Abstract. Antarctic sea ice is an important component of the Earth system. However, its role in the Earth system is still not
10 very clear due to limited Antarctic sea ice thickness (SIT) data. A reliable sea ice reanalysis can be useful to study Antarctic
SIT and its role in the Earth system. Among various Antarctic sea ice reanalysis products, the Global Ice-Ocean Modeling and
Assimilation System (GIOMAS) output is widely used in the research of Antarctic sea ice. As more Antarctic SIT observations
with quality control are released, a further evaluation of Antarctic SIT from GIOMAS is conducted in this study based on in-
15 situ and satellite observations. Generally, though only sea ice concentration is assimilated, GIOMAS can basically reproduce
the observed variability of sea ice volume and its changes in the trend before and after 2013, indicating that GIOMAS is a
good option to study the long-term variation of Antarctic sea ice. However, due to deficiencies in model and asymmetric
changes in SIT caused by assimilation, GIOMAS underestimates Antarctic SIT especially in deformed ice regions, which has
an impact on not only the mean state of SIT but also the variability. Thus, besides the further development of model,
20 assimilating additional sea ice observations (e.g., SIT and sea ice drift) with advanced assimilation methods may be conducive
to a more accurate estimation of Antarctic SIT.

1 Introduction

Antarctic sea ice plays an important role in the Earth system. Firstly, Antarctic sea ice can influence the Earth climate system.
For instance, changes in Antarctic sea ice could affect freshwater flux of the Southern Ocean that directly influences the
stratification of the ocean (Goosse and Zunz, 2014; Haumann et al., 2016). Besides, Antarctic sea ice acts as a protective buffer
25 for Antarctic ice shelves, with the thinning or absence of sea ice increasing the possibility of ice shelf disintegration (Robel,
2017; Massom et al., 2018). Secondly, Antarctic sea ice has a significant impact on the biosphere of the Earth system. Studies
have shown that the variation of Antarctic sea ice thickness (SIT) will affect the maximum biomass of algae in different ice
layers, which will influence the food web of the Southern Ocean (Massom and Stammerjohn, 2010; Schultz, 2013). Thirdly,

30 Antarctic sea ice has impacts on human activities such as shipping and fishery management (Dahood et al., 2019; Mishra et al., 2021). Hence, studies on Antarctic sea ice are of great scientific and socio-economic importance.

To truly understand changes in sea ice of the Southern Ocean, SIT is needed to estimate the sea ice volume (SIV), since it is through volume changes that sea ice has its greatest impact on the water column (Maksym et al., 2012; Hobbs et al., 2016). Although changes in Antarctic sea ice extent (SIE) have been investigated extensively (Turner et al., 2015; Parkinson, 2019), they may not be a robust proxy of large scale changes in SIV, and many studies related to Antarctic sea ice are limited by the
35 short of reliable SIT data. For example, freshwater flux of the Southern Ocean, which affects the stratification of ocean, cannot be accurately estimated (Haumann et al., 2016). In addition, the skill of sea ice prediction cannot meet the need of human activities in the Antarctic (Mishra et al., 2021). Studies have shown that the skill of Antarctic sea ice prediction could be improved with better SIT initialization (Bushuk et al., 2021). So far, Antarctic SIT data used in studies are mainly from observations, model data, and reanalysis products.

40 Antarctic SIT observations can be divided into in-situ and satellite observations. In-situ observations can provide the local state of Antarctic SIT. However, the brevity and sparse distribution of in-situ SIT observations pose considerable challenges to understand the large-scale characteristics of SIT (Worby et al., 2008). While satellite observations have wider spatiotemporal coverage than in-situ observations. However, previous studies indicate that there is large uncertainty in SIT data retrieval from satellite altimeters owing to the relatively small freeboard of Antarctic sea ice compared to that in the Arctic (Maksym and
45 Markus, 2008) and the lack of knowledge about coincident snow cover thickness as well as sea ice and snow density (Alexandrov et al., 2010). In addition, results of numerical simulations are used to investigate the long-term variation of Antarctic SIT (Zhang, 2007; Holland et al., 2014), but discrepancies are identified not only between models and observations but also among models (Shu et al., 2015; Tsujino et al., 2020), indicating the large uncertainty in model estimates.

