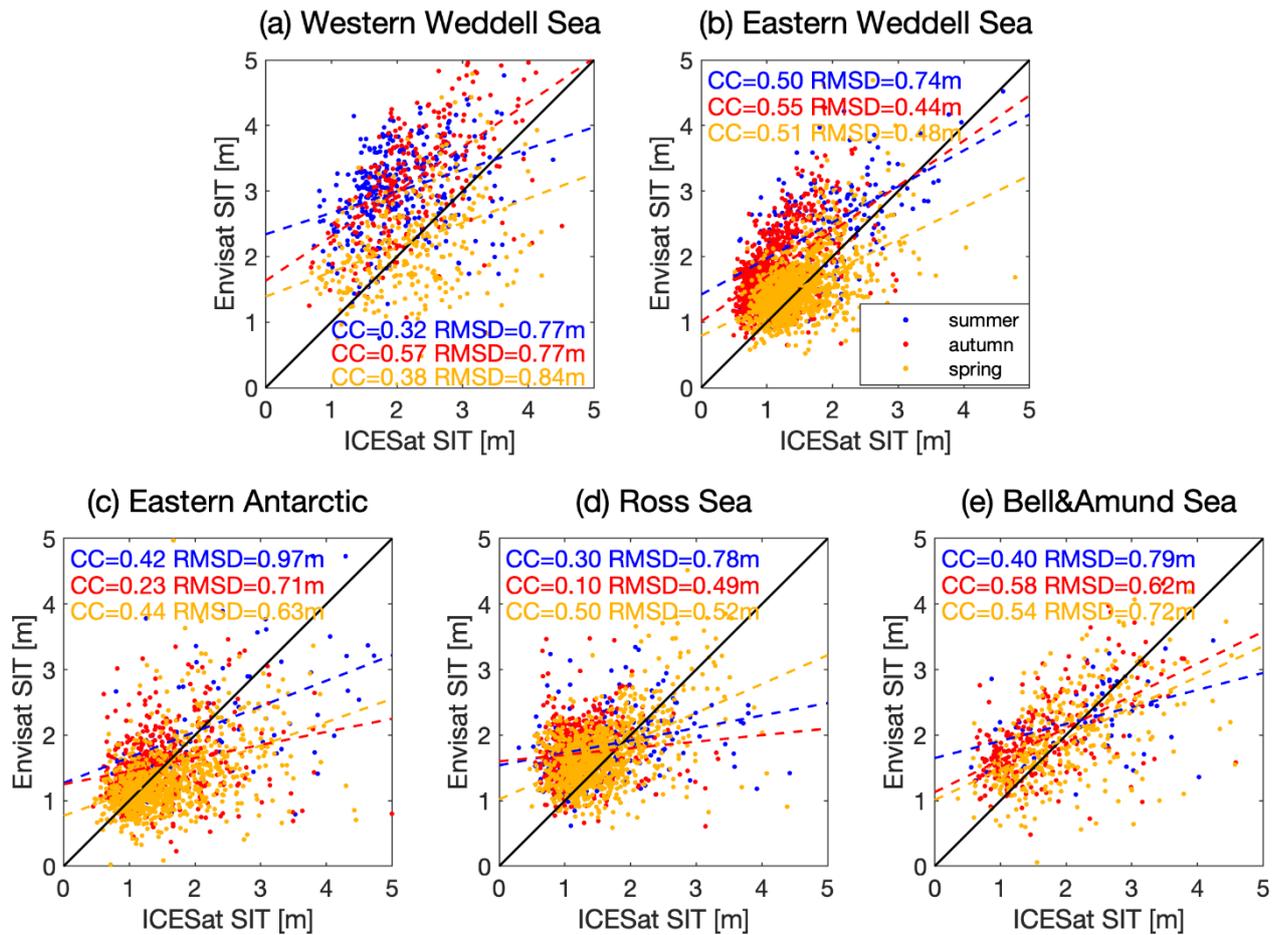

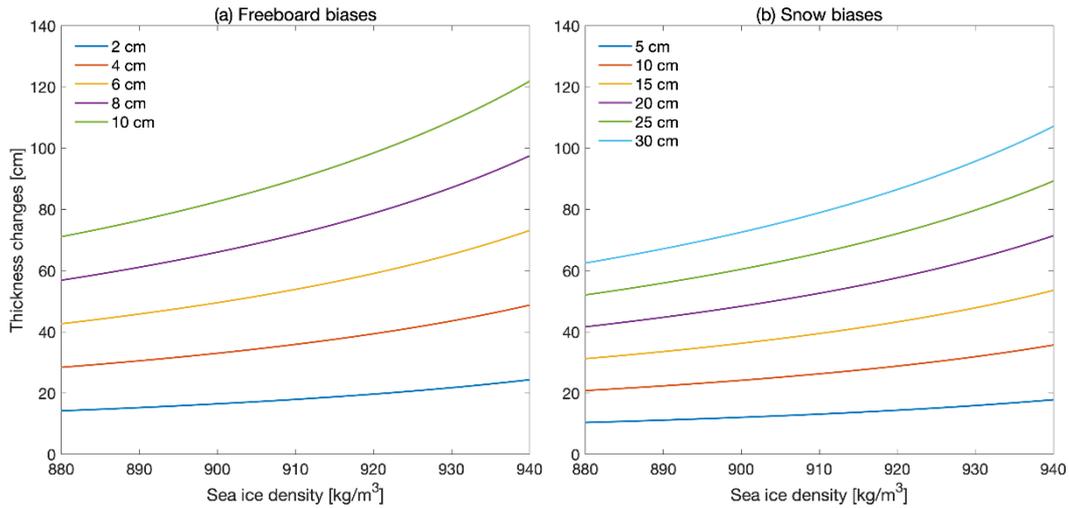

Figure 8. [The dynamic FDD differences and sea ice thickness differences from summer to autumn \(FMMJ\) and from autumn to spring \(MJON\) derived from Envisat and ICESat in 2004, 2005 and 2006. The dynamic FDD patterns are derived by forward tracking daily FDD with sea ice motion data. The FDD differences and sea ice thickness differences from summer to autumn \(MJ-FM\) and from autumn to spring \(ON-MJ\) derived from Envisat and ICESat in 2004, 2005 and 2006. Note that while the FDD represents thermodynamic ice growth, the right two columns simply show a difference in two SIT maps.](#)

770

775 **Figure 9:** Scatterplots of the individual data pairs between Envisat SIT and ICESat SIT for each region and each season. The data are taken from all seasons available. Since the comparison pairs are too few in Indian Ocean and western Pacific Ocean, we combine these two regions into Eastern Antarctic. The respective correlation coefficients and RMSDs are indicated in the panels. The black line is the 1-to-1 fit line and the dashed colored lines stand for linear regression lines.

780 [Figure 10: Sensitivity of sea ice thickness changes to sea ice freeboard biases and snow depth biases as function of sea ice density. \(a\) SIT changes computed with Eq. \(1\) for different sea ice freeboard biases \(2 cm to 10 cm\). \(b\) Similar to \(a\) but computed for different snow depth biases \(5 cm to 30 cm\).](#)

785

**Table 1:** ICESat operating periods and Envisat periods used for the comparisons. The three seasons are divided according to the ICESat operating periods. Note that ON is Oct-Nov, FM is Feb-Mar, and MJ is May-June.

Years	Summer (FM)		Autumn (MJ)		Spring (ON)	