It should be noted that reanalysis has unique advantages over observed and simulated SIT. Theoretically, reanalysis can provide
50 more accurate or comprehensive state estimations than can otherwise be obtained through either observations or models alone, which merges the information from both observations and models through data assimilation. Compared with observations, reanalysis data can provide coordinated and gridded data with homogenous sampling in time and space over a long period (Parker, 2016). And compared with model only data, reanalysis data can produce the state estimations closer to observations because of data assimilation (Lindsay and Zhang, 2006; Rollenhagen et al., 2009). Hence, SIT reanalysis data has been widely
55 adopted in studies on the Antarctic sea ice (Abernathy et al., 2016; Kumar et al., 2017). Nevertheless, there are still large uncertainties of present sea ice reanalysis in the Southern Ocean (Uotila et al., 2019; Shi et al., 2021), suggesting the necessity and importance of evaluating them.

Among a number of Antarctic sea ice reanalysis, the Global Ice-Ocean Modeling and Assimilation System (GIOMAS) is one of the most widely used in studies of Antarctic sea ice. For instance, GIOMAS has been regarded as the reference in the
60 assessments of simulations (Shu et al., 2015; Uotila et al., 2017; DuVivier et al., 2020) and predictions (Ordoñez et al., 2018; Morioka et al., 2021). However, GIOMAS has been less widely evaluated, in part because there are far fewer observations of Antarctic SIT against which evaluation is possible (DuVivier et al., 2020).

65 Due to advances in observing technology as well as algorithm in recent years, the quality of Antarctic SIT observations is improved. For example, compared to the European Remote-Sensing Satellites (i.e., ERS-1 and ERS-2), the Synthetic-Aperture Interferometric Radar Altimeter (SIRAL) on board CryoSat-2 (CS2) is equipped with two radar antennas, which significantly improves the accuracy of sea ice freeboard. CS2 also has a much wider spatial coverage with improved along-track resolution because of the design of the satellite orbit and multiple operation modes (Parrinello et al., 2018). And Paul et al. (2018) developed an adaptive retracker threshold for CS2 to produce a consistent sea ice freeboard data. Besides, more Antarctic SIT observations has been available with the accumulation of observations. For instance, more in-situ observations are obtained from dedicated research stations, icebreakers and autonomous underwater vehicles due to increasing research activities in the Antarctic. These provide an opportunity to further evaluate Antarctic SIT of GIOMAS.

70 The paper is organized as follows. In Sect. 2, Antarctic SIT from GIOMAS and observations are introduced. In Sect. 3, Antarctic SIT of GIOMAS is evaluated with observations from different aspects, including the climatology, the linear trend, the intensity of variability, as well as the frequency distribution. The final section provides the conclusions and discussion.

75 **2 Data and methods**

2.1 SIT from GIOMAS

GIOMAS consists of a global Parallel Ocean and sea Ice Model (POIM) with data assimilation capabilities, which is developed at University of Washington (Zhang and Rothrock, 2003). The ocean component of POIM is the Parallel Ocean Program, and the sea ice component of POIM is the 8-category thickness and enthalpy distribution sea ice model. The National Centres for Environmental Prediction-National Centre for Atmospheric Research (NCEP-NCAR) daily reanalysis (Kalnay et al., 1996) provides the atmospheric forcing for POIM. Furthermore, in GIOMAS, the modelled sea ice concentration (SIC) is nudged towards observed SIC derived from Special Sensor Microwave Imager launched by the Defense Meteorological Satellite Program (Weaver et al., 1987), and other modelled variables including SIT are adjusted subsequently. More technical details for POIM and assimilation procedures can be found in Zhang and Rothrock (2003) and Lindsay and Zhang (2006), respectively. GIOMAS data is available from 1979 to present with a global coverage and data involved in the assessment spans from January 1979 to December 2018 (Fig. 1a). The average horizontal spatial resolution is 0.8 degrees of longitude \times 0.8 degrees of latitude (around 60 km \times 60 km), and the temporal resolution is one month for all variables. Additionally, GIOMAS also provides daily outputs for some variables including SIT, SIC and snow depth, and the monthly SIT of GIOMAS is assessed in this study. SIT data of GIOMAS is the equivalent SIT, which represents SIV per unit area.

90 **2.2 SIT from satellite altimeters and in-situ observations**

Satellite-altimeter observations involved in this study are from radar altimeters on board Envisat (ES) and CS2, which is generated by the Sea Ice Climate Change Initiative (SICCI) project under the European Space Agency (ESA) CCI program.

ES was equipped with the Radar Altimeter 2, measuring sea ice freeboard (thickness of sea ice above sea surface) mainly based on K_u -band frequency (Hendricks et al., 2018b). The Antarctic SIT data derived from ES freeboard spans from December 95 2002 to November 2011 (Fig. 1a) with a coverage of the entire Antarctica (Fig. 1b). The spatial resolution is 50 km \times 50 km and the temporal resolution is 1 month. CS2 was equipped with the SIRAL, measuring the sea ice freeboard mainly based on K_u -band frequency like ES (Hendricks et al., 2018a). CS2 Antarctic SIT dataset spans from November 2010 to April 2017 (Fig. 1a) and the spatial coverage and the spatiotemporal resolution are same as ES SIT dataset.

In-situ SIT observations involved in this study are from upward looking sonar (ULS), shipborne and airborne measurements. 100 ULS is a kind of mooring measurement at fixed locations, measuring sea ice draft (thickness of sea ice below the water surface) with a time interval shorter than 15 minutes (Behrendt et al., 2013). Ice draft needs to be converted into total SIT in an empirical way according to (Harms et al., 2001). Thirteen ULSs used in this study were deployed in the Weddell Sea (Fig. 1b) by Alfred Wegener Institute (AWI) and spanned from 1990 to 2010 intermittently (Fig. 1a).

The ship-based observations are made up of the Antarctic Sea Ice Processes & Climate program (ASPeCt), ANT-XXIX/6 105 (Schwegmann, 2013) and ANT-XXIX/7 (Ricker, 2016). The ASPeCt dataset not only includes ASPeCt observations collected from 1981 to 2005 (Worby et al., 2008), but also includes the ASPeCt bridge-based sea ice observations collected from 2007 to 2012. The ship tracks cover all sectors of the Southern Ocean (Fig. 1b) and the average spacing of data points is 6 nautical miles. The air-based SIT observations include data collected by the airborne electromagnetic system with a high frequency of 0.5 Hz and an average spacing of 3-4 m (Lemke, 2009, 2014), which is mainly located in the northwest Weddell Sea (Fig. 1b).

110 2.3 Data processing and methods

According to Parkinson and Cavalieri (2012), the summer, autumn, winter and spring refer to January-March, April-June, 115 July-September and October-December, respectively. As shown in Fig. 1b, the Southern Ocean is divided into the Weddell Sea (60° W-20° E), the Indian Ocean (20° E-90°E), the western Pacific Ocean (90°E-160°E), the Ross Sea (160°E-130°W) and the Amundsen/Bellingshausen Sea (130°W-60°W).

All analyses in this study take place on the grid of observations, which means that GIOMAS was converted to the observed 120 grid. Anomalies are defined as departures from the climatological annual cycle, and the intensity of variability is defined as the standard deviation of anomalies. During the overlapped time of ES and CS2 (November 2010 to November 2011), the difference in SIV anomalies between ES and CS2 (i.e., root mean squared error is 574.4 km³) is much less than the variation of SIV anomalies (i.e., their standard deviations in ES and CS2 are 969.6 km³ and 1004.3 km³, respectively). Thus, ES from December 2002 to October 2010 and CS2 from November 2010 to April 2017 are spliced together to calculate trend. In addition, since the trajectories of air-based SIT observations are mainly distributed in the northwest Weddell Sea where is dominated by deformed sea ice (Fig. 1b), and the amount of air-based data is much greater than that of ship-based observations due to the differences in average spacing between ship-based (i.e., 3-4 m) and air-based observations (i.e., 11 km). Therefore, the comparison between GIOMAS and air-based observations is only conducted in the Weddell Sea.