	ICESat	Envisat	ICESat	Envisat	ICESat	Envisat
2004	Feb 17 to Mar 20	Feb 1 to Mar 31	May 18 to Jun 20	May 1 to Jun 30	Oct 3 to Nov 8	Oct 1 to Nov 31
2005	Feb 17 to Mar 22	Feb 1 to Mar 31	May 20 to Jun 22	May 1 to Jun 30	Oct 21 to Nov 23	Oct 1 to Nov 31
2006	Feb 22 to Mar 26	Feb 1 to Mar 31	May 24 to Jun 25	May 1 to Jun 30	Oct 25 to Nov 26	Oct 1 to Nov 31
2007	Mar 12 to Apr 14	Mar 1 to Apr 30	–	–	Oct 2 to Nov 4	Oct 1 to Nov 31
2008	Feb 17 to Mar 20	Feb 1 to Mar 31	–	–	–	–

**Table 2:** A summary of the sea ice thickness data used during the comparison, including different data sources, spatial resolution, temporal resolution and snow product.

Source	Instrument	Operation time	Footprint	Grid resolution	Temporal resolution	Snow product
Envisat satellite	Radar altimeter	2002-2011	2–10 km	50 km grid	Monthly average	AMSR-E climatology
ICESat satellite	Laser altimeter	2003-2009	70 m	100 km grid	See Table 1	ASPeCt observations
Weddell Sea ULS	Upward Looking Sonars	1990-2010	6–8 m	Single point	Monthly average	built into Eq. (4)

790

**Table 3:** Respective operation times of the ULS, Envisat and ICESat sea ice thickness data set during the comparison between ULS and satellite SIT.

	ULS	ENV	ICE
Site 207	Apr 2005 to Mar 2008	Apr 2005 to Mar 2008	MJ05 to FM08
Site 229	Jan 2003 to Nov 2005	Jan 2003 to Nov 2005	FM04 to ON05
Site 231	Mar 2005 to Feb 2008	Mar 2005 to Feb 2008	FM05 to ON07

**Table 4:** Statistical results of the comparison between two satellite SIT data with ULS data. [N is the number of comparison pairs.](#)

Site	Envisat-ULS			ICESat-ULS			N
	MD (m)	SD (m)	RMSD (m)	MD (m)	SD (m)	RMSD (m)	

207	1.63	0.67	0.60	1.73	0.70	0.62	5