125 3 Results

Figure 2 shows the climatological annual cycle of Antarctic SIV. Although obvious uncertainties of SIV can be found in both ES and CS2, the annual cycle of ES is similar to that of CS2. Both ES and CS2 show that the melt rate of sea ice is nearly twice the growth rate. And there are also some differences in the SIV climatology between ES and CS2. The SIV of ES is greater than that of CS2 in the summer and vice versa in the winter, and larger uncertainties of SIV can be found in ES. The SIV difference between ES and CS2 may be owing to differences in footprints, resolutions and retracker algorithms between the Radar Altimeter 2 on board ES and the Synthetic-Aperture Interferometric Radar Altimeter on board CS2. These differences may lead to overestimation of freeboards for ES in the first-year ice zone and overestimation of freeboards for CS2 in the multiyear ice zone and near the coasts (Schwegmann et al., 2016). GIOMAS can reproduce the asymmetry in the annual cycle of Antarctic SIV observed by ES and CS2 while underestimates SIV by about 48.5% on average when compared to ES as well as CS2. And the underestimation is seasonally dependent, with weaker underestimation in summer and stronger one in winter.

Figure 3 shows the spatial distribution of SIT bias in summer as well as winter to investigate details of SIV underestimation in these two seasons. In both seasons, significant negative SIT bias of GIOMAS can be found in the deformed ice zone, such as the northwestern Weddell Sea and coasts of the Amundsen/Bellingshausen Sea as well as the East Antarctic. While the extent of negative bias is wider in the winter (Figs. 3b and d) rather than in the summer (Figs. 3a and c), which results in seasonal differences of the SIV underestimation (Fig. 2). In addition, there are weakly positive SIT biases in the southwestern Weddell Sea during winter (Figs. 3b and d), which may be due to model bias in simulating sea ice transport in the western Weddell Sea (Shi et al., 2021). Considering sea ice deformation is also related to sea ice motion tightly, a better simulation of sea ice motion is required to achieve more accurate reconstruction of Antarctic SIT. And the positive bias in winter Ross Sea SIT can only be found in the comparison between GIOMAS and CS2, maybe caused by smaller freeboard of CS2 than ES in the winter Weddell Sea (Schwegmann et al., 2016). Notably, it is still disputed whether radar altimeter signals originate from the snow/ice or snow/air interface or from somewhere in-between. These uncertainties, combined with often thick snow and complex snow metamorphism in the Antarctic, may contribute to the overestimation of the Antarctic SIT from ES and CS2. Thus, the underestimation of SIT from GIOMAS may be partially attributed to the uncertainties of SIT retrieved from ES and CS2.

Due to large uncertainties in above satellite observations, the SIT of GIOMAS is further assessed by ULS measurement in the Weddell Sea. Considering significant variation of sea ice over horizontal distances as small as a few meters, the standard deviation of ULS is displayed in Fig. 4a. It is obvious that the variability of ULS near the shore (e.g., 206, 207, 212, 217, 232 and 233) is stronger than that of ULS far from the shore (e.g., 208, 209, 210, 227, 229, 230 and 231), indicating larger sea ice deformation near the shore. As Fig. 4b shows, GIOMAS significantly underestimates the nearshore SIT all year round while slightly overestimates SIT far from shore in the winter, implying the deficiency of GIOMAS in the simulation of sea ice deformation, which leads to underestimation of SIT in the Weddell Sea from a perspective of regional average. The above

160 deficiency of GIOMAS might be attributed to the insufficient model resolution, which is not able to well resolve the coastal
lines and hinders GIOMAS from reproducing the ice deformation near shore. Therefore, GIOMAS is indeed to underestimate
the climatology of Antarctic SIT, mainly in the deformed sea ice zone, compared with satellite and in-situ observations. In
addition to the model drawbacks of GIOMAS, this underestimation might also be introduced by the assimilation procedure of
GIOMAS. Although only satellite SIC is nudged in GIOMAS, it will modify the SIT distribution to accommodate the change
in SIC, which removes sea ice from the distribution without considering its SIT if modelled SIC is too large, while adds sea
ice to the 0.1-m ice thickness bin if modelled SIC is too small. This asymmetric addition and removal of ice leads to a thinning
165 of the mean ice thickness (Lindsay and Zhang, 2006).

Antarctic SIE shows different trends before and after 2014 (Parkinson, 2019), and SIV can better represent the overall sea ice
state. Therefore, it is necessary to examine whether there are similar changes in the trend of Antarctic SIV. As Figure 5 shows,
the observed Antarctic SIV anomaly increased gradually from 2003, reached the maximum (3158.1 km³) in November 2013,
and then abruptly declined from September 2013 to April 2017. The evolution of SIV anomaly is comparable to that of SIE
170 anomaly, while the time of the SIV anomaly peak is earlier than that of the SIE anomaly peak nearly by one year. Although
there are differences in the SIV trend between GIOMAS and satellite observation, GIOMAS can basically reproduce the
changes in the observed SIV trend before and after 2013. Besides, the correlation of SIV anomalies between GIOMAS and
observations is 0.82, which passes a two-tailed t test at 99% significant level. And given the advantages of reanalysis over
observations or models individually especially in the polar region (Buehner et al., 2017), GIOMAS data would be a good
175 choice to study the variability and long-term trends of Antarctic sea ice.

Considering the obvious variability of SIV in Fig. 5, Figure 6 displays spatial differences in the intensity of SIT anomalies
variability between GIOMAS and satellite observations. Compared with ES and CS2, GIOMAS underestimates the SIT
variability in the Southern Ocean, especially in the deformed ice zone (Figs. 6a-b), which resembles the spatial pattern of Fig.
3. The underestimation can be found also in the comparison between GIOMAS and ULS. The SIT variability is underestimated
180 near the shore, while overestimated away from the shore (Fig. 6c), which is consistent with Fig. 4b. These phenomena suggest
that there appears to be a relationship between the mean SIT and the variability. As Blanchard-Wrigglesworth and Bitz (2014)
suggested, models with a thinner mean ice state tend to have SIT anomalies with smaller amplitude. Thus, the bias of SIT has
an impact not only on the climatology of SIT but also on the variability of SIT.

In addition to ULS observations, the rest of in-situ sea ice observations is sparse in the Southern Ocean and mainly provided
185 by shipborne and airborne measurements. Figure 7 shows the SIT frequency distribution of GIOMAS and ship-based as well
as air-based in-situ observations. The peaks of observations are mainly around 0-0.6 m while the frequencies of GIOMAS SIT
are mainly distributed in 0-1.4 m in the Southern Ocean (Fig. 7a). In different sectors (Figs. 7b-f), the frequency distribution
of observed SIT data is similar to that in the whole Southern Ocean while the peak of GIOMAS SIT frequency varies from 0.2
m to 1.4 m. Compared with observations, for the Southern Ocean, GIOMAS has a higher frequency within 0.6-1.8 m while a
190 lower frequency in the rest bins compared with ship-based observations (Fig. 7a), which seems to imply the overestimation of
SIT. And similar results can be found in different sectors (Figs. 7b-f). However, the sample selection bias should be noted in

the ship-based observations due to ship's track avoiding areas of thicker ice, which results in its estimation biased toward thinner ice (Timmermann, 2004; Williams et al., 2015). Besides, GIOMAS has a lower frequency of thick ice in the Weddell Sea compared with air-based observations, suggesting the weakness of GIOMAS in the simulation of sea ice deformation.

195 **4 Conclusions and discussion**

200 Considering the important role of SIT in studies of Antarctic sea ice and the wide application of GIOMAS, the Antarctic SIT of GIOMAS is assessed in this paper with satellite and in-situ observations. In general, GIOMAS can basically reproduce the observed variability and linear trends of SIV even though only satellite SIC data is assimilated by nudging. For the climatology, GIOMAS can reproduce the asymmetry in the annual cycle of Antarctic SIV. For the long-term SIV variation, the variation of
205 GIOMAS is in phase with that of observations, and it is also able to capture the changes in linear trends before and after 2013. These suggest that GIOMAS is useful to study the long-term variation of Antarctic sea ice. However, significant negative bias in SIT can be found in the comparison between of GIOMAS and observations. Compared with satellite measurements, GIOMAS tends to underestimate SIT, especially in regions of strong ice deformation. And this underestimation is of seasonal dependence with greater underestimation in the winter. Although above underestimation can be partially attributed to the uncertainties of SIT retrieved from satellite, SIT underestimation in the northwest Weddell Sea is further verified by the comparison between GIOMAS and ULS observations. And the spatial distribution of the differences in the magnitude of SIT variability resembles that of the differences in SIT climatology between GIOMAS and observations. And given the relationship between mean state of SIT and variability (Blanchard-Wrigglesworth and Bitz, 2014), this phenomenon indicates that SIT underestimation might have an impact on not only the SIT climatology but also the SIT variability. In addition, GIOMAS
210 underestimates SIT in the Weddell Sea compared with air-based observations while overestimates SIT compared with ship-based observations, which can be due to the negative bias in ship-based SIT estimation (Timmermann, 2004; Williams et al., 2015).

215 However, this study is also limited by observations of Antarctic SIT due to their unsuitability for the evaluation. For example, though SIT from ICESat (Kern et al., 2016) equipped with the Geoscience Laser Altimeter System is available from 2004 to 2008 and proved to have lower bias in SIT estimation than radar altimeter measurements (Willatt et al., 2010; Wang et al., 2020), it is not adopted in this study. The reasons are as follows. First, ICESat SIT is not available in winter (July-September), when greater underestimation of SIT is found in GIOMAS (Fig. 2). Second, the data size of ICESat is relatively smaller than that of ES and CS2 because ICESat provides seasonal mean data and its time range is narrower. Therefore, the additional assessment on SIT of GIOMAS will be conducted when the Antarctic SIT derived from ICESat-2 is available.

220 The above SIT underestimation of GIOMAS can be partially attributed to the model weakness. For example, insufficient model resolution restricts GIOMAS to reproduce the ice deformation near shore. And also the asymmetric SIT changes introduced by assimilation cannot be ignored in GIOMAS. Thus, besides the further development of the model, there are two suggested ways to improve the estimation of Antarctic SIT from the perspective of data assimilation. Firstly, additional sea ice

225 observations other than SIC should be assimilated. For example, besides Antarctic SIT derived from EnviSat-2 and CryoSat-2 used in this study, the Antarctic SIT retrieved from ICESat-2 is also to be released in the near future, and hence assimilating these SIT observations directly may suppress the bias of SIT (e.g., Yang et al., 2014; Fritzner et al., 2019; Luo et al., 2021). Also, assimilating sea ice drift observations can improve the simulation of sea ice motion and deformation, which can improve the estimation of SIT (e.g., Lindsay and Zhang, 2006; Mu et al., 2020). Secondly, advanced data assimilation methods should be adopted to provide balanced estimation of model state. For instance, the innovation of SIC can be converted to the increment of SIT in a more balanced way through the flow-dependent covariance of Ensemble Kalman Filter (e.g., Massonnet et al., 2013; Yang et al., 2015).

230 Besides, in the course of global warming, Antarctic SIE rose gradually and reached a record high in 2014 before decreasing dramatically, which is obviously different from the dramatic drop in Arctic SIE during the satellite era (e.g., Turner and Comiso, 2017). Results from a recent study suggest that the trend in Antarctic ice coverage may be due to changes in atmospheric (e.g., Holland and Kwok, 2012) and oceanic (e.g., Meehl et al., 2019) processes. Without better SIT and SIV estimates, it is difficult to characterize how Antarctic sea ice cover is responding to changing climate, or which climate parameters are most influential (Vaughan et al., 2013). Thus, more Antarctic sea ice observations and more studies on data assimilation are urgently needed to accurately evaluate the Antarctic SIT, which can help to improve the reconstruction and prediction of Antarctic SIV and to support research related to Antarctic sea ice.

240 **Data availability**

The GIOMAS reanalysis data are available at http://psc.apl.washington.edu/zhang/Global_seaice/data.html. The satellite-based Antarctic sea ice thickness observations from Envisat and CryoSat-2 are available at <https://doi.org/10.5285/b1f1ac03077b4aa784c5a413a2210bf5> and <https://doi.org/10.5285/48fc3d1e8ada405c8486ada522dae9e8>, respectively. The Weddell Sea upward-looking sonar sea ice draft data are available at <https://doi.pangaea.de/10.1594/PANGAEA.785565>. The shipborne sea ice thickness observations are available at <http://aspect.antarctica.gov.au/data>, <https://doi.org/10.1594/PANGAEA.819540> and <https://doi.org/10.1594/PANGAEA.831976>. The sea ice thickness observations from airborne electromagnetic system are freely available at <https://doi.pangaea.de/10.1594/PANGAEA.771229> and <https://epic.awi.de/id/eprint/36245/>.

Author contribution

250 QY and HL developed the concept of the paper. SL and HL performed analysis and drafted the manuscript. JW collected the remote sensing and observation data. QY, JZ, QS and JW gave comments and helped revise the manuscript. All of the co-authors contributed to scientific interpretations.
